Bartonella henselae, a species first recognized in 1990 (Slater *et al.*, 1990), is the main etiologic agent of CSD (Regnery *et al.*, 1992a) and is also responsible for bacillary angiomatosis and peliosis hepatis in immunocompromised (mainly AIDS) patients (Koehler *et al.*, 1997), bacteremia and endocarditis (Anderson and Neuman, 1997). Cats are the main reservoir of *B. henselae*. Bacteremic cats are asymptomatic, and the bacterium is transmitted to the cats via the cat flea *Ctenocephalides felis* (Koehler, Glaser and Tappero, 1994; Chomel *et al.*, 1996). Humans may be contaminated by cat scratches or bites. The role of the cat flea (*C. felis*) as a vector for human transmission has been proposed (Chomel *et al.*, 1996; Anderson and Neuman, 1997). *Bartonella henselae* has also been recently recovered from ticks (Chang *et al.*, 2001; Sanogo *et al.*, 2003), but the role of tick is not known. Contact with cats is the main epidemiological factor associated with CSD (Regnery, Martin and Olson, 1992; Kordick *et al.*, 1995), endocarditis (Raoult *et al.*, 1996, 2003; Fournier *et al.*, 2001) and bacillary angiomatosis (Tappero *et al.*, 1993b; Koehler *et al.*, 1997; Gasquet *et al.*, 1998).

The epidemiology of other pathogenic species of *Bartonella* is not well understood, but the role of several vectors in the transmission of *Bartonella* species is acknowledged since DNA amplification of several species has been reported in ticks (Chang *et al.*, 2001) and fleas (Rolain *et al.*, 2003d).

CLINICAL FEATURES

Carrion's Disease

The disease may present as an acute septicemia with hemolysis, known as Oroya fever (acute form) (Gray *et al.*, 1990; Maguina Vargas, 1998), and a chronic form named as verruga peruana. Asymptomatic acute infections have also been reported (Amano *et al.*, 1997). The acute phase corresponds to a massive invasion of erythrocytes and is responsible for a mortality rate of 40–85% without treatment (Ihler, 1996). In most cases of fatal Oroya fever, death has been a result of secondary infection, primarily with *Salmonella* (Bass, Vincent and Person, 1997b). During this phase, bacteria are easily shown in red blood cells after Giemsa or immunofluorescence staining (Rolain *et al.*, 2003g). Among the endemic population, Carrion's disease is also present as a chronic form called verruga peruana which is characterized by benign cutaneous vascular lesions (Arias-Stella, Lieberman and Erlandson, 1986; Maguina Vargas, 1998). These benign lesions are usually friable and bleed readily (Ihler, 1996).

Trench Fever and Chronic Bacteremia

Trench fever, also known as quintan fever, is characterized by infection of blood by *B. quintana*. The disease is transmitted by the human body louse. The incubation period for the disease is between 15 and 25 days. Clinical manifestations of trench fever range from asymptomatic infection to severe illness. The classical presentation reported among troops during World War I corresponds to a febrile illness of acute onset and periodic nature, often accompanied by severe headache and pain in the long bones of the legs (Maurin and Raoult, 1996).

The term quintan fever refers to the 5-day recurrences most often observed. Although trench fever often results in prolonged disability, no fatalities have been recorded. Few illnesses become chronic, with or without attacks of fever and aching (Byam *et al.*, 1919). Persistent bacteremia has long been a recognized symptom of *B. quintana* infection among troops during the World Wars (Maurin and Raoult, 1996). *Bartonella quintana* has been demonstrated to cause bacteremia in homeless patients (Foucalt *et al.*, 2002) and in patients with AIDS (Koehler *et al.*, 2003). In these patients, *B. quintana* may cause acute, severe illnesses but often produces a chronic infection persisting for months with few or no symptoms (Raoult *et al.*, 1994; Drancourt *et al.*, 1996b).

Cat-Scratch Disease

Classical clinical CSD is defined as typical CSD, and other clinical manifestations of infections caused by *B. henselae* have been designed as atypical CSD (Bass, Vincent and Person, 1997a). In typical CSD, nearly all patients give a history of a scratch or bite by and contact with a cat. This is manifested by a regional lymphadenopathy several days after being bitten by a cat. The infection is usually self-limited, but late in the course, in about 10% of patients, the node(s) may suppurate if they are not drained, preferably by needle aspiration. Most patients with typical CSD remain afebrile and are not ill throughout the course of the disease (Carithers, 1985; Margileth, 1993; Bass, Vincent and Person, 1997a). Lymphadenopathy occurs most often in nodes that drain the area where cat scratches occur, most often the axilla, the neck and the groin (Carithers, 1985; Margileth, 1993). Systemic or severe disease complicates CSD in 5–14%, without lymphadenopathy (Carithers, 1985; Margileth, 1993).

Compared with typical CSD patients, atypical CSD patients have prolonged fever (>2 weeks), malaise, fatigue, myalgia and arthralgia, weight loss and splenomegaly. In immunocompromised patients, especially in HIV-infection patients, severe, progressive, disseminated disease may occur (Koehler *et al.*, 2003). Without appropriate therapy, infection spreads systematically to involve virtually all organs, and the outcome is often fatal (Bass, Vincent and Person, 1997a). Visceral manifestation of CSD in children is a possible atypical clinical manifestation of CSD. Other atypical presentation of CSD includes conjunctival granuloma with adjacent preauricular lymphadenitis that evolves and regresses spontaneously over a course of weeks to months (Parinaud's oculoglandular syndrome). This syndrome is the most common form of atypical CSD (about 5%) (Bass, Vincent and Person, 1997a). The disease is transmitted by exposure to infected cats, with inoculation of the organism indirectly into the eye. CSD encephalopathy may occur in 0.17–2% of the cases (Bass, Vincent and Person, 1997a). The onset of neurologic complications varies from a few days to 2 months after the onset of lymphadenopathy. Symptoms include convulsions, persistent headache, malaise and lethargy, lasting for 1 to several weeks. Transient blindness with stellate macular retinitis due to *B. henselae* includes unilateral loss of vision, with central scotoma, optic disc swelling and macular star formation, and there is spontaneous resolution, with complete recovery of vision usually within 1–3 months (Carithers and Margileth, 1991). Both encephalopathy and neuroretinitis are unusual complications of CSD.

Although *B. quintana* is not considered an agent of CSD, the bacterium has been isolated from the blood of patients with lymphadenopathy only (Raoult *et al.*, 1994; Drancourt *et al.*, 1996b). In the cases described by Raoult *et al.* (1994) and Drancourt *et al.* (1996b), the only epidemiologic risk factor identified was the presence of infected cat fleas, and recently, we have found *B. quintana* DNA in cat fleas (Rolain *et al.*, 2003d).

Endocarditis

Bartonella quintana (Spach *et al.*, 1993, 1995a; Drancourt *et al.*, 1995; Raoult *et al.*, 1996, 2003; Fournier *et al.*, 2001), *B. henselae*

(Hadfield *et al.*, 1993; Drancourt *et al.*, 1996a; Raoult *et al.*, 1996, 2003; Fournier *et al.*, 2001), *B. elizabethae* (Daly *et al.*, 1993) and *B. vinsonii* subsp. *berkhoffii* (Roux *et al.*, 2000) have been isolated from patients suffering from bacterial endocarditis. The first case of *Bartonella* endocarditis was reported in an HIV-infected homosexual man in 1993 (Spach *et al.*, 1993). *Bartonella quintana* endocarditis has been reported subsequently in three non-HIV-infected, homeless men in France (Drancourt *et al.*, 1995). All patients required valve replacements because of extensive valvular damages, and pathologic investigation confirmed the diagnosis of endocarditis. Following these reports, the first cases in a series of 22 *Bartonella* endocarditis have been reported, with 5, 4 and 13 cases due to *B. quintana*, *B. henselae* and *Bartonella* spp., respectively (Fournier *et al.*, 2001). *Bartonella quintana* endocarditis can be differentiated from *B. henselae* endocarditis mainly on the basis of associated epidemiologic factors. *Bartonella quintana* endocarditis is most often observed in homeless, chronic alcoholic patients, without previous known valvulopathy, whereas *B. henselae* endocarditis most often occurs in patients with known valvulopathy who had had contact with cats. We have reported a series of 101 cases of *Bartonella* endocarditis, diagnosed by serology, PCR and/or culture (Raoult *et al.*, 2003). In this series, 12 patients died and in 2 patients, the infection relapsed.

Bacillary Angiomatosis and Peliosis Hepatitis

Bacillary angiomatosis is a vascular proliferative disease most often involving the skin but may disseminate to other organs. The disease was first described in HIV-infected patients (Stoler *et al.*, 1983) and organ transplant recipients (Kemper *et al.*, 1990) but may also affect immunocompetent patients (Cockerell *et al.*, 1987). Both *B. quintana* and *B. henselae* are considered etiologic agents of bacillary angiomatosis (Koehler *et al.*, 1992; Spach, 1992). Primary skin lesions correspond to papules, which then increases to form nodules. These lesions may bleed when punctured. The clinical differential diagnosis includes pyogenic granuloma, hemangioma, subcutaneous tumors and Kaposi's sarcoma (Maurin and Raoult, 1996). Cutaneous bacillary angiomatosis lesions may be accompanied by involvement of bone marrow, liver, spleen or lymph nodes (Cockerell *et al.*, 1987; Koehler *et al.*, 1988; Marasco, Lester and Parsonnet, 1989; Milam *et al.*, 1990). Conversely, involvement of the skin does not always occur in bacillary angiomatosis, and patients may only have spleen, liver or lymph node infection (Kemper *et al.*, 1990; Shinella and Alba Greco, 1990).

Peliosis hepatitis is defined as a vascular proliferation of sinusoid hepatic capillaries, resulting in blood-filled spaces in the liver. This disease was first described in patients with tuberculosis and advanced cancers and in association with the use of drugs such as anabolic steroids (Koehler, 1996). *Bartonella henselae* has been recently recognized as an agent of peliosis hepatitis in HIV-infected patients (Perkocha *et al.*, 1990; Maurin, Birtles and Raoult, 1997). Peliosis hepatitis may be considered a visceral manifestation of bacillary angiomatosis, and the term bacillary peliosis has been proposed.

DIAGNOSIS

Because of the nonspecific clinical manifestations, laboratory testing is often necessary to confirm the diagnosis. Diagnosis of infections due to *Bartonella* spp. is often difficult because of the fastidious nature of these bacteria and limitations of serology. Indeed, histological examination of biopsies and PCR, among others, remain essential for the diagnosis of such infections.

Specimen Collection

Several samples are used in establishing the diagnosis of infections due to *Bartonella* spp.: blood, biopsy specimens and arthropods

(xenodiagnosis). These specimen collections should be made as early as possible during illness.

Blood can be obtained either on citrate-containing vial for culture or on ethylenediaminetetraacetic acid (EDTA) for PCR diagnosis. EDTA anticoagulant should be avoided for culture because it leads to detachment of the cell monolayer from coverslips. The best anticoagulant for an optimal yield is sodium citrate. Blood should be obtained before antimicrobial therapy. If inoculation of cell culture or PCR process delays for more than 24 h, plasma, buffy coat or whole blood must be frozen at -70°C or in liquid nitrogen.

For serologic diagnosis, blood sample should be collected early during the disease and a second sample obtained after 1 or 2 weeks. Serum samples should be stored at -20°C or lower for long periods, without degradation of the antibodies. Moreover, blood smears are useful mainly for the diagnosis of Carrion's disease.

Biopsy specimens useful for a diagnosis of CSD are lymph nodes, and those for a diagnosis of endocarditis due to *Bartonella* are cardiac valve and vascular aneurysm or graft.

Bartonellae can be detected by culture, PCR and immunodetection (Rolain *et al.*, 2003d; Sanogo *et al.*, 2003) in various arthropods including ticks, lice and fleas (Rydkina *et al.*, 1999; Chang *et al.*, 2001; Fournier *et al.*, 2002; Rolain *et al.*, 2003d; Sanogo *et al.*, 2003). The arthropod should primarily undergo surface disinfection with iodinated alcohol and then be crushed in medium and inoculated onto a shell vial for culture (Kelly, Raoult and Mason, 1991). Specimen collection of arthropods can be made easily (stored dried in a box) and sent by mail to a reference laboratory for analysis.

Direct Diagnosis

Culture

Bacteria of the genus *Bartonella* may be isolated from blood and biopsies either on axenic medium (Drancourt *et al.*, 1995; Spach *et al.*, 1995b) or in cell-culture systems (Koehler *et al.*, 1992; Zbinden, Höchli and Nadal, 1995). *Bartonella* can be grown on blood agar at 37°C in a 5% CO_2 atmosphere, except for *B. bacilliformis* which is best grown at 30°C . Primary isolation of the bacteria necessitates 12–15 days of incubation and can be as long as 45 days, and thus, agar plates should be conserved for 2 months (Koehler *et al.*, 1992). Sensitivity can be increased after cell lysis (Koehler *et al.*, 1992; Welch *et al.*, 1992) or after freezing the samples (Brenner *et al.*, 1997). Blood culture systems that are currently used in laboratories support the growth of *Bartonella* (Larson *et al.*, 1994). The two techniques of culture, axenic and with cells, should be used to increase the sensitivity of the isolation (Drancourt *et al.*, 1995). Culture of *Bartonella* spp. may be successful with blood samples from bacteremic patients (La Scola and Raoult, 1999; Foucault *et al.*, 2002) and with cardiac valve specimens of endocarditis patients (Fournier *et al.*, 2001; Raoult *et al.*, 2003) as well as skin, lymph node or other organ biopsy samples from patients with bacillary angiomatosis (La Scola and Raoult, 1999). In contrast, *B. henselae* is rarely reported from patients with CSD (La Scola and Raoult, 1999).

Immunodetection

Immunological detection of *Bartonella* spp. has been achieved in various situations such as bacillary angiomatosis in cutaneous biopsies (Reed *et al.*, 1992), peliosis hepatitis (Reed *et al.*, 1992; Slater and Welch, 1995), CSD in lymph nodes (Slater and Welch, 1995) and in heart valves of patients suffering from *Bartonella* endocarditis (Lepidi, Fournier and Raoult, 2000).

Immunofluorescence detection of *B. henselae* during CSD is performed directly on lymph node smears (Rolain *et al.*, 2003e). Immunofluorescence detection in red blood cells has been reported

both in *B. quintana* bacteremic homeless peoples (Rolain *et al.*, 2002) and in patients suffering from Oroya fever (Rolain *et al.*, 2003g).

Molecular Biology

Amplification by PCR of citrate synthase gene (*gltA*) (Drancourt *et al.*, 1995; Birtles and Raoult, 1996), 16S rRNA gene (Regnery *et al.*, 1992a; Raoult *et al.*, 1994), the 16S-23S rRNA *ITS* (Roux and Raoult, 1995), the 60-kDa heat-shock protein gene (*groEL*) (Marston, Sumner and Regnery, 1999) and the *pap31* gene (Zeaiter, Fournier and Raoult, 2002) is currently used for the diagnosis of *Bartonella*-related infections. If the former is amplified, it is further sequenced for identification or diagnosis is confirmed using restriction fragment length polymorphism (RFLP) or hybridization (Norman *et al.*, 1995; Matar *et al.*, 1999; Renesto *et al.*, 2001; Margolis *et al.*, 2003). These techniques are very specific, but their sensitivity may vary according to the type of samples. Thus, the current strategy for the diagnosis of *Bartonella* infections is to use two different target genes (*ITS* gene and *pap31*), and if results of the two PCRs are discordant, use a third gene (*groEL*) (Zeaiter, Fournier and Raoult, 2002). Clinical samples are considered positive only if at least two genes are positive and if sequences obtained give the same identification (Rolain *et al.*, 2003e). Amplification of *Bartonella* spp. DNA in tissue biopsy samples is mainly useful for patients with CSD (lymph node or other organs) (Anderson, Sims and Regnery, 1994; Goral *et al.*, 1994; Zeaiter, Fournier and Raoult, 2002; Rolain *et al.*, 2003a,e), bacillary angiomatosis (angiomatous lesions of skin or other organs) (Relman *et al.*, 1990) or endocarditis (when cardiac valve is removed) (Fournier *et al.*, 2001; Raoult *et al.*, 2003). By using serum samples, we have developed a new one-step nested PCR with the LightCycler (LCN-PCR) for the diagnosis of *Bartonella* endocarditis (Zeaiter *et al.*, 2003). Primers used derived from the riboflavin synthase-encoding gene *ribC*, and specificity of this method was 100% and sensitivity increased to 58.1% (Zeaiter *et al.*, 2003).

Indirect Diagnosis

Serology is the only noninvasive method useful in the diagnosis of *Bartonella* infections, especially for CSD, bacteremia and endocarditis (Maurin, Rolain and Raoult, 2002). Two techniques have been developed for the serology of *Bartonella* infections: immunofluorescence assay (IFA) and enzyme immunoassay (EIA). The major difficulty of these methods is discrepancies in titers obtained among these techniques, depending on the way bacterial antigens are prepared. Indeed, antigens can be prepared either from bacteria cultivated in cells or directly from agar cultures. The IFA was first described for CSD by Regnery *et al.* (1992b) who used *B. henselae* grown in Vero cells as antigens. It remains the most frequently used in-house technique for CSD, with reported sensitivities varying considerably, from nearly 100% to <30% (Regnery *et al.*, 1992b; Sander, Berner and Ruess, 2001; Maurin, Rolain and Raoult, 2002). Commercially prepared antigens are now available for *B. henselae* and *B. quintana* serology (Zbinden *et al.*, 1997; Sander *et al.*, 1998; Harrison and Doshi, 1999). Sensitivity and specificity of one of these tests have been compared with those of our in-house IFA (Maurin, Rolain and Raoult, 2002). The sensitivity of a serological test was greatly influenced by the cutoff values used for each test. At a cutoff titer of 64, the commercial test had higher sensitivity (91.2% versus 52.9%) than our in-house test, in detecting antibodies in CSD patients, but sensitivity was only 87%. Conversely, we have demonstrated that our in-house test was superior to the commercial test for the diagnosis of *Bartonella* endocarditis and bacteremia in homeless patients (Maurin, Rolain and Raoult, 2002). Significant differences in antibody titers were found between the two IFAs, and at a cutoff titer of ≥ 1024 , our in-house test was 100% predictive of *Bartonella* endocarditis (Maurin, Rolain and Raoult, 2002). This was also found to be true in a

study showing that IFA had a positive predictive value of 95% for an immunoglobulin G (IgG) titer to *B. henselae* and/or *B. quintana* ($\geq 1:800$) in patients with endocarditis (Fournier, Mainardi and Raoult, 2002). False negative is due either to antigenic heterogeneity among *B. henselae* species or to *B. clarridgeiae* (Drancourt *et al.*, 1996a). Conversely, we have found that patients without CSD may have positive serology either with commercial test or with in-house tests, especially in cases of more severe diseases such as mycobacterial infections, lymphoma or Kaposi's sarcoma (Giladi *et al.*, 2001; Ridder *et al.*, 2002; Rolain *et al.*, 2003e). The specificity of serology has been studied, and cross-reactions have been shown either between the different species of *Bartonella* (Dalton *et al.*, 1995; Sander *et al.*, 1998) or between *Bartonella* spp. and *Coxiella burnetii* (La Scola and Raoult, 1996) or *Chlamydia* (Maurin *et al.*, 1997). These cross-reactions should be considered in blood culture-negative endocarditis, where these pathogens are implicated. Moreover, the seroprevalence in a particular geographic area as well as the antigen preparation of the various IFAs used should be considered before interpreting results (Sander, Berner and Ruess, 2001). Even when two different serological tests were coupled, the specificity and the sensitivity were not sufficient for the diagnosis of CSD (Maurin, Rolain and Raoult, 2002). False-negative PCR could be due to a previous infection, with disappearance of the bacteria in the lymph node, whereas antibodies against *B. henselae* are still present, suggesting that the results of PCR strongly depend on the duration of illness (Ridder *et al.*, 2002). Since CSD lymphadenopathy may last for months, it is possible that patients with positive serology and negative PCR had had a previous infection due to *B. henselae* which was not acute at the time of sampling. This may also explain why isolation of the bacteria from lymph nodes is so difficult (La Scola and Raoult, 1999), because bacteria disappear from the node and positive serology reflects a previous infection.

TREATMENT

In vitro Susceptibility to Antibiotics

Antibiotic susceptibility testing of *Bartonella* spp. has been carried out using methods adapted to their fastidious growth and has shown that many antibiotics are bacteriostatic *in vitro* (Maurin *et al.*, 1995; Sobraques *et al.*, 1999; Rolain *et al.*, 2000). *Bartonella* spp. are susceptible to aminoglycosides, chloramphenicol, tetracyclines, macrolides, rifampin, fluoroquinolones and co-trimoxazole (Maurin *et al.*, 1995; Ives *et al.*, 1997). However, minimum inhibitory concentrations (MICs) poorly correlate with the *in vivo* efficacy of antibiotics in patients suffering from *Bartonella*-related infections (Maurin *et al.*, 1995). Failures of treatment using a β -lactam, a macrolide, a tetracycline, rifampin or fluoroquinolone for either disease have been reported (Spach and Koehler, 1998). Relapses are also frequent following withdrawal of treatment. Such discrepancies between *in vitro* and clinical data may be explained by the lack of bactericidal effect of antibiotics against *Bartonella* spp., except for aminoglycosides (Rolain, Maurin and Raoult, 2000). The lack of bactericidal activity of antibiotics was also confirmed in cell-culture models for both *B. henselae* in murine macrophage-like cells (Musso, Drancourt and Raoult, 1995) and *B. quintana* in red blood cells (Rolain *et al.*, 2003f).

Treatment in Humans

Before the antibiotic era, the only available treatment for acute anemia during Oroya fever was blood transfusion, but the effectiveness of this treatment was poor and the mortality rate was high (about 80% of cases) (Schultz, 1968). Now the recommended therapy for Oroya fever is chloramphenicol because this antibiotic is also effective against salmonellosis and other enteropathogenic bacteria that often

complicate the disease (Uertega and Payne, 1955; Cuadra, 1956; Gray *et al.*, 1990; Maguina *et al.*, 2001). Therapeutic failures and persistent bacteremia have been reported when this drug was used, and treatment with chloramphenicol appears not to eliminate the patient's risk of developing the eruptive phase of bartonellosis. Chloramphenicol is effective in most of the patients with few exceptions, and thus, a combination with another antibiotic (especially a β -lactam compound) should be recommended. Cotrimoxazole, macrolides and fluoroquinolones have also been used successfully in some patients and may represent safe alternatives (Maguina Vargas, 1998). Chloramphenicol is not effective for treating verruga peruana (Maguina Vargas, 1998). Since 1975, rifampin has become the drug of choice for treating the eruptive phase of Carrion's disease. However, failures have also been reported with rifampin (Maguina Vargas, 1998). Ciprofloxacin as well as azithromycin has been used successfully in adults with multiple eruptive-phase lesions (Maguina and Gotuzzo, 2000).

CSD typically does not respond to antibiotic therapy (Spaulding and Hennessy, 1960; Margileth, 1992), and patients should be reassured that the adenopathy is benign and that it will subside spontaneously within 2–4 months (Margileth, 2000). Management consists of analgesics for pain, prudent follow-up and drainage when necessary (Margileth, 2000). The only prospective double-blind, placebo-controlled study of treatment for immunocompetent patients with uncomplicated CSD with azithromycin was reported by Bass *et al.* (1998). Although, no significant difference in the rate or degree of resolution between the two groups was found at 30 days, patients treated with azithromycin had a significantly faster reduction of lymph node volume during the first month of azithromycin treatment as compared with that in placebo (Bass *et al.*, 1998). The current recommendation for the moderate-to-severely-ill patient is no treatment. The azithromycin regimen could be an alternative for patients with large, bulky lymphadenopathy (Bass *et al.*, 1998). When CSD lymph nodes suppurate, needle aspiration is probably the best treatment, and the patient usually notes decreased pain within 24–48 h (Margileth, 2000).

Most cases of Trench fever were reported before the antibiotic era. There were no fatal cases of Trench fever during World War, and aspirin was the most effective drug for the pain (Hurst, 1942). However, successful treatment with tetracycline or chloramphenicol has been reported after World War II in some trench fever patients (Bass, Vincent and Person, 1997b). We have demonstrated in a randomized, placebo-controlled clinical trial that patients with chronic bacteremia should be treated with gentamycin for 14 days and with doxycycline for 28 days (Foucault, Raoult and Brouqui, 2003). These results have been confirmed in a randomized, placebo-controlled clinical trial (Foucault, Raoult and Brouqui, 2003). Consequently, patients with chronic *B. quintana* bacteremia should be treated with gentamycin (3 mg/kg intravenously once a day) for 14 days, with doxycycline (200 mg/day per oral once a day) for 28 days (Foucault, Raoult and Brouqui, 2003). Patients with chronic bacteremia should be evaluated for endocarditis. Patients with renal insufficiency, obesity or increased fluid volume should be monitored closely and the dose of gentamicin adjusted with a twice-daily dosing schedule to avoid nephrotoxicity of the drug.

Antibiotic treatment of bacillary angiomatosis and peliosis hepatis has never been studied systematically. The first described patient with bacillary angiomatosis was treated empirically with erythromycin, and the lesion completely resolved (Stoler *et al.*, 1983). Subsequently, erythromycin has become the drug of first choice and has been used successfully to treat many patients with bacillary angiomatosis (Koehler and Tappero, 1993; Tappero *et al.*, 1993a). Doxycycline and fluoroquinolones can be used as alternatives (Slater *et al.*, 1990; Lucey *et al.*, 1992; Koehler and Tappero, 1993). Intravenous administration of erythromycin should be used in patients with severe disease (Koehler and Tappero, 1993). Combination therapy, with the addition of rifampin to either erythromycin or doxycycline, is recommended for immunocompromised patients with acute, life-threatening *Bartonella*

infection. Treatment should be given for at least 3 months for bacillary angiomatosis and 4 months for peliosis hepatis to prevent relapses (Krekorian *et al.*, 1990; Szaniawski *et al.*, 1990; Koehler *et al.*, 1992; Cotell and Noskin, 1994; Gazineo *et al.*, 2001; Koehler and Relman, 2002).

Among patients with *Bartonella* endocarditis that we reported, those receiving an aminoglycoside were more likely to fully recover and, if aminoglycoside was prescribed for at least 14 days, more likely to survive, confirming the important role of this antibiotic compound in the treatment of *Bartonella* endocarditis (Raoult *et al.*, 2003). These data strongly suggest the use of aminoglycoside therapy for at least 14 days for cases of *Bartonella* spp. endocarditis, and this antibiotic should be accompanied by doxycycline for 6 weeks (Raoult *et al.*, 2003). Since *B. quintana* bacteremia is optimally treated with doxycycline plus gentamicin (Foucault, Raoult and Brouqui, 2003), in the absence of any prospective study, it is logical that this regimen should be used for endocarditis when *Bartonella* spp. are identified as the causative agent.

PREVENTION

Bartonella quintana infections can be prevented by eradicating body lice (Maurin and Raoult, 1996), and for *B. henselae*, immunocompromised patients should avoid contacts with cats (Koehler, Glaser and Tappero, 1994; Maurin and Raoult, 1996), and also eradicate cat fleas (Koehler, Glaser and Tappero, 1994).

Mycoplasma spp.

Christiane Bébéar, Sabine Pereyre and Cécile M. Bébéar

Laboratoire de Bactériologie, Université Victor Segalen Bordeaux 2, Bordeaux, France

INTRODUCTION

Mycoplasmas are ubiquitous microorganisms which have been known as animal pathogens since the end of the nineteenth century. They are the smallest prokaryotes able to multiply autonomously. Even though the term mycoplasma only applies, taxonomically, to the genus *Mycoplasma*, it is still commonly used to indicate these organisms as a whole. It will be used in this chapter to designate any of the organisms in the class Mollicutes.

The first mycoplasma was isolated in 1898, by Nocard and Roux. It was *Mycoplasma mycoides* spp. *mycoides* the cause of contagious bovine peripneumonia. The first recorded case of a human mycoplasma infection, an abscess of the Bartholin gland, was described in 1937 by Dienes and Edsall. The species isolated was probably *M. hominis*. In 1954 Shepard isolated mycoplasmas from the urogenital tract. These mycoplasmas produced particularly small colonies. They were called T strain, indicating tiny colonies, and are now known as ureaplasmas. It was only in 1962 that Chanock, Hayflick and Barile succeeded in culturing *M. pneumoniae*, the cause of primary atypical pneumonia, in an acellular medium. They then identified the Eaton agent, which had been cultured on chick embryo, as a mycoplasma. Among the potential human pathogens, *M. genitalium* was discovered in 1981 from urethral swabs collected from men with nongonococcal urethritis (NGU) (Taylor-Robinson, 1995). More recently, two species of mycoplasmas were found in HIV-seropositive patients, *M. fermentans*, known elsewhere since 1952, and *M. penetrans* (Lo *et al.*, 1991).

DESCRIPTION OF THE ORGANISMS

Taxonomy and Phylogeny

Mycoplasmas are completely lacking a cell wall. They belong to the class Mollicutes (*mollis cutis*, soft skin). This class consists of four orders, Mycoplasmatales, Entomoplasmatales, Acholeplasmatales and Anaeroplasmatales, which are distinguished on the basis of their natural habitat, their sterol requirements and a certain number of other properties. The class Mollicutes include at least 183 known species.

Taxonomy of Mollicutes has developed a great deal with the introduction of molecular methods and has been recently reviewed (Johansson and Pettersson, 2002). The species isolated from humans belong mainly to the order Mycoplasmatales, family Mycoplasmataceae, that includes two genera, *Mycoplasma* and *Ureaplasma* (Table 24.1). Facultatively anaerobic, they require sterols for growth. Their principal energy sources are sugars and arginine or urea in the case of *Ureaplasma* genus. Thirteen of the 107 known *Mycoplasma* species and one of the seven *Ureaplasma* species, *Ureaplasma urealyticum* have been isolated from humans. *Ureaplasma urealyticum* is a heterogeneous species which has been proposed for division into two separate species, *U. urealyticum* and *U. parvum*, corresponding to the two former biovars, 1 and 2 (Kong *et al.*, 1999). They will be considered together as *Ureaplasma* spp. Other species of *Mycoplasma* and *Ureaplasma* genera are of animal origin. *Acholeplasma laidlawii*, the type species of the genus *Acholeplasma*, and *A. oculi* have been

Table 24.1 Taxonomy and main characteristics of mycoplasmas (Johansson and Pettersson, 2002)

Classification	G + C%	Genome size (kbp)	Sterol requirement	Host
Order I: Mycoplasmatales				
Family I: Mycoplasmataceae				
Genus I: <i>Mycoplasma</i> (107 species)	23–40	580–1360	Yes	Humans, animals
Genus II: <i>Ureaplasma</i> (7 species)	27–30	750–1170	Yes	Humans, animals
Order II: Entomoplasmatales				
Family I: Entomoplasmataceae				
Genus I: <i>Entomoplasma</i>	27–29	790–1140	Yes	Insects, plants
Genus II: <i>Mesoplasma</i>	27–30	870–1100	No	Insects, plants
Family II: Spiroplasmataceae				
Genus I: <i>Spiroplasma</i>	25–30	780–2240	Yes	Insects, plants
Order III: Acholeplasmatales				
Family I: Acholeplasmataceae				
Genus I: <i>Acholeplasma</i>	27–36	1500–1690	No	Animals, some plants and insects
Order IV: Anaeroplasmatales				
Family I: Anaeroplasmataceae				
Genus I: <i>Anaeroplasma</i>	29–33	1600	Yes	Bovine and ovine rumen
Genus II: <i>Asteroleplasma</i>	40	1600	No	

described rarely in humans. Phytoplasmas present in insects and plants, closely related to acholeplasmas, cannot be cultivated. The *Entomoplasmatales* are mycoplasmas isolated from insects and plants. The order contains the *Entomoplasma*, *Mesoplasma* and *Spiroplasma* (mycoplasmas with a helical morphology) genera (Johansson and Pettersson, 2002).

Phylogenetically, mycoplasmas are very simple microorganisms. Despite their small size, as demonstrated by 16S rRNA sequence comparison, they are highly evolved bacteria coming from anaerobic clostridia-like Gram-positive ancestors containing a low level of guanine + cytosine. Mycoplasmas probably evolved from these ancestors by successive reduction in the genome and loss of the cell wall. The closest bacterial species to this phylogenetic branch are *Clostridium innocuum* and *C. ramosum* (Woese, 1987). Based on 16S rRNA sequences, noncultivable wall-less parasitic bacteria, which infect animals including primates and are observed in the blood, attaching to erythrocytes, are given the *Candidatus* status in the genus *Mycoplasma*. They were previously classified in the genus *Haemobartonella* and *Eperythrozoon*.

Habitat

Mollicutes are ubiquitous microorganisms. In nature, flowers and plant surfaces constitute an important reservoir. Insects act as vectors and can also suffer from specific mycoplasma-induced diseases. Mycoplasmas are also found in animals, especially animals in intensive production facilities and laboratory animals, and humans.

The 16 species found in humans are listed in Table 24.2. Mycoplasmas can be grouped by the site where they are usually isolated in immunocompetent subjects, the respiratory and genital tracts. Most of the mycoplasmas isolated from the oropharynx are simple commensals (*M. salivarium*, *M. orale*, *M. buccale*, *M. faucium*, *M. lipophilum* and *A. laidlawii*). Only *M. pneumoniae* colonizes the lower respiratory tract and possesses certain pathogenic capacity. Seven species can be considered genital mycoplasmas. Two of these, *Ureaplasma* spp. and *M. hominis* are part of the genital commensal flora of a great number of people (Taylor-Robinson, 1996). Frequency of colonization varies with age, hormonal factors, race, socioeconomic level and sexual activity. It is difficult to evaluate the rate of colonization in the general population, although it is known to be higher in women than in men. It may be as high as 50% vaginally in women for *Ureaplasma* spp.,

while for *M. hominis* it is probably less than 10%. Both species are responsible for human infections (Taylor-Robinson, 1996; Blanchard and B  b  ar, 2002). The role of the other species (*M. genitalium*, *M. fermentans* and *M. penetrans*) is much less well known because they are rarely detected by culture. However, the use of polymerase chain reaction (PCR) technology has considerably improved our knowledge of *M. genitalium* occurrence in several diseases. *Mycoplasma spermatophilum* and *M. primatum* have been detected rarely. The natural habitat of *M. pirum* is unknown.

Occasionally, animal mycoplasmas are detected in immunosuppressed hosts. Furthermore, mycoplasmas are frequent contaminants of cell cultures, particularly continuous cell lines. Five species (*M. hyorhinis*, *M. orale*, *M. fermentans*, *M. arginini* and *A. laidlawii*) are responsible for about 95% of contaminations. Their frequency and the possible consequences for the use of these cells necessitate regular surveillance (Drexler and Uphoff, 2000).

PRINCIPAL PROPERTIES

Morphology and Structure

Mycoplasmas are very small organisms (0.2–0.3 µm). When examined by dark field or phase contrast microscopy, they appear to be pleomorphic, coccoid or filamentous, depending on the species and culture conditions. Spiroplasmas are helical in shape. They are not stained by Gram stain. A technique of DNA fluorochrome staining is available for screening cell cultures for mycoplasma contamination but is not specific for mycoplasmas.

Electron microscopy shows that certain species, *M. pneumoniae*, *M. genitalium*, *M. penetrans* and some animal mycoplasmas, have a specialized terminal structure. This slender extremity, the tip, plays an important role in the attachment of mycoplasmas to different substrates, including host cells and in their mobility using a gliding movement.

Mycoplasmas have no cell wall and differ from L-forms by the absence of precursors of peptidoglycan and binding proteins for penicillins. All of the species of the genus *Mycoplasma* and *Ureaplasma* possess a cytoplasmic membrane containing cholesterol.

The genome of mycoplasmas varies in size, from 580 kbp in *M. genitalium*, which was completely sequenced in 1995, to 2200 kbp in *Spiroplasma* spp. The guanine + cytosine content ranges from

<i>Ureaplasma</i> spp. ^b	–	+	–	–	+
<i>A. laidlawii</i>	+	–	+	–	–
<i>A. oculi</i>	?	?	+	–	–

^a In immunocompetent patients: + = proven role; ? = questionable; – = nonpathogenic.

^b Metabolizes urea, *Ureaplasma* spp. include *U. urealyticum* and *U. parvum*.

23 to 40%. With the exception of acholeplasmas, they use the codon UGA to code for tryptophane. They possess one or two rRNA operons, and their number of tRNAs is reduced. The recent sequencing of the entire genome of eight mycoplasmas, including the human species, *M. genitalium* (Fraser *et al.*, 1995), *M. pneumoniae* (Himmelreich *et al.*, 1996), *M. penetrans* (Sasaki *et al.*, 2002) and *U. parvum* (Glass *et al.*, 2000), has marked a turning point in the molecular genetic analysis of these organisms. As mycoplasmas include the smallest known self-replicating organisms, their molecular study is an important step to define the minimal set of genes essential for life. Furthermore, despite their small size, comparative genome analysis of mycoplasmas shows a considerable variety with many specific adaptations (Dandekar *et al.*, 2002).

Nutritional Requirements

Because of their small number of genes, mycoplasmas have a very limited capacity to synthesize their component parts. This renders them rather fastidious. In order to grow they require nucleic acid precursors (yeast extract) and the cholesterol contained in serum (except for acholeplasmas and other nonhuman species).

The optimum atmospheric conditions are equally variable. *Mycoplasma pneumoniae* and *M. genitalium* are aerobic, but their growth is stimulated in the presence of 5% CO₂. *Mycoplasma hominis* and *Ureaplasma* spp. are indifferent but grow better on agar media in an atmosphere containing 5% CO₂. The optimum temperature for growth is approximately 36–38 °C.

In broth culture, the generation time varies from 1 h for *Ureaplasma* spp. to 6 h for *M. pneumoniae* and more for *M. genitalium*. Broth cultures do not usually become cloudy. On agar media, colonies are slow growing. As they are extremely small (15–300 µm), they must be observed with the help of low-power magnification. The appearance of the colonies is variable but takes on a characteristic fried-egg aspect because the organisms penetrate deeply into the agar in the central region of the colony (Figure 24.1). Colonies of *Ureaplasma* spp. are very small and irregular.

Biochemical Characteristics

Species of mycoplasmas isolated from humans can be grouped as glucose fermenters (including *M. pneumoniae*, *M. genitalium*, *M. fermentans* and *M. penetrans*) and nonfermenters. Nonfermenters such as *M. hominis* draw their energy from the hydrolysis of arginine by the metabolic pathway of arginine dihydrolase. *Mycoplasma*

fermentans and *M. penetrans* use both arginine and glucose. The source of energy of *Ureaplasma* spp. involves the degradation of urea. These characteristics are used to identify mycoplasmas of human origin (Table 24.2).

Mycoplasma pneumoniae is able to reduce 2,3,5-triphenyl-tetrazolium chloride. Hemadsorption and hemagglutination of guinea-pig or chicken erythrocytes and production of peroxides which confer hemolytic abilities are also found in this species.

Antigenic Structure

Membrane antigens probably play an essential role in the host response to infection. *Mycoplasma pneumoniae* possesses a glycolipid which is not completely specific and can be found in diverse tissues, microorganisms, plants and several membrane-bound proteins playing a role in attachment. The P1 protein (170 kDa), found on the narrow extremity, is the major cytoadhesin, although other proteins also participate [P30, HMW (high molecular weight) 1–3 and others (Krause, 1998)]. Although variability of cytoadhesin P1 has been described, allowing to separate two groups of strains, *M. pneumoniae* is an homogeneous species. *Mycoplasma hominis* is much more heterogeneous. However, no serovar or subspecies could be clearly distinguished among *M. hominis* strains (Ladefoged, 2000). An additional level of antigenic variability, related to variations in the size of antigen proteins, has been described for several species of mycoplasmas, *Ureaplasma* spp. in particular (Zheng *et al.*, 1995). The two different *Ureaplasma* species, include 14 serovars (serovars 2, 4, 5 and 7–13 for *U. urealyticum* and serovars 1, 3, 6 and 14 for *U. parvum*).

PATHOGENESIS

Mycoplasma pneumoniae

The pathogenesis of infection with *M. pneumoniae* has been studied using different models, organ cultures and experimental animal models, hamster inoculated intranasally and chimpanzees. In these animal models, *M. pneumoniae* colonizes the respiratory epithelium diffusely and provokes lesions comparable histopathologically to those observed in humans (perivascular and peribronchiolar infiltration of mononuclear cells). Recently, a murine model was proposed (Hardy *et al.*, 2003).

Two mechanisms contribute to the pathogenesis of *M. pneumoniae* infections, attachment of *M. pneumoniae* to the respiratory epithelium followed by localized cellular lesions and immunopathological disorders which can lead to lesions elsewhere (Razin, Yogev and Naot, 1998). *Mycoplasma pneumoniae* can adhere to a number of substrates, glass, plastic, red blood cells and respiratory epithelial cells. *In vivo*, this attachment permits the mycoplasma to escape the ciliary movement and come into close contact with the cell membrane. This role is confirmed by the loss of pathogenicity for hamster of nonadherent strains. Attachment, which takes place at the narrow extremity of the terminal structure, is mediated by several proteins including P1, the principal cytoadhesin involved. The host cells have receptors containing sialic acid. The attachment blocks ciliary action and causes cellular alterations due to the production by *M. pneumoniae* of peroxides and superoxides which also act as a hemolysin.

Immunopathological mechanisms are suspected to be involved in some of the lesions provoked by *M. pneumoniae*. The histological appearance of these lesions, the presence of lesions at distance, from which mycoplasmas are rarely isolated, and the presence of autoantibodies reacting with a variety of host tissues argue in favor of this hypothesis. The formation of autoantibodies reacting with the I antigen of erythrocytes is responsible for production of cold agglutinins.

Figure 24.1 Fried-egg colonies of *M. hominis* (Mh) and small granular colonies of *Ureaplasma* spp. (U). Magnification $\times 170$.

Genital Mycoplasmas

The pathogenesis of genital mycoplasma infections is less well known. Various models of genital infections have been developed using different animals. In mice, establishment of *M. hominis* and *Ureaplasma* spp. in the vagina is improved by treating the animals with hormones. Extension of the infection toward the upper genital tract has been observed. In male chimpanzees, intraurethral inoculation of *Ureaplasma* spp. or *M. genitalium* leads to a local leukocyte reaction followed sometimes by dissemination in the blood for *M. genitalium*. Upper genital tract infections (salpingitis and parametritis) have been provoked after inoculation of female monkeys with *M. genitalium* (Taylor-Robinson, 1995, 1996).

The attachment process has been described for the three species, *Ureaplasma* spp., *M. hominis* and *M. genitalium*. This last organism possesses an adhesin, MgPa, which is very similar to P1 of *M. pneumoniae* and facilitates its attachment on epithelial cells. Factors involved in *Ureaplasma* spp. or *M. hominis* attachment are much less known.

Diverse enzymatic activities (urease and IgA1 protease for *Ureaplasma* spp. and phospholipase for *Ureaplasma* spp. and *M. hominis*), the depletion of arginine for *M. hominis*, the production of certain metabolites such as ammonia, explain in part their pathogenicity. It is not known whether one of the two *Ureaplasma* spp. has a particular pathogenic capability.

Although mycoplasmas are generally considered as extracellular organisms, intracellular localization has been reported for several species including *M. genitalium*, *M. hominis*, *M. penetrans* as well as *M. pneumoniae*. This localization may protect the mycoplasma against host defenses and contribute to disease chronicity (Waites, Rikihisa and Taylor-Robinson, 2003).

EPIDEMIOLOGICAL AND CLINICAL CHARACTERISTICS

Respiratory Infections

M. pneumoniae

Mycoplasma pneumoniae causes acute respiratory infections, most frequently in children from 4 years of age to young adults, but it can be observed in younger children and in older persons. The infection is endemic in the population with epidemic peaks every 4–7 years. Surges occurred in Europe in 1987, 1992 and 1999. Although more frequent in cold weather, there is not a clear seasonal trend in frequency. This infection is not very contagious, but spread throughout households is common. The persistence of *M. pneumoniae* in the respiratory tract contributes to the endemic nature of the disease. Other than during epidemics, when it can be found in the oropharynx of healthy subjects, *M. pneumoniae* is not usually found among the commensal flora of the respiratory tract.

Infection often starts as a simple tracheobronchitis. *M. pneumoniae* is the second most common cause of community-acquired pneumonia after *Streptococcus pneumoniae* and is probably responsible for 15–20% of X-ray-proven cases of pneumonia (Foy, 1993). Higher rates have been observed in children (Principi *et al.*, 2001). In its characteristic form, this disease develops as a primary atypical pneumonia with a progressive installation, fever, involvement of the upper respiratory tract, dry cough and marked radiological lesions. It evolves slowly and progressively. The disease is ordinarily mild. Respiratory symptoms alone do not distinguish *M. pneumoniae* from other causes of atypical pneumonia. Association with other symptoms can be a better indication, cutaneous lesions (Stevens Johnson syndrome and multiform erythema), otitis media, pharyngitis, neurological involvement (meningitis and meningoencephalitis), hemolytic anemia due to the presence of cold hemagglutinins, coagulation problems, arthritis, myocarditis, pericarditis and involvement of the pancreas,

digestive tract and kidneys (Jacobs, 2002). These complications may occur alone and therefore be difficult to associate with their causal agent. Although an autoimmune response is thought to play a role in some extrapulmonary complications, *M. pneumoniae* has been directly isolated or identified by PCR from extrapulmonary sites such as synovial, pericardial and cerebrospinal (CSF) fluids. Its possible role as etiologic or exacerbating factor in bronchial asthma is still debated (Martin *et al.*, 2001).

Other Mycoplasmas

In adults, these are all commensal organisms with the possible exception of *M. fermentans*. A certain number of cases of fulminant infections with a syndrome of respiratory distress with or without systemic involvement have been reported in subjects previously in good health (Lo *et al.*, 1993). In experimental animal models, it has been shown that *M. fermentans* can produce cellular lesions (Stadtländer *et al.*, 1993). *M. fermentans* may be a little known cause of respiratory infections.

Urogenital Tract Infections

In Men

Ureaplasma spp. and *M. genitalium* cause nonchlamydial nongonococcal urethritis (NGU). *Ureaplasma* spp. have long been implicated as a cause of acute NGU on the basis of isolation studies including quantification of the organisms, controlled therapeutic and serological studies and human and animal inoculation studies (Taylor-Robinson, Ainsworth and McCormack, 1999). However, the proportion of cases due to ureaplasmas is unclear and controversial because of the frequent isolation of *Ureaplasma* spp. in the urethra of healthy men, and this ranked them behind *Chlamydia trachomatis* and *M. genitalium* as a cause of acute NGU. Recently, *Ureaplasma* spp. have been implicated in chronic NGU with symptoms or signs re-emerging after treatment (Homer *et al.*, 2001).

Because of the development of PCR, our knowledge on the pathogenic role of *M. genitalium* has significantly increased. *M. genitalium* is strongly associated with acute NGU (Totten *et al.*, 2001), independent of the presence of *C. trachomatis* or ureaplasmas, as reported by a number of studies from different countries. *M. genitalium* might be responsible for 15–25% of acute NGU. It has also been associated with chronic NGU after treatment. *M. genitalium* and *Ureaplasma* spp. have been detected in some cases of sexually acquired reactive arthritis. Evidence that *M. hominis* plays a role in NGU is lacking.

There is still controversy concerning the role of genital mycoplasmas in prostatitis. *M. genitalium* was detected by PCR in 4% of prostatic biopsies from chronic idiopathic prostatitis. There are also a few reports implicating ureaplasmas or *M. hominis* as causes of epididymitis. Nevertheless, the role of mycoplasmas in prostatitis or epididymitis seems to be minimal.

In Women

Mycoplasmas do not cause vaginitis but proliferate in women with bacterial vaginosis (BV), together with other microorganisms such as *Gardnerella vaginalis* and anaerobes. *M. hominis* is strongly associated with BV and is found in the vagina of two-thirds of women with BV in high numbers compared to less than 10% of healthy women. *Ureaplasma* spp. have been associated with BV to a lesser extent and could be responsible for some cases of urethral syndrome in women. *M. genitalium* seems to have no role in BV but has been associated with mucopurulent cervicitis (Manhart *et al.*, 2001).

BV may lead to pelvic inflammatory disease (PID), and *M. hominis* has been isolated from the endometrium and fallopian tubes of 10% of women with salpingitis, accompanied by a significant antibody response. However, PID is a disease of multifactorial etiology, and whether *M. hominis* is a primary agent of PID or acts in association with other bacteria in a context of BV is still controversial. In contrast, there is little evidence that *Ureaplasma* spp. play a similar role in PID. *M. genitalium*, significantly associated with cervicitis and endometritis (Cohen *et al.*, 2002), could be an agent of PID as indicated by serological data and primate inoculation studies.

Furthermore, several studies have reported interdependence between *M. hominis* and *Trichomonas vaginalis* which could be a carrier of the *M. hominis* infection *in vivo* (Taylor-Robinson, 1998).

Reproduction Disorders and Infections in Pregnancy

The role of mycoplasmas in infertility is still unknown. Evidence to incriminate *Ureaplasma* spp. in male and female infertility is sparse. *Ureaplasma* spp. have been reported to decrease sperm motility and alter the spermatozoa morphology. Experimental models showed that ureaplasmas, and recently *M. genitalium*, could adhere to spermatozoa. Whether it is necessary to detect and treat genital mycoplasmas in *in vitro* fertilization is still debatable.

Doubts also remain about the role of genital mycoplasmas in recurrent spontaneous abortion, stillbirth, prematurity or low birth weight (Cassell *et al.*, 1993).

Mycoplasma hominis and *Ureaplasma* spp. were shown to be responsible for some cases of chorioamnionitis and endometritis. They have also been incriminated in post-partum or post-abortion fevers accompanied by isolation of both organisms from the blood (Neman-Simha *et al.*, 1992). In some cases, it could represent the transient invasion of bloodstream following vaginal delivery or it could be a real septicemia leading to a neonatal infection. It should be noticed that *M. hominis* has been implicated more frequently than *Ureaplasma* spp. in post-partum fever.

Disorders of the Urinary Tract

Animal models and human isolation studies have suggested a possible causal association of *Ureaplasma* spp. in the development of infectious stones. The mechanism could be related to the urease activity of ureaplasmas with crystallization of struvite and calcium phosphates in urines (Grenabo, Hedelin and Pettersson, 1988).

Mycoplasma hominis appears to cause a small number of cases of acute pyelonephritis in immunocompetent patients as indicated by the isolation of the microorganisms from the upper urinary tract accompanied by a specific antibody response.

Neonatal Infections

Colonization of neonates by genital mycoplasmas could occur *in utero*, but more frequently at the time of delivery by contact with mycoplasmas from the lower genital tract of the mother. The frequency of colonized newborns could be up to 50% when the mother is colonized. The highest rates concern the low birth weight neonates. Colonization of infants tends to decrease rapidly after 3 months.

Several clinical features such as bacteremia, septicemia, respiratory tract and central nervous system infections have been described for both *Ureaplasma* spp. and *M. hominis* (Waites *et al.*, 1988). Respiratory tract infections are manifested most frequently as pneumonia and in some rare cases as respiratory distress syndromes. Since 1988, several studies have reported the association of colonization of the respiratory tract by *Ureaplasma* spp. with bronchopulmonary dysplasia in low birth weight infants (<1000 g) (Wang *et al.*, 1993). This association

has yet to be confirmed, as bronchopulmonary dysplasia is a complex multifactorial pathology. However, if a causality link is confirmed, it could lead to a distinct change in the therapeutic management of this disease.

Both the common genital mycoplasma species could invade the CSF fluid of neonates causing some cases of meningo-encephalitis with neurological damage or death. However, most of the infected newborns had a subclinical meningitis without sequelae (Waites, Rikihisa and Taylor-Robinson, 2003).

Systemic Infections

Mycoplasmas can infect organs other than the respiratory or urogenital tracts. These infections are certainly underestimated, as mycoplasmas are usually considered late in diagnosis when negative results have been observed for other microorganisms or in case of treatment failure.

Extrapulmonary or extragenital infections (mainly septic arthritis) occur frequently in an immunodeficiency state. Mycoplasmas have been identified, by culture or PCR, in about 40% of cases of septic arthritis in patients with hypogammaglobulinemia (Furr, Taylor-Robinson and Webster, 1994). *Ureaplasma* spp. are the most frequently isolated species, followed by *M. hominis*, *M. pneumoniae* and other species in some cases. These arthritis are generally cured successfully by antibiotics, but only with a concomitant treatment of the immunosuppression.

Other infections by mycoplasmas have often been discovered fortuitously. As *M. hominis* is able to grow on blood agar used in routine culture, it explains why it is much more frequently isolated than the other species (Meyer and Clough, 1993; Blanchard and Béb ar, 2002). *M. hominis* has been demonstrated to be responsible for septicemia, retroperitoneal abscesses and peritonitis, hematoma infections, vascular and catheter-related infections, sternal wound infections associated with mediastinitis after thoracic surgery, prosthetic valve endocarditis, brain abscesses and pneumonia mainly by hematogenous spread. In most of the cases, these infections occurred in immunocompromised or transplanted patients or patients with major disruptions of anatomic barriers or polytraumas.

Exceptional cases of human infections due to animal mycoplasmas, *M. arginini* and *M. felis*, have been reported in immunocompromised patients.

The possible role of mycoplasmas in HIV disease has been a matter of debate and was fueled by the ability of these bacteria to promote HIV replication *in vitro* and/or HIV-associated cytopathic effects (Blanchard and Montagnier, 1994). The role of *M. fermentans* and then of *M. penetrans*, a species isolated from the urine of HIV-positive homosexual male, has been suggested in some reports. However, no conclusive evidence has demonstrated none other than an opportunistic role for mycoplasmas in HIV infection. *M. penetrans* has been recently isolated from the blood and the throat of a HIV-negative patient with primary antiphospholipid syndrome.

Recently, another matter of debate concerned the association of *M. fermentans* infection, detected either serologically or by PCR, and chronic fatigue syndrome or Gulf War illness. However, others did not find such an association, and in 2004, no evidence suggest that infection by *M. fermentans* is associated with the development of such diseases (Blanchard and Béb ar, 2002).

DIAGNOSTIC METHODS

Laboratory diagnosis can be performed using direct detection of mycoplasmas, by culture or molecular methods (PCR) or using serology. Both methods are available for *M. pneumoniae*. Direct detection is the only method adapted to genital mycoplasmas (B b ar *et al.*, 1997; Waites *et al.*, 2001a).

Specimens

Specimens Type

Whatever the sampling method used, it must collect cells to which mycoplasmas have adhered. Most of the specimens suitable for culture can also be used for PCR.

Different types of sampling methods are proposed for the respiratory tract. Sputum specimens are not very useful because they contain too many contaminants. Throat swabs and nasopharyngeal aspirates for young children give good results because of the diffuse nature of the infection. Bronchial brushing, bronchoalveolar lavages, pleural fluid specimens and biopsies can also be taken.

Genital mycoplasmas can be cultured from urethral swabs, first-void urine, semen, prostatic secretions, cervico-vaginal swabs, endometrial biopsies, tubal brushing, pouch of Douglas fluid, amniotic fluid, placenta, endotracheal samples from neonates, etc.

Mycoplasmas can be detected in other samples, CSF, synovial fluid, biopsies, mucocutaneous specimens and blood. However, the classic media used for blood culture contain anticoagulants which act as inhibitors for the growth of mycoplasmas.

Transport and Storage

As soon as specimens are taken, the swabs must be placed in the appropriate transport medium in order to avoid drying. Different media can be used for transport and storage, sucrose phosphate transport medium (2SP) containing 5% fetal bovine serum, without antibiotics and likely to be used for selection of both mycoplasmas and *Chlamydia*, by either culture or PCR, commercial transport media or culture media.

All samples must be transmitted to the laboratory as soon as possible. If they cannot be cultured immediately, they should be stored at 4 °C for a maximum of 48 h and beyond that at -70 °C or in liquid nitrogen.

Culture

Culture of mycoplasmas is relatively simple for certain species such as *M. hominis* and *Ureaplasma* spp., more delicate for *M. pneumoniae*, very fastidious and rarely successful for *M. genitalium* and to a less extent for *M. fermentans* and *M. penetrans*.

Growth Media

The growth media used are complex and rendered selective by the addition of a β -lactam antibiotic (penicillin or ampicillin) and sometimes polymyxin.

For the culture of *M. pneumoniae*, the medium frequently used is a Hayflick modified medium containing heart infusion broth supplemented with 10% (v/v) freshly prepared yeast extract (25% wt/v) and 20% horse serum (Waites *et al.*, 2001a). SP-4 medium is more complex and contains fetal bovine serum. A number of species of mycoplasmas grow better in this medium. Liquid media contain glucose (0.5%) and phenol red (0.002%). The pH ranges from 7.4 to 7.6. *M. hominis* grows on modified Hayflick medium and SP-4 medium, (initial pH around 7.2). The broth form of the two media contains arginine (1%) instead of glucose. *M. hominis* grows also on the medium at pH 6.0 designed for the culture of *Ureaplasma* spp.

Ureaplasma spp. are cultured at pH 6.0, on a medium based on trypticase soy broth, enriched with yeast extract, horse serum, cysteine and urea. The liquid medium contains the pH indicator, phenol red (Waites *et al.*, 2001a).

The medium SP-4 is the best adapted for the growth of fastidious species. It is enriched with glucose for *M. genitalium* and

with glucose and sometimes arginine for *M. fermentans*, *M. penetrans* and *M. pirum*.

Whatever the species sought, it is better to use both liquid and agar media (initially or after subculture). Broth cultures should be serially diluted 1:10 from 10^{-1} to 10^{-4} , in order to eliminate any possible inhibitors present in the tissue and for quantitative evaluation. Agar media should be dot inoculated. Liquid specimens (bronchoalveolar lavage and urine) should be centrifuged before plating. Given the fastidious nature of mycoplasmas, quality control of the culture media is essential.

Detection of Growth

In liquid media containing glucose, growth of fermenting species (particularly *M. pneumoniae*) is detected by a change in color of the pH indicator (acidification of the medium). Growth of *Ureaplasma* spp. produces an alcalinization of the liquid medium containing urea as does the growth of *M. hominis* and other such species on broth media containing arginine (Table 24.2). The color change occurs after 18–24 h for *Ureaplasma* spp., 48 h for *M. hominis*, 6–20 days for *M. pneumoniae* and even longer for more fastidious species.

After specimens have been plated and incubated under appropriate conditions for the particular species sought, colonies must be observed with magnification. The appearance varies from species to species. *M. pneumoniae* is often granular, while colonies of *M. hominis* are small (200–300 μ m), fried-egg shaped. Colonies of *Ureaplasma* spp. are irregular and very small (15–60 μ m) (Figure 24.1). Colonies grown on solid media containing urea and manganous sulfate or calcium chloride and are black which makes them easier to see and more difficult to confuse with artifacts such as crystals in the medium. These colonies can be observed directly after culture of the specimen on agar, or as control, after subculture of liquid media which have changed color.

Identification

Mycoplasma pneumoniae is identified on the basis of certain biochemical properties (fermentation of glucose and lack of arginine hydrolysis), hemadsorption or hemagglutination of guinea pig or chicken erythrocytes (absent in commensal respiratory mycoplasmas) and hemolysis. Antigenic identification, the previous reference method, is rarely used in the absence of commercially available immune serum. Furthermore, it is difficult to separate *M. pneumoniae* and *M. genitalium* using this method in that they present closely related antigens and similar biochemical properties. Amplification of genetic material from culture by PCR is an excellent method of identification.

Identification of *Ureaplasma* spp. and *M. hominis* is relatively simple. The change of a color indicator due to metabolic properties and the physical appearance of colonies are the principal methods. It is necessary to control the aspect of colonies because a color change can be caused by the presence of other bacteria or cells. Antigenic identification is very rarely performed, and separation of serovars is not current practice. Identification of the two species, *U. urealyticum* and *U. parvum*, can be performed by PCR (see paragraph 7.3.2).

Different commercial kits have been proposed for the detection of *Ureaplasma* spp. and *M. hominis* from lower genital tract specimens. They give satisfactory results if identification is verified by the physical appearance of colonies on agar.

Interpretation of Culture Results

Isolation of *M. pneumoniae* from a patient with a respiratory infection is an important indicator because this organism is not part of the commensal flora.

Isolation of *Ureaplasma* spp. or *M. hominis* poses a more delicate problem of interpretation. Isolation from normally sterile specimens is significant, but for other specimens where they can be present as commensals, it is useful to make a quantitative evaluation. The criteria proposed as significant for NGU are as follows: 10^4 color-changing unity (CCU)/ml for a urethral swab and 10^3 CCU/ml for first-void urine. The presence of *Ureaplasma* spp. in cervicovaginal swabs is very difficult to interpret because of its natural frequency. *M. hominis* can be found in high numbers ($\geq 10^4$ CCU/ml) during a vaginosis. Its presence can also suggest an infection higher up in the genital tract. In this case, clinical signs and associated bacteriological elements must be taken into account. The presence of mycoplasmas in peripheral neonatal specimens can be due to simple contamination. Isolation from endotracheal specimens in high number ($\geq 10^3$ CCU/ml) is more significant.

Non-Culture Methods

Culture is well adapted to the detection of *M. hominis* and *Ureaplasma* spp. from specimens where they can be found easily, such as urogenital specimens. Nonculture methods are useful for detection of fastidious and slow-growing organisms such as *M. pneumoniae* and *M. genitalium*. They are also adapted to the detection of all mycoplasma species, including *M. hominis* and *Ureaplasma* spp., from some specimens where they are difficult to grow, such as synovial fluids or tissues.

Antigenic detection and DNA probes have been proposed for *M. pneumoniae*. Because of their lack of sensitivity, they have been replaced by PCR. For instance, complete sequences of the 16S rRNA genes are available from almost all the established mycoplasma species and could be selected as target sequences in PCR-based tests. Some examples of target sequences for amplification of several human mycoplasmas will be taken. However, despite many developments in the use of PCR for mycoplasma detection, there is still a major drawback, the lack of standardization of the techniques, related to the lack of evaluated commercially available kit dedicated to mycoplasmas and the use of in-house PCRs.

PCR for *M. pneumoniae*

PCR detection of *M. pneumoniae* was first proposed 15 years ago (Bernet *et al.*, 1989). Many reports proposing different in-house PCRs in respiratory tract infections have been reviewed recently (Loens *et al.*, 2003). Amplification techniques demonstrated to be highly sensitive and specific and could become the preferred diagnostic procedures for *M. pneumoniae* infection, if available at a reasonable cost and standardized.

Different extraction methods are proposed. Because of the simple structure of mycoplasmas, sample preparation by freeze boiling could be sufficient (Ieven *et al.*, 1996). Several target regions have been used, 16S rRNA gene, ATPase operon gene, *tuf* gene and P1 adhesin gene. In comparative studies, P1 gene primers were found to give more sensitive results than 16S rRNA gene primers. Nested PCR was also proposed (Abele-Horn *et al.*, 1998; Dorigo-Zetsma *et al.*, 1999). Different techniques can be used for detection of amplification products.

Multiplex PCR tests detecting *M. pneumoniae* and other respiratory pathogens such as *C. pneumoniae* and *Legionella pneumophila* may prove useful, but the major progress will certainly be the development of real-time PCR allowing quantitative detection of *M. pneumoniae* DNA (Ursi *et al.*, 2003). Alternative amplification techniques such as Nucleic Acid Sequence Base Amplification have also been reported (Loens *et al.*, 2003).

PCR can also be used to separate, for epidemiological purpose, the two groups of *M. pneumoniae* strains (Cousin-Allery *et al.*, 2000).

PCR for Other Mycoplasmas

The PCR technique is practically the only method for detection of *M. genitalium* (Jensen *et al.*, 1991; de Barbeyrac *et al.*, 1993). The most frequently used target is *MgPa* adhesin gene. Real-time PCR was recently proposed (Yoshida *et al.*, 2002).

Concerning other mycoplasma species, PCR remains the best method for detection of *M. fermentans*, using amplification of insertion-like elements (Wang *et al.*, 1992) and *M. penetrans*. PCR is potentially interesting for the detection in some specific specimens of *Ureaplasma* spp., using amplification of the urease gene (Blanchard *et al.*, 1993) or other target and allows characterization of the two species *U. urealyticum* and *U. parvum* (Robertson *et al.*, 1993; Kong *et al.*, 2000). PCR is also widely used to detect mycoplasmal contamination of cell cultures (Teysou *et al.*, 1993; Drexler and Uphoff, 2000).

Serology

M. pneumoniae

Because of their simplicity, serologic tests are very often used to diagnose respiratory infections, mainly in severe illness. Even if PCR or culture are available, *M. pneumoniae* serology gives additional information when showing antibody response in infected patients. Its drawback is that it only allows a retrospective diagnosis. Antibody response to protein and glycolipid antigens of *M. pneumoniae* can be detected after about 1 week of illness, depending on the test, and peaks at 3–6 weeks and then declines gradually (Waites, Rikihisa and Taylor-Robinson, 2003).

Demonstration of seroconversion (fourfold change in titer) between two successive sera collected 2–4 weeks apart, or a high level of antibodies detected by a single or late test, is an important element of diagnosis. The presence of IgM often considered as evidence of acute infection is particularly interesting to detect in children. IgM are less often observed in adults.

Complement fixation (CF) reaction detects antibodies directed against a glycolipid antigen. Thus it was the reference test in the past; it is still valid as long as certain criteria of interpretation are strictly adhered to (seroconversion or a titer of at least 64). Nevertheless, it lacks sensitivity and specificity because of possible cross-reactions with other bacteria, mainly *M. genitalium*, but also with some human tissues or plants. False-positive reactions due to cross-reactive auto-antibodies can be observed in neurological or pancreatic illness, usually at a low level. CF detects IgM and IgG responses but does not differentiate among antibody classes.

Alternative techniques with greater sensitivity are proposed, immunofluorescence assays, particle agglutination assays using latex beads or gelatin and mainly EIAs (Enzyme-linked Immuno Assays) (Waites, Talkington and Béb ear, 2001b). EIAs are the most widely used techniques. Different antigen preparations and a variety of assay conditions (96-well microtiter plate formats, strips of 8-well format and rapid EIAs using qualitative membrane-based test) are available. They can detect IgG and IgM simultaneously or separately.

Cold agglutinins, IgM antibodies to the I antigen of erythrocytes, are found in only 30–50% of *M. pneumoniae* infections. Furthermore, their presence at a significant titer (≥ 64) is not specific of these infections.

Genital Mycoplasmas

Several techniques have been proposed for detection of antibodies during *Ureaplasma* spp. and *M. hominis* infections. The results of these tests were difficult to interpret because of the ubiquity of these species in humans and because of the lack of information concerning the level of immunity found in general population. Efforts to develop serologic tests for *M. genitalium* have been blocked by the problem of

antigens in common with *M. pneumoniae*. Serologic tests for genital mycoplasma infections are not commercially available in Europe or US and are not recommended for routine diagnostic.

Antibiotic Susceptibility

Antibiotic Susceptibility Testing

The nutritional requirements and cultural conditions of mycoplasmas are rather distant from the standard conditions recommended for bacteria. Actually no specific guidelines for susceptibility testing of mycoplasmas are available but recommendations have been recently summarized (Waites *et al.*, 2001a).

Standard broth, microbroth and agar dilution methods used for susceptibility testing of bacteria have been adapted for use with mycoplasmas. Agar media are recommended for mycoplasmas which produce colonies easily observed with a binocular microscope (practically all the species of the genus *Mycoplasma*), while broth media are recommended for *Ureaplasma* spp. Initial inoculum should be quantified and contain 10^4 – 10^5 CCU/ml. After a period of incubation appropriate for the species, the results should be read when growth becomes visible on the control medium containing no antibiotic. The MIC is the lowest concentration of antibiotic inhibiting the growth of colonies or a color change of the pH indicator. These methods, performed with appropriate controls, give useful results for the treatment of mycoplasmal infections.

Susceptibility testing kits, available in Europe, have been adapted only for use with *Ureaplasma* spp. and *M. hominis*. They consist of microwells containing dried antimicrobials, generally in one or two concentrations corresponding to the threshold proposed for conventional bacteria to classify a strain as susceptible, intermediate or resistant. The results obtained with these kits are satisfactory, but the kits should be better used after isolation of the organism than directly on the original specimen.

Generally, agar disk diffusion is not acceptable for mycoplasma susceptibility testing. However, the agar gradient diffusion technique or E-test has been recently adapted to determine fluoroquinolone, tetracycline and macrolide susceptibilities for *M. hominis* and *Ureaplasma* spp. (Waites *et al.*, 2001a).

No breakpoints specific for mycoplasmas are available actually; so it may be preferable to merely report MICs. Some laboratories have adopted the breakpoints used for the interpretation of MICs for other bacteria. MIC values of ≤ 1 $\mu\text{g/ml}$ should be considered predictive of effective treatment (Taylor-Robinson and Béb  ar, 1997).

Intrinsic Antibiotic Resistance

Two kinds of intrinsic resistance are present in mycoplasmas, one related to the class Mollicutes and one related to the different mycoplasma and ureaplasma species (B  b  ar and B  b  ar, 2002). Innate antibiotic resistance has been used to isolate mycoplasmas from specimens contaminated with other bacteria and to differentiate mycoplasma species.

The lack of a cell wall makes all the members of the class Mollicutes intrinsically resistant to β -lactams and to all antimicrobials, such as glycopeptides and fosfomycin, which target the cell wall. In addition, mycoplasmas are also resistant to polymyxins, sulfonamides, trimethoprim, nalidixic acid and rifampin. The molecular mechanism of resistance to rifampin investigated in *S. citri* was shown to be a natural mutation of the *rpoB* gene encoding the β subunit of the DNA-dependent RNA polymerase, the target of rifampin, preventing the binding of the antibiotic to its target.

Resistance to the macrolide-lincosamide-streptogramin-ketolide (MLSK) group differs between species.

Mycoplasma pneumoniae and *M. genitalium* are naturally susceptible to all MLSK antibiotics, except to lincomycin which shows modest

activity against these two species (Table 24.3). *Ureaplasma* spp. are susceptible to macrolides and ketolides. *Mycoplasma hominis* is resistant to 14-membered ring Macrolides, including erythromycin and its derivatives, and to the 15-membered ring azithromycin but is susceptible to the 16-membered macrolide, josamycin. *Mycoplasma hominis* is susceptible to lincosamides but not to telithromycin. The genetic basis of the intrinsic resistance of *M. hominis* to erythromycin is related to mutations in the peptidyltransferase loop of domain V of 23S rRNA (Furneri *et al.*, 2000; Pereyre *et al.*, 2002).

Activities of Antibiotics Used for Treatment

The number of antibiotics that can be used for treating mycoplasmal infections is limited. The most widely used include tetracyclines, MLSK group and fluoroquinolones. Phenicol and aminoglycosides are kept for the treatment of special cases.

Tetracyclines, MLSK and fluoroquinolones share the advantages of being potentially active against the bacteria which could be associated with mycoplasmas in respiratory and urogenital tract infections. They share also the ability to reach high intracellular concentrations where mycoplasmas could localize. Only fluoroquinolones and ketolides have shown mycoplasmicidal qualities.

A compilation of MIC data obtained with different antimicrobials against human mycoplasmas is shown in Table 24.3. A lot of data are available for *M. pneumoniae*, *M. hominis* and *Ureaplasma* spp. The results for a very small number of strains of *M. genitalium* that are currently available indicate that this species has an antibiotic susceptibility profile similar to that of *M. pneumoniae* (Renaudin, Tully and B  b  ar, 1992).

Among the different mechanisms of acquired bacterial resistance, target alterations and efflux mechanisms have been described in mycoplasmas. Both genetic mutations or acquisition of new genes via gene transfer have been documented. Indeed, mycoplasmas are characterized by high mutation frequencies, and transposons carrying antibiotic resistance have been recognized in these bacteria (Roberts, 1992).

Tetracyclines: Acquired resistance to tetracyclines concerns only *Ureaplasma* spp. and *M. hominis*, but not *M. pneumoniae*. High-level resistance to tetracyclines (MICs ≥ 8 $\mu\text{g/ml}$) in *M. hominis* and *Ureaplasma* spp. has been associated with the presence of the *tet(M)* determinant (Roberts *et al.*, 1985; Roberts and Kenny, 1986), associated with a conjugative transposon, member of the Tn1545 family named Tn916, widely distributed among urogenital bacteria. The *tet(M)* determinant encodes the TetM protein which protects the ribosome from the action of tetracyclines and confers cross-resistance to all tetracyclines. Glycylcyclines such as tigecycline remain active against tetracycline-resistant strains of *M. hominis* containing *tet(M)* gene but not against *tet(M)*-containing *Ureaplasma* spp. In addition, the *tet(M)* resistance gene is one of the commonly used markers in genetic studies performed in mycoplasmas.

The occurrence of tetracycline resistance in genital mycoplasmas varies geographically and according to prior antimicrobial exposure. It was evaluated to about 10% in patients attending STD clinics in UK and less than 5% in France in 1993 (B  b  ar *et al.*, 1993). This resistance rate seems to increase significantly in some regions of France, especially for *M. hominis* (B  b  ar *et al.*, personal communication).

MLSK group: Acquired resistance to MLSK appears to remain a rare phenomenon. Some cases of macrolide resistance have been reported during treatment with macrolide of *M. pneumoniae* infection, and resistant strains of *M. pneumoniae* have been obtained *in vitro* by selection in the presence of various macrolides, streptogramins and a ketolide. A variety of mutations could be selected *in vitro*, mutations in the peptidyl transferase loop of domain V in the 23S rRNA, but also point mutations, insertions or deletions in L4 and L22 ribosomal protein genes (Lucier *et al.*, 1995; Pereyre *et al.*, 2004).

Table 24.3 Minimal inhibitory concentration ranges for various antimicrobials against *M. pneumoniae*, *M. genitalium*, *M. hominis* and *Ureaplasma* spp. (adapted from Béb  ar *et al.*, 2002; Kenny and Cartwright, 2001)

^a Susceptible strains.

The frequency of acquired macrolide resistance in clinical strains of *M. hominis* and *Ureaplasma* spp. is not known but, like for *M. pneumoniae*, is probably very low. Acquired resistance to 16-membered macrolides and lincosamides has been recently described in a patient repetitively exposed to antibiotics (Pereyre *et al.*, 2002). Neither the methyltransferase enzyme (Erm family) nor the enzyme modifying the antibiotic have been identified so far in mycoplasmas.

Fluoroquinolones: Resistance to fluoroquinolones has been reported only for genital mycoplasmas. High-level resistance was observed in clinical isolates of *M. hominis* (B  b  ar *et al.*, 1999) and *Ureaplasma* spp. (B  b  ar *et al.*, 2003) obtained from patients treated previously with fluoroquinolones. These strains presented target alterations, located in the quinolone resistance-determining regions of the gyrase *gyrA* gene and of the topoisomerase IV *parC* and *parE* genes. Therapeutic failures of *M. genitalium*-positive NGU have been associated with mutations in the *gyrA* and *parC* genes of *M. genitalium* for patients treated with levofloxacin (Deguchi *et al.*, 2001).

Furthermore, an active efflux system, possibly an ATP-binding cassette-type efflux pump, was reported recently in ethidium bromide (EtBr)-selected strains of *M. hominis* showing a MDR resistance phenotype with increased MICs of ciprofloxacin and EtBr (Raheison *et al.*, 2002).

Other products: High-level resistance to aminoglycosides has been described in strains of *M. fermentans* isolated from cell cultures, but

not from human sources. The resistance gene *aacA-aphD* found in the transposon Tn4001 which confers resistance to gentamicin and the *cat* gene encoding chloramphenicol acetyltransferase are used as markers in genetic studies of mycoplasmas.

TREATMENT, PREVENTION AND CONTROL

M. pneumoniae Infection

The number of evaluations of the *in vivo* activity of antibiotics in infections due to mycoplasmas is low. However, since most of the antimicrobial agents active against mycoplasmas are only bacteriostatic, eradicating mycoplasmas depends on the efficacy of the host immune system.

An experimental model has been used for assessing the efficacy of erythromycin, roxithromycin and pristinamycin in the treatment of respiratory infection caused by intranasal inoculation of *M. pneumoniae* in hamster. Recently, an experimental model of pneumonia was described in mice with *M. pneumoniae* (Hardy *et al.*, 2003). Different clinical trials showed also the efficiency of such treatments for community-acquired pneumonia (B  b  ar *et al.*, 1993).

Because of the lack of simple, rapid detection methods, suspected *M. pneumoniae* infections are treated before they can be confirmed.

Macrolides are usually prescribed for patients of all ages. Recently, clinical effectiveness of azithromycin prophylaxis was demonstrated during a *M. pneumoniae* outbreak in a closed setting (Hyde *et al.*, 2001). For adults, fluoroquinolones, which are active *in vitro*, are an interesting alternative, but the number of documented studies is still rather low. The antibiotic treatment can shorten the course of the disease.

Different types of vaccines against *M. pneumoniae* have been tested. None are presently available. The most promising will probably contain the antigenic fraction of purified P1 protein.

Genital Mycoplasma Infections

The treatment of genital mycoplasma infections can occur after demonstration of their role in the infection or in the absence of microbiological proof when they are suspected to be possibly involved. The choice of antibiotic to treat these infections must take into account the specific species isolated or suspected, any other microorganisms isolated or possibly associated and the physical circumstances of the development of the disease.

In adults, the treatment of these infections is the same as for *C. trachomatis* with which they are sometimes associated. Generally, tetracyclines are the antibiotics of first choice. There have been some cases of therapeutic failure related to resistance *in vitro*. The fluoroquinolones are certainly interesting. When these antibiotics are contraindicated (pregnancy and neonatal infections), macrolides are considered first. The activity must be tested *in vitro*. It is sometimes necessary to treat neonates with tetracycline such as when the strain involved is resistant to erythromycin. These cases are very rare. A recent study compared the antibiotic treatment efficacy of tetracyclines and azithromycin in *M. genitalium*-infected adults (Falk, Fredlund and Jensen, 2003). The data suggested that tetracyclines are not sufficient to eradicate *M. genitalium* and randomized controlled treatment trials are needed.

The length and method of administration of the treatment depend on the location of the infection. As most active antibiotics have a bacteriostatic effect on mycoplasmas, the course of treatment must be sufficiently long. Clinical and biological criteria come into play to confirm the efficacy of treatment. Clearing of mycoplasmas is a valid criteria for sites which are normally sterile, but it is no longer reliable for sites where mycoplasmas can be found naturally. It must, nevertheless, be indicated that even though treatment of mycoplasma infections is relatively simple in otherwise healthy subjects, it is much more complicated in immunosuppressed subjects. It is then essential to verify eradication of the organism which can be difficult.

Chlamydia spp. and Related Organisms

S. J. Furrows¹ and G. L. Ridgway²

¹Department of Clinical Parasitology, The Hospital of Tropical Diseases; and ²Pathology Department, The London Clinic, London, UK

INTRODUCTION

Organisms comprising the order Chlamydiales are bacteria adapted to an existence as obligate intracellular parasites of eukaryotic cells. They have an affinity with Gram-negative organisms and infect a wide range of avian, mammalian and invertebrate hosts. The range of clinical syndromes found in human chlamydial infection is wide and includes ocular, respiratory and genital infections.

DESCRIPTION OF THE ORGANISM

Chlamydial Classification

First recognised in 1907, the chlamydiae were initially thought to be viruses and have undergone several reclassifications subsequently.

According to current thinking, the order Chlamydiales contains four defined families: Chlamydiaceae, Parachlamydiaceae, Waddliaceae and Simkaniaceae (Everett, Bush and Andersen, 1999; Bush and Everett, 2001). The important human and animal pathogens belong to the family Chlamydiaceae, which contains two genera: *Chlamydia* spp. and *Chlamydophila* spp. (Figure 25.1).

Chlamydia trachomatis

Chlamydia trachomatis is primarily a human pathogen, causing ocular, urogenital and neonatal infections. Historically, it was subdivided into three strains or biovars: trachoma, lymphogranuloma venereum (LGV) and mouse pneumonitis (Nigg and Eaton, 1944). Serotyping of *C. trachomatis* according to antigenic determinants on the major outer membrane protein (MOMP) subdivides the species

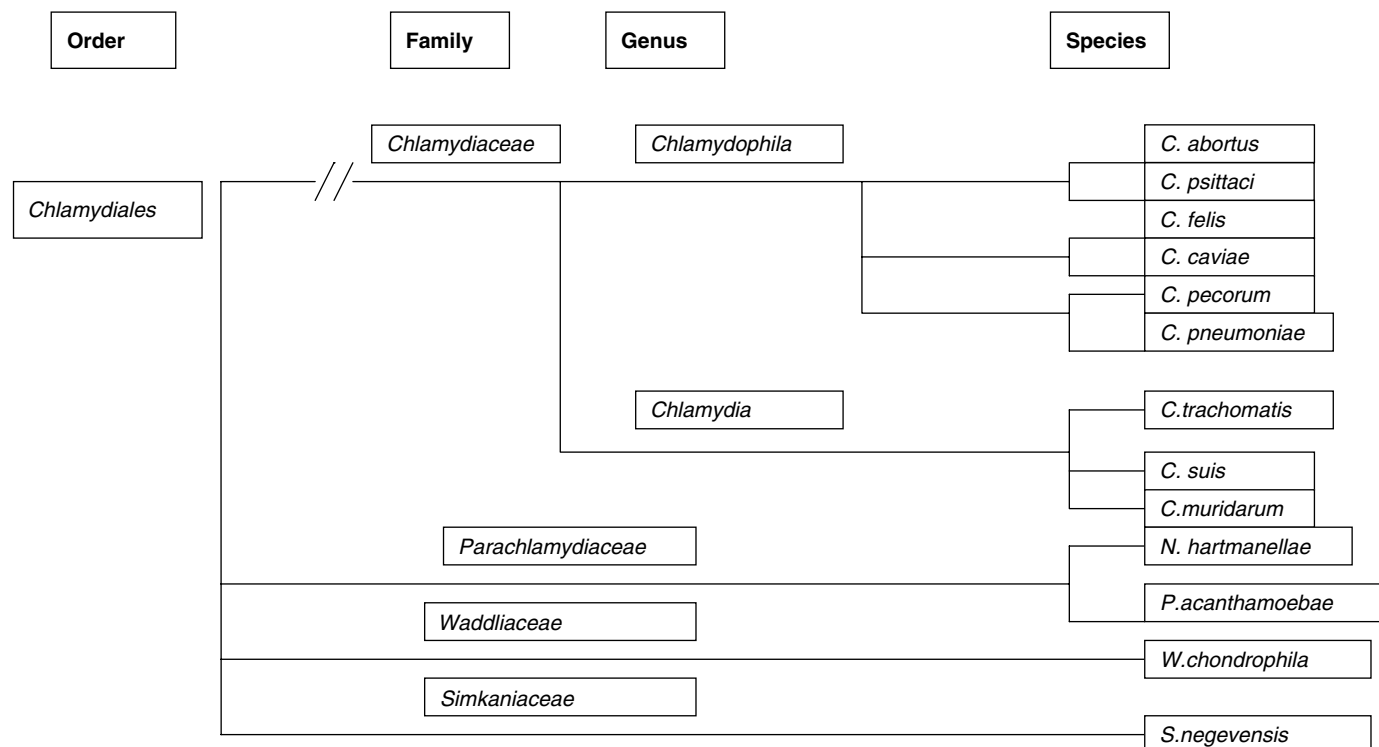

Figure 25.1 From www.chlamydiae.com. Adapted from Bush RM, Everett KDE (2001).

into 18 serovars affecting humans (Wang and Grayston, 1991). Serovars A, B, Ba and C are associated primarily with ocular disease; serovars D–K are associated with oculogenital disease, which may be transmitted to neonates; and serovars L1–L3 are associated with LGV.

Chlamydomphila pneumoniae

Chlamydomphila pneumoniae was originally isolated in 1965 from the conjunctiva of a Taiwanese child participating in a trachoma vaccine trial (Kuo *et al.*, 1986). Subsequent isolation in respiratory illness led to the acronym TWAR (Taiwan acute respiratory) strains. In 1989, TWAR strain was established as a new species of *Chlamydia pneumoniae*, recently reclassified as *C. pneumoniae* on the basis of ribosomal RNA sequence data (Everett, Bush and Andersen, 1999). *Chlamydomphila pneumoniae* lacks an animal reservoir and is transmitted from person to person. *Chlamydomphila pneumoniae* is a common cause of respiratory infection. More controversially, it has been associated with chronic cardiovascular and neurological illnesses. The exact role, if any, of *C. pneumoniae* in the pathogenesis of these diseases is still unclear.

Chlamydomphila psittaci

Chlamydomphila psittaci is a diverse group of organisms: at least 11 types are distinguished using microimmunofluorescence, 16S rRNA gene sequencing and polymerase chain reaction (PCR)/sequencing of the MOMP (Andersen, 1997; Takahashi *et al.*, 1997; Bush and Everett, 2001). These strains are thought to differ in virulence, but all are potentially transmissible to humans. *Chlamydomphila psittaci* primarily affects birds, and infection has been documented in over 130 avian species (Macfarlane and Macrae, 1983). Infection is spread to humans by the respiratory route, to cause an ornithosis (infection of avian or animal origin) or psittacosis (infection acquired from parrots or related birds). Human-to-human transmission is very rare (Byrom, Walls and Mair, 1979).

Chlamydomphila felis

Chlamydomphila felis is endemic among housecats worldwide, primarily causing inflammation of feline conjunctiva, rhinitis and respiratory problems. It is recovered from the stomach and reproductive tract. Zoonotic infection of humans with *C. felis* has been reported (Hartley *et al.*, 2001).

Chlamydomphila abortus

Chlamydomphila abortus strains are endemic among ruminants and colonise the placenta. There are several case reports of miscarriages in women exposed to infected sheep and goats, with the diagnosis confirmed by serology or by PCR (Jorgensen, 1997; Pospischil *et al.*, 2002).

Other chlamydial species include *Chlamydomphila caviae*, *Chlamydomphila pecorum*, *Chlamydia suis* and *Chlamydia muridarum* (Figure 25.1). These species have not been shown to colonise or infect humans; hence, they are not discussed further in this chapter.

Life Cycle

The life cycle of chlamydial species (including both *Chlamydia* and *Chlamydomphila*) is both unique and complex (Figure 25.2). A useful review of the developmental biology is found in Hatch (1999). A metabolically inert extracellular infectious transport particle of 200–300 nm size called the elementary body (EB) alternates with a larger intracellular reproductive particle of 1000 nm size called the

Figure 25.2 Diagram of chlamydial replication. Reproduced by permission of Karin D.E. Everett.

reticulate body (RB). The infective cycle commences when an EB is taken up by potentially phagocytic epithelial cells to form a phagosome. The EB protects itself from destruction within the phagosome by inhibiting fusion of host cell lysosomes (Scidmore, Fischer and Hackstadt, 2003). Its rigid trilaminar cell wall becomes bilaminar as cross-linking sulphide bonds are reduced, allowing compounds required for development and maturity to move in and out of the organism. The dense nucleoid of the EB unfolds and develops into the diffuse DNA characteristic of the RB. This takes place over about 6 h, at which time the transformed RB begins to divide by binary fission. As cell division continues, so the inclusion moves centripetally to enclose partially the host nucleus. At this time, *C. trachomatis*, but not the other species, lays down a glycogen matrix (Moulder, 1991). Division continues over the next 18–20 h, whereupon some of the RBs begin to condense into EBs. Protein synthesis ceases and the dense nucleoid reappears along with the thickened cell wall. Meanwhile, other RBs continue to divide. Inclusions of *C. trachomatis* mature around 48 h. The other species mature somewhat later at around 72 h. The whole process is carefully controlled by the chlamydiae, such that even normal host cell apoptosis is inhibited (Fan *et al.*, 1998; Carratelli *et al.*, 2002). Programmed rupture of the host cell membrane culminates in the release of the EBs into the surrounding environment.

There is evidence that under certain conditions, the cycle of EB/RB/EB development is arrested at the RB stage, leading to persistent (often termed latent) infection (Kutlin, Roblin and Hammerschlag, 1998). This phenomenon is known to be important in non-human and ocular infections and may have importance in chronic genital infection and in the possible role of *C. pneumoniae* in coronary atherosclerosis. The precise mechanism involved is not known, but many factors, such as the action of interferon- γ (IFN- γ), or tryptophan and cysteine deprivation, or antibiotics such as penicillins, may lead to an inhibited developmental cycle.

Genome

The genomes of several of the family Chlamydiaceae have now been sequenced. Published sequences include *C. trachomatis* serotypes B, D and L2 (Stephens, Kalman and Lammel, 1998) and *C. pneumoniae* strains J139 and CUL039 (Kalman *et al.*, 1999). General findings are that the chlamydial genome is smaller than any other prokaryote, with the sole exception of *Mycoplasma* spp. The complete genome of

C. trachomatis serovar D is 1.043 million base pairs, and for *C. pneumoniae* is 1.23 million base pairs. The genome appears relatively stable, with few gene rearrangements. Genes such as *omp1*, which encodes the MOMP, have been identified. Many candidate genes for chlamydial adhesins and for membrane proteins have also been identified. Certain metabolic pathways are missing, including amino acid and purine–pyrimidine biosynthesis, anaerobic fermentation and transformation competence proteins. Their absence may reflect the dependency of chlamydial species on the host cell machinery for the synthesis of these compounds. Interestingly, the necessary genes are present for the synthesis of penicillin-binding proteins, yet these proteins are not expressed. Speculation also exists over the possible presence of genes with eukaryotic homology.

Most strains of *C. trachomatis*, and some strains of *C. psittaci*, contain a plasmid of approximately 7.5 kb (McClenaghan, Honeycombe and Bevan, 1988). The function of the plasmid is unknown, although the extensive conservation between strains implies a critical function. *Chlamydomonas pneumoniae* does not contain any extrachromosomal genetic material (Grayston *et al.*, 1989).

Structure and Major Antigens

Lipopolysaccharide

Chlamydiae have a genus-specific lipopolysaccharide (LPS) antigen. This LPS is similar to the rough LPS of certain salmonellae, but it carries a trisaccharide epitope of 3-deoxy-D-manno-octulosonic acid, which is specific to the family Chlamydiaceae. This epitope is immunodominant and is exposed on the surface of RBs and EBs. The LPS is likely to be important in the pathogenesis of chlamydial infection, by induction of tumour necrosis factor- α (TNF- α) and other proinflammatory cytokines, leading to scarring and fibrosis. The potency of chlamydial LPS is considerably less than that of gonococcal or salmonella LPS (Ingalls *et al.*, 1995), which may explain the prevalence of asymptomatic infection.

There are many protein antigens, with genus, species and serotype specificity.

MOMP

The dominant surface antigen is the MOMP, encoded by the *omp1* gene. This 40-kDa protein is the basis of the serological classification of *C. trachomatis* (Wang and Grayston, 1991). The antigenicity of MOMP appears to be less significant in *C. pneumoniae*, and its antigenic variation is much less marked in both *C. pneumoniae* and *C. psittaci* (Carter *et al.*, 1991).

Omc Proteins

Genes termed *omp2* and *omp3* encode two cysteine-rich proteins of the outer membrane complex of approximately 60 kDa and 12–15 kDa, respectively, termed OmcA and OmcB. They are synthesised during the transition of RB to EB, and the S–S-linked complex may provide the cell wall rigidity of the EB (Everett and Hatch, 1995).

Polymorphic Outer Membrane Proteins

Another group of surface-exposed proteins are the polymorphic outer membrane proteins (PMPs). There are at least 9 of these in *C. trachomatis*, and more than 20 in *C. pneumoniae* (Stephens, Kalman and Lammel, 1998; Kalman *et al.*, 1999). Their role is not yet defined.

Type III Secretory System

The chlamydiae possess genes for a type III secretory system, which may contribute to pathogenicity and confer survival advantages (Hueck, 1998; Winstanley and Hart, 2001). The type III secretory system is characteristic of Gram-negative organisms and is surface activated by contact with eukaryotic host cells. The surface of EBs and RBs is characterised by many spike-like, protein-containing projections, which may be associated with this secretory system. The projections on RBs have been shown to penetrate the inclusion membrane. Upon activation of the type III system, chlamydial proteins are injected into the cytoplasm of the host cell. Putative candidate proteins include inclusion membrane (Inc) proteins, which modify the inclusion membrane and subvert host cell signalling, proteins involved in the transport of essential nutrients into the inclusion and proteins involved in the modulation of apoptosis.

Heat Shock Proteins

The 12-, 60- and 75-kDa heat shock proteins are closely related to their counterparts in *Escherichia coli* (GroEL, GroES and DnaK) and also to related mitochondrial proteins in humans (Hsp10, Hsp60 and Hsp70). They are highly conserved chaperonins involved in protein folding. Hsp60 is highly immunogenic and is thought to play a major role in pathogenicity. The mechanism for this relates to an interaction with IFN- γ which, although inhibitory to chlamydiae, may result in the upregulation of Hsp60 at the expense of MOMP. This in turn might lead to a host autoimmune response, leading to the fibrosis and scarring associated with chlamydial infection. Many studies have shown an association between antibodies to chlamydia heat shock

Figure 25.3 Diagram of the cell envelope. Reproduced by permission of Karin D.E. Everett.

proteins and the chronic sequelae of chlamydial infection (Ward, 1999), although this does not prove causation. A study of endemic trachoma in the Gambia found an association between antibodies to chlamydial heat shock proteins and conjunctival scarring (Peeling *et al.*, 1998).

EPIDEMIOLOGY

Chlamydia trachomatis is the commonest cause of bacterial genital infection in both men and women in the developed world and is the major cause of secondary (preventable) infertility. The World Health Organization (WHO) estimates that there are 90 million new cases each year (Gerbase *et al.*, 1998). Prevalence is almost certainly underreported, not least because many infections are asymptomatic. An apparent greater prevalence in women than men (7:1) probably reflects greater opportunity to screen women than men. Peak prevalence in women is between 16 and 25 years of age. Studies in family practitioner settings in the United Kingdom suggest that the prevalence in this age group is within the range 3–6%. In men, the age of peak prevalence is older, reflecting the higher age of peak sexual activity. Risk factors for infection include multiple sexual partners, recent partner change and low socioeconomic status.

Trachoma, the infection caused by ocular strains of *C. trachomatis* (serotypes A–C), is endemic in North and sub-Saharan Africa, the Middle East, northern Asia, the Far East, Australasia and Latin America. In some villages, there is a greater than 90% attack rate. True figures for prevalence are unknown, with estimates in the range of 600 million people affected, of whom some 6 million will be blinded (Thylefors *et al.*, 1995). Trachoma is spread directly from eye to eye or indirectly by flies that transmit infected secretions from person to person (so called ocular promiscuity).

LGV is confined to the tropics and is sexually transmitted.

Chlamydophila pneumoniae is now recognised as a common respiratory pathogen (Hahn *et al.*, 2002), responsible for between 6 and 20% of community-acquired pneumonia. Humans are the only known reservoir, and transmission is via the respiratory route. Serological studies show that seropositivity rates are low in the under-5s, but rise rapidly during school age, such that by early adulthood, 50% are seropositive. This seropositivity rate increases gradually with age, reaching approximately 75% in the elderly. In addition, studies suggest that *C. pneumoniae* may go on to cause chronic infection of the respiratory tract and, possibly, of other sites such as the vascular system and central nervous system.

Chlamydophila psittaci is carried by animals, classically psittacine birds, and has no human reservoir. Human infection is almost always the result of zoonotic exposure and may occur both sporadically and in outbreaks (Yung and Grayson, 1988). Humans are infected via the respiratory route, particularly via inhaled infected dust in proximity to sick birds. Human-to-human transmission is unusual, except with virulent strains. Psittacosis is now rare, and many earlier references may have been erroneously assigned to *C. psittaci* before the role of *C. pneumoniae* was appreciated: such studies based the diagnosis of psittacosis on positive serology using the genus-specific complement fixation test method, which we now appreciate does not distinguish between *C. psittaci* and *C. pneumoniae*.

PATHOGENICITY

Host immunity is thought to be responsible for the pathogenesis of many of the clinical features of chlamydial infection. The host immune response to chlamydial infection is complex and far from fully understood (Cohen and Brunham, 1999). It is relatively ineffectual against acute infection. Cell-mediated immunity is thought to be important in the hypersensitivity reaction that leads to lasting tissue damage, particularly in recurrent and persistent infections. The host immune response may be considered as follows.

Antibody Response

Antibody to LPS is group specific and forms the basis of the now largely obsolete complement fixation test for chlamydial antibody. Species-specific antibodies of immunoglobulin G (IgG), IgM and IgA classes are produced in serum and in local secretions against MOMP, in response to chlamydial infection. The type and degree of response reflect the site and nature of infection. IgG and IgM levels are generally greater in systemic infections such as LGV or pelvic inflammatory disease (PID). IgM appears early but may persist, particularly in complicated infections. Serotype-specific antibodies are known to be neutralising in cell culture and may also play a part in short-term restriction of chlamydial infection. The role of IgA as a marker of persistent infection, particularly with *C. pneumoniae*, is controversial. In cases of reinfection by *C. pneumoniae*, IgM class antibody may not appear, whilst in recurrent *C. trachomatis* infection early antibody may reflect previously infecting serotypes.

Cellular Response

In acute infection, there is a brisk polymorphonuclear response, and polymorphonuclear leucocytes (PMNLs) are shown *in vitro* to inactivate chlamydiae. However, they have a limited role in the eradication of persistent infection. Resistance to infection and clearance of primary infection are due in large part to T-cell function, with both CD4 and CD8 cells having a protective role. MOMP-specific T-helper 1 (Th1) CD4 cells may have an important role in immunity, while Hsp60-specific Th2 CD4 cells are associated with the pathological sequelae of persistent infection. Much less is known about the role of cytotoxic CD8 cells in chlamydial immunity.

Cytokines

Infection of epithelial mucosal cells with *C. trachomatis* has been shown to generate several cytokines, including interleukin-1 α (IL-1 α), IL-6, IL-8, GRO- α and granulocyte-macrophage colony-stimulating factor (GM-CSF), which generate and sustain an inflammatory response (Rasmussen *et al.*, 1997). IFNs, in particular IFN- γ , play an important part in the immune response to chlamydial infection by inhibiting intracellular replication at the RB stage through tryptophan depletion. However, this may result in continuing secretions of chlamydial antigens, leading to further sensitisation and also induction of persistent non-replicating infection (Beatty, Morrison and Byrne, 1994). TNF- α is produced and may contribute to the tissue damage resulting from infection.

CLINICAL FEATURES

Chlamydia trachomatis

Chlamydia trachomatis is capable of infecting several different systems, to cause ocular, genital, rheumatological and neonatal infections, in addition to the tropical infection LGV.

Ocular Infections

The most important ocular infection syndrome is trachoma (Mecaskey *et al.*, 2003), caused predominantly by the trachoma serovars A–C. The incubation period is uncertain but is probably within the range 7–14 days. Acute infection presents as a follicular conjunctivitis, with congestion and oedema affecting both the palpebral and bulbar conjunctivae. There is papillary hyperplasia, giving the palpebral conjunctiva a velvety appearance. In hyperendemic areas, infection tends to be more pronounced in the upper lid. Follicles rupture to

leave shallow pits termed Herbert's pits. Keratitis develops in the cornea. Recurrent infection leads to limbal scarring and new vessel formation (pannus). Palpebral conjunctival scarring (cicatrization) leads to in-turning of the eyelashes (entropion), which scrape the bulbar corneal surface (trichiasis). It is the cycle of recurrent infection, with conjunctival scarring and pannus extending over the cornea, which results in impaired vision or blindness.

Clinical diagnosis of trachoma is based on WHO classification. Two or more of the following are required:

1. upper tarsal lymphoid follicles;
2. conjunctival scarring;
3. pannus;
4. limbal follicles or Herbert's pits.

Further staging of disease takes account of the intensity of disease and presence of complications.

Another ocular infection syndrome caused by *C. trachomatis* is adult inclusion conjunctivitis (paratrachoma) (Viswalingam, Wishart and Woodland, 1983). This is a disease of developed countries, characterised by infection with the genital serovars D–K of *C. trachomatis*. The incubation period is 2–3 weeks. Transmission is by contact of eyes with infected genital secretions. An acute follicular conjunctivitis develops, which affects the lower conjunctiva more than the upper. Severe disease presents as diffuse punctate keratoconjunctivitis. Pannus and scarring are unusual. The disease, if untreated, runs a fluctuating course before healing without cicatrization. It is important to enquire about exposure to genital infection, either in the patient or in their partner.

Genital Infections

Genital infection in men presents most commonly as non-gonococcal urethritis (NGU). In most communities, this is far commoner than gonococcal urethritis (GU). *Chlamydia trachomatis* is responsible for 30–50% of cases of NGU; other cases may be caused by *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis* or herpes simplex. The incubation period for NGU is between 7 and 14 days (Stamm *et al.*, 1984), compared with 2–5 days for GU. A mucopurulent discharge is followed by dysuria and urethral irritation. Symptoms may be minimal, and some 40% of men with NGU are asymptomatic. NGU and GU may occur simultaneously. Treatment of the GU only, with a single dose of antibiotics ineffective against *C. trachomatis*, will result in post-gonococcal urethritis (PGU). PGU usually appears about 1 week after the treatment of GU, reflecting the difference in incubation period. Symptoms and signs are identical to those of NGU. *Chlamydia trachomatis* is responsible for 80–90% of cases of PGU.

Epididymitis is a recognised complication of chlamydial genital infection in men. Urethritis is usually also present. *Chlamydia trachomatis* is the commonest cause of epididymitis in men aged under 35 years, being responsible for 50% of cases (Berger *et al.*, 1979). Its role in prostatitis remains controversial: Although some investigators have detected *C. trachomatis* in prostatic secretions (Shortliffe, Sellers and Schachter, 1992), the balance of evidence at present does not support a role in either acute or chronic prostatitis. Rectal infection is well documented, particularly in anoreceptive homosexual males, and should be considered in the differential diagnosis of proctitis.

Infection of the female genital tract commences with urethritis and cervicitis and may progress to endometritis, salpingitis and peritoneal involvement (perihepatitis). Approximately 70% of women with chlamydial genital infection are asymptomatic (Cates and Wasserheit, 1991). Many women, if untreated, will go on to develop serious long-term sequelae of infection such as PID, infertility and ectopic pregnancy.

Urethritis alone occurs in some 25% of infected women. Symptoms are absent or mild and include abdominal discomfort and dysuria. The relationship of urethral infection to urethral syndrome (dysuria and frequency with less than 10^5 organisms per millilitre of urine) is controversial. In one study of 59 women with urethral syndrome, 42 also had pyuria and 11 of those 42 were infected with *C. trachomatis* (Stamm *et al.*, 1980).

Cervicitis is the commonest manifestation of chlamydial infection in women. It is frequently asymptomatic, though mucopurulent cervicitis may be apparent on speculum examination. Symptoms, where present, include a mucopurulent vaginal discharge and vaginal bleeding. Chlamydial infection cannot be distinguished on clinical grounds from other causes of vaginal discharge. In prepubertal children, the vaginal epithelium is columnar. With the onset of puberty, the epithelium becomes squamous as the columnar epithelium retreats to the endocervix. In consequence, chlamydial infection of the vaginal epithelium is not seen in adults but occurs in female children.

Endometritis and salpingitis due to chlamydial infection encompass the condition PID. Although PID is the result of a polymicrobial infection, there is no doubt that the most important initiating micro-organism is *C. trachomatis*, followed closely by *Neisseria gonorrhoeae*. The proportion of women with acute PID from whom chlamydiae is isolated varies in different populations but is usually between 20 and 40% (Bevan, Ridgway and Rothermel, 2003). Concurrent infection with both organisms is not uncommon. An estimated 8% of women with cervical *C. trachomatis* infection progress to acute salpingitis (Cates and Wasserheit, 1991). Salpingitis is often subclinical but may cause acute illness with fever and pelvic pain. Examination reveals lower abdominal and adnexal tenderness. Tubal abscess may occur. Spread to the peritoneum results in perihepatitis (Fitz–Hugh–Curtis syndrome), an inflammation of the peritoneal covering of the liver, which presents with right upper quadrant pain and may mimic gall bladder disease (Bolton and Darougar, 1983). At laparoscopy, there is reddening of the tubal serosal surface, with intense fibrosis giving rise to friable strands described as violin string adhesions between the liver surface and the abdominal wall (Van Dongen, 1993).

Chlamydial PID is the commonest preventable cause of infertility. Chronic chlamydial infection of the upper genital tract leads to chronic inflammation and scarring, resulting in abdominal pain, secondary infertility and an increased risk of ectopic pregnancy. Some 10% of women are infertile following a single infection, rising to more than 50% after more than two episodes. Although most women with infertility due to tubular disease do not have a history of chlamydial infection or PID, approximately 80% have positive genital chlamydial serology, compared with 20% of women with non-tubal infertility (Osser, Persson and Liedholm, 1989). The risk of ectopic pregnancy is increased by seven to ten times following chlamydial PID.

The effect of chlamydial infection on pregnancy is not well understood. Apart from causing a vaginal discharge consequent on mucopurulent cervicitis, the main concern is with ascending genital tract infection, leading to amnionitis and perinatal endometritis. Acute non-gonococcal salpingitis is unusual in pregnancy. The role of chlamydial infection in premature rupture of membranes, prematurity and neonatal death is not clear. While some reports have reported an association, others have not been able to confirm this. The role of *C. trachomatis* in post-delivery sepsis is even less clear-cut. There is no doubt that chlamydial infection is a risk factor for pelvic sepsis after therapeutic abortion, but less certainty that the organism is an important cause of puerperal sepsis.

Sexually Acquired Reactive Arthritis

This is a rheumatoid seronegative condition which includes non-dysenteric Reiter's syndrome. Symptoms appear 1–4 weeks after lower genital infection and affect the large joints, particularly of the

legs, or the sacroiliac joints. Men are more frequently affected than women (10:1). Approximately 1% of men with urethritis develop sexually acquired reactive arthritis (SARA). The classic triad of Reiter's syndrome (urethritis, conjunctivitis and arthritis) occurs in 30–50% (Keat, Thomas and Taylor-Robinson, 1983). In over 90% of patients, more than one joint is involved. Skin involvement may include the penis (circinate balanitis) or keratoderma of the palms and soles.

Two-thirds of patients with SARA carry the HLA-B27 haplotype. The reactive arthritis is thought to be an immune-mediated inflammatory response to an infection at a distant site. *Chlamydia trachomatis* may act as a trigger organism with an enhanced immune response in susceptible individuals but is not responsible for all cases. Resolution usually occurs without specific treatment, but relapse is common.

Neonatal and Childhood Infections

True congenital infection has never been described. Infection is always associated with ruptured membranes. The incidence of transmission from mother to neonate may be higher than previously thought, now that molecular methods of diagnosis are available: one PCR-based study found a vertical transmission rate, from infected mothers to their infants, of 55%, with 45% developing conjunctivitis and 30% pneumonia (Shen, Wu and Liu, 1995). The pharynx, middle ear, rectum and vagina may also be colonised, with a delay of up to 7 months before cultures are positive (Bell *et al.*, 1992). If untreated, the infection may persist for over 2 years. Antenatal screening for *C. trachomatis* has been shown to be effective at reducing neonatal morbidity (Pereira *et al.*, 1990) and is recommended in Centers for Disease Control and Prevention (CDC) guidelines (Centers for Disease Control and Prevention, 2002).

Neonatal inclusion conjunctivitis (ophthalmia neonatorum) due to chlamydial infection is much commoner than gonococcal ophthalmia. The incubation period for chlamydial infection is significantly longer (6–21 days), compared to the 48-h incubation period for gonococcal ophthalmia. The conditions are clinically very similar and may occur together: it is important to ensure that gonococcal ophthalmia does not mask a chlamydial infection, as treatment for the former may not be adequate for the latter. Chlamydial ophthalmia presents with a watery ocular discharge, which may progress to a purulent conjunctivitis with marked periorbital oedema. Because the conjunctiva at birth lacks a lymphoid layer, follicles do not develop initially but may be seen after 3–6 weeks. Unlike trachoma, the lower conjunctival surface is more heavily infected than the upper. Although scarring has been reported, the condition seems to be self-limiting after a relapsing course (Schachter and Dawson, 1978).

Pneumonitis presents within 3 weeks to 3 months of birth. Pneumonitis develops when organisms present in the conjunctiva pass down the nasolacrimal duct into the pharynx. Infection via the eustachian tube may cause otitis media. There is a history of conjunctivitis in approximately half of babies with chlamydial pneumonitis (Tippie, Beem and Saxon, 1979). Most cases of pneumonitis are afebrile (Beem and Saxon, 1977). There may be tachypnoea and a characteristic staccato cough. In severe cases, there may be episodes of apnoea and respiratory failure. On examination, there may be scattered crepitations in the lung fields, but there is good air entry and no wheeze. There are patchy interstitial infiltrates and hyperinflation on chest X-ray. If untreated, infection may persist for weeks or months. There is a peripheral blood eosinophilia, hypergammaglobulinemia and raised anti-chlamydial IgM titres. Pulmonary function tests show an obstructive picture, with significant limitation of expiratory airflow and signs of abnormally elevated volumes of trapped air. There is a possible association between *C. trachomatis* pneumonitis and childhood asthma (Weiss, Newcomb and Beem, 1986). Another study describes a positive association between serological evidence of previous infection with *C. trachomatis* and asthma-related symptoms

(Bjornsson *et al.*, 1996). Chlamydiae may be shed from the rectum in the first year of life, particularly in babies with pneumonia. Such shedding does not occur until 2–3 months after birth, suggesting that it reflects colonisation of the gastrointestinal tract. The long-term sequelae of this colonisation is unknown.

Lymphogranuloma Venereum

LGV is a sexually transmitted disease caused by the L1–L3 serovars of *C. trachomatis*. It is endemic in the tropics, notably Africa, India, Southeast Asia, South America and the Caribbean, and may occur as a sporadic disease elsewhere. As with other chlamydial genital infections, asymptomatic carrier sites, including the female cervix and the rectal mucosa of homosexual men, are important reservoirs.

The primary genital lesion in men is an insignificant and often painless papule, ulcer or vesicle on the penis. Similar lesions may occur on the vulva in women. The lesion appears between 3 and 30 days after infection and heals rapidly without leaving a scar. There is unilateral lymphadenopathy in two-thirds of patients (Schachter and Dawson, 1978). The secondary stage occurs after 1–6 weeks and is characterised by regional lymphadenopathy and systemic symptoms (Schachter and Osaba, 1983). Regional inguinal lymph nodes in the groin become enlarged and tender, with fixation and erythema of the overlying skin. The inflammatory process spreads from the lymph nodes into the surrounding tissue, forming an inflammatory mass. Abscesses within the mass coalesce to form buboes, which may break down to discharge externally as chronic fistulae. Enlargement of inguinal and femoral nodes may lead to a characteristic groove sign. Buboes should not be excised or drained other than by aspiration. They usually subside, but disruption to lymph drainage may occur. In women and anoreceptive men, internal lesions (vaginal, cervical and rectal) may go unnoticed. The lymph node drainage is to the pararectal nodes, and these may discharge via the rectum. Systemic symptoms of this second stage include fever, headache and myalgia. If untreated, the disease may proceed to the third stage, which is more serious in women and homosexual men. In these groups, rectal stricture or rectovaginal and rectal fistulae may occur (Lynch *et al.*, 1999; Papagrigoriadis and Rennie, 1999). Carcinomatous change is not unknown. The vulva, scrotum or penis may become affected by ulceration and oedematous granulomatous hypertrophy ('*esthiomene*', Greek meaning 'eating away'). Impaired lymphatic drainage may lead to elephantiasis of the vulva or scrotum.

The differential diagnosis for LGV includes other causes of genital ulceration such as syphilis, chancroid and granuloma inguinale. The possibility of dual infection should be borne in mind. Typically, patients with LGV have very high titres of chlamydial antibody, both generic and species specific. The diagnosis of LGV may be confirmed with positive chlamydial serology, isolation of *C. trachomatis* from affected tissue or pus or histopathology. Antigen or nucleic acid amplification test (NAAT) tests may be effective but have not been fully evaluated.

Chlamydia pneumoniae

The incubation period for infection due to *C. pneumoniae* is about 21 days, which is relatively long for a respiratory pathogen. Most *C. pneumoniae* infections are asymptomatic. Acute infection, when symptomatic, presents most commonly with bronchitis or pneumonia. Typically, there is a biphasic illness characterised by insidious-onset pharyngitis, followed by hoarseness and persistent non-productive cough. Fever, if present, is low grade. Upper respiratory infections, including sinusitis and pharyngitis, may occur either in isolation or in conjunction with a lower respiratory tract infection. Symptoms due to *C. pneumoniae* respiratory infection may persist for weeks or months despite appropriate antibiotic therapy. Radiological changes are variable and indistinguishable from those associated with other

aetiological agents. Both lobar and more diffuse changes may be seen. Studies show that up to 56% of chlamydial pneumonias are mixed with other causative agents such as *Streptococcus pneumoniae* and *Mycoplasma pneumoniae* (Kauppinen *et al.*, 1995). It is suggested that the cilostatic effect of *C. pneumoniae* may predispose to invasion by the pneumococcus, leading to a more severe pneumonia.

Chlamydomphila pneumoniae is also implicated in chronic respiratory infection. Several studies have highlighted a role in persistent cough syndrome. Chronic *C. pneumoniae* infection is common in patients with chronic bronchitis, as demonstrated by high serum levels of specific IgG and IgA. Studies on chronic obstructive pulmonary disease (COPD) suggest that 4–18% of exacerbations may be associated with *C. pneumoniae*, often as part of a mixed infection. *Chlamydomphila pneumoniae* has also been implicated in the development of adult-onset asthma and in exacerbations of both adult and childhood asthma (Hahn, Dodge and Golubjatnikov, 1991). The mainstay of diagnosis in respiratory infections is serology, performed on acute and convalescent serum samples taken at least 3 weeks apart.

Chlamydomphila pneumoniae has also been linked with non-respiratory infections, with varying degrees of evidence. A possible association between chronic *C. pneumoniae* infection and chronic coronary heart disease was first described in 1988 (Saikku *et al.*, 1988). Some, but not all, studies have shown persistence of antibodies, demonstrated chlamydia-like particles in atheromatous plaques on electron microscopy and isolated *C. pneumoniae* from atheromatous plaques. These results are not sufficiently conclusive, and animal models for pathogenesis studies are not satisfactory. Antibiotic treatment for atheroma is not currently indicated. Other studies have suggested a causative role for *C. pneumoniae* in neurological diseases including Alzheimer's disease, stroke and multiple sclerosis. Although the organism has occasionally been grown from cerebrospinal fluid (CSF) in some of these disease states, there is no consensus on its significance (Furrows *et al.*, 2004).

Chlamydomphila psittaci

Chlamydomphila psittaci causes the zoonotic respiratory infections psittacosis or ornithosis (Yung and Grayson, 1988). The incubation period is classically 1–2 weeks but may be up to 4 weeks. Although onset may be insidious, with malaise and limb pains, it is more commonly abrupt, with high fever, rigors and headache. Clinical manifestations are often non-specific. The most common symptom is fever, which occurs in at least 50% of patients. There may be a cough, but sputum is scanty and respiratory distress unusual except in severe disease. The pulse rate is characteristically slow. Physical signs in the chest are usually confined to fine crackles on auscultation, with little or no evidence of consolidation. Extrapulmonary signs and symptoms include epistaxis, pharyngeal oedema, hepatomegaly, splenomegaly, drowsiness, confusion, adenopathy, palatal petechiae, herpes labialis, myalgia and Horder's spots (a pink blanching maculopapular eruption resembling the rose spots of typhoid fever). Complications of infection include hepatitis, meningoencephalitis, pancreatitis, nephritis and endocarditis.

Routine haematological and biochemical investigations are generally unhelpful in diagnosis. The white cell count is normal or only slightly elevated but shows a relative neutropenia in about 25% of cases. Eosinophilia has been seen in convalescence. Liver function tests are mildly abnormal in 50% of cases and may suggest cholestasis. The chest X-ray is abnormal in approximately 75% of cases, with a variety of appearances described such as lobar consolidation, homogenous ground-glass appearance or patchy reticular shadowing. Diagnosis is by acute and convalescent (at least 10 days later) serology. Isolation of the organism from blood or respiratory secretions should not be attempted without proper containment facilities because of the danger to laboratory workers. Much previous epidemiology of psittacosis precedes the recognition of *C. pneumoniae* as a pathogen. This is particularly a problem

where diagnosis has been based on the group-reactive complement fixation test, which cannot distinguish between the two diseases.

Other Chlamydial Species

Sporadic zoonotic abortion due to *C. abortus* has been confirmed by genetic analysis of isolates from women who work with sheep. *Chlamydomphila felis* is endemic among housecats worldwide, primarily causing inflammation of feline conjunctiva, rhinitis and respiratory problems. Zoonotic infection of humans with *C. felis* involving conjunctivitis, endocarditis and pyelonephritis has been reported (Regan, Dathan and Trehan, 1979; Hartley *et al.*, 2001).

LABORATORY DIAGNOSIS

Several techniques are available for laboratory diagnosis of chlamydial infection. Diagnosis has traditionally been by cell culture, which is expensive and technically demanding. Antigen detection methods and molecular assays are now widely used. Chlamydiae cannot be cultivated in artificial cell-free media.

Specimen Collection

Detection tests are performed on scrapings or swabs from infected sites or on first-catch urine samples. Chlamydial infection is intracellular, so the sample must contain cells that requires firm scraping or swabbing of the site. Samples from the male urethra should be taken by swabbing 2–4 cm within the urethra. For endocervical swabs, the endocervix should first be wiped clear of excess secretions and then swabbed. Conjunctival swabs for trachoma should be taken by everting the affected upper eyelid and swabbing firmly. Specimens from cases of neonatal ophthalmia are taken by firmly swabbing the lower eyelid. Urine samples, used to detect urogenital infection, should be first-catch samples, as these will contain the greatest amount of urethral secretions. It is important to check with the laboratory which test is being used, as the swab material, transport medium and transport conditions vary for each test. In general, cotton-tipped plastic swabs are suitable, but some molecular assays require specially provided swabs. Swabs for culture should be expressed into chlamydial transport medium. The swab should not be left in the medium. Urine samples are not suitable for chlamydial culture. Transport medium should be transported at 4 °C and then stored at –70 °C if not immediately cultured. Swabs for immunofluorescence should be rolled on to a Teflon-coated slide, fixed in methanol and air dried (Table 25.1).

Microscopy

Direct microscopy of a sample will not detect chlamydiae but may provide indirect evidence of infection. In NGU, microscopy of a Gram-stained urethral smear demonstrates greater than 4 polymorphonuclear lymphocytes (PMNL) per high power field (×100 objective) and an absence of intracellular diplococci. A spun first-catch urine deposit will yield greater than 15 PMNL per low power field (×40 objective). Either sample may then be used for antigen detection or NAAT tests for chlamydial infection.

Cell Culture

Cell culture is the traditional method of diagnosis and, although highly specific, is less sensitive than desirable (at best 90% compared with NAATs). It is a time-consuming method, requiring specialised cell-culture equipment, making it impracticable for most diagnostic laboratories.

Table 25.1 Use of routine laboratory tests for diagnosis of chlamydial infections

Clinical presentation	Specimen	Available laboratory test
Cervicitis (<i>C. trachomatis</i> D–K)	Endocervical swab	NAAT, EIA, DIF, culture
Pelvic inflammatory disease/Fitz–Hugh–Curtis syndrome (<i>C. trachomatis</i> D–K)	First-catch urine	NAAT, EIA, DIF
	Endocervical swab	NAAT, EIA, DIF, culture
Urethritis (<i>C. trachomatis</i> D–K)	Fallopian/peritoneal swab	NAAT, EIA, DIF, culture
	Urethral swab	NAAT, EIA, DIF, culture
Lymphogranuloma venereum (<i>C. trachomatis</i> L1–L3)	First-catch urine	NAAT, EIA, DIF
	Serum	EIA, MIF, CFT
	Swab of cervix/urethra/rectum/ulcer	Culture, DIF, EIA
Trachoma (<i>C. trachomatis</i> A–C)	Lymph node aspirate	Culture
	Conjunctival swab (upper fornix)	NAAT, EIA, DIF, culture
Paratrachoma (<i>C. trachomatis</i> D–K)	Conjunctival swab (lower fornix)	NAAT, EIA, DIF, culture
Ophthalmia neonatorum (<i>C. trachomatis</i> D–K)	Conjunctival swab (lower fornix)	NAAT, EIA, DIF, culture
Neonatal pneumonia (<i>C. trachomatis</i> D–K)	Serum	IgM (EIA, MIF)
	Nasopharyngeal aspirate	NAAT, EIA, DIF, culture
Ornithosis (<i>C. psittaci</i>)	Serum	MIF, CFT, WHIF
Community-acquired pneumonia (<i>C. pneumoniae</i>)	Serum	MIF
	Respiratory secretions	EIA, DIF

CFT, complement fixation test; DIF, direct immunofluorescence; EIA, enzyme immunoassay; MIF, microimmunofluorescence; NAAT, nucleic acid amplification tests, e.g. polymerase chain reaction, strand displacement assay, transcription-mediated assay, ligase chain reaction (no longer available); WHIF, whole-cell immunofluorescence. Adapted from Blanchard TJ, Mabey DCW (1997), *Principles and Practice of Clinical Bacteriology*, 1st edition.

Many cell lines are suitable for chlamydial culture. McCoy cells (derived from a mouse fibroblast L cell line), HeLa 229, buffalo green monkey and baby hamster kidney (BHK21) are most commonly used to culture *C. trachomatis*. The human fibroblast HL cell line or Hep2 cells are used for the culture of *C. pneumoniae*. *Chlamydomphila psittaci* is a category 3 pathogen, and culture should not be attempted in the routine laboratory.

EBs derived from the clinical specimen are added to a monolayer of host cells. The host cells must be in a stationary phase, i.e. not synthesising macromolecules. Classically, host cells were treated with γ -irradiation to achieve stationary phase, but now chemical treatment such as cytochalasin B, idoxuridine or cycloheximide is used. Cycloheximide has the advantage that host cells do not require pre-treatment. Centrifugal force (300 g) or treatment of the cell sheet with polycations such as diethylaminoethyl (DEAE)-dextran is employed to overcome opposing negative cell-surface charges between the monolayer and the EBs. Culture requires careful choice of water and reagents, including fetal calf serum, balanced salts, glutamine, amino acids and glucose. Cultures are incubated in 10% carbon dioxide for 48–72 h, depending on the chlamydial species (shorter for *C. trachomatis* and longer incubation for *C. pneumoniae* and *C. psittaci*). Cells are then stained with a variety of reagents to demonstrate the presence of inclusions. *Chlamydia trachomatis*, the only species with glycogen-containing inclusions, is stained with glycogen-specific stains such as iodine or periodic acid–Schiff stain. All species stain with Giemsa and inclusions show autofluorescence if viewed by dark ground illumination. The advent of monoclonal antibodies and fluorochromes has resulted in more specific staining of cell sheets. These antibodies are usually raised against either the group-specific LPS or species-specific MOMP (Boman *et al.*, 1997). For optimal isolation, a blind passage is required.

Direct Immunofluorescent Tests

Direct immunofluorescent test (DIF) may be used as a culture confirmation test or for direct detection of EBs in clinical material, particularly from the genital tract and eye (Uyeda *et al.*, 1984). The technology is based upon highly specific monoclonal antibodies, which may be group specific (directed against the LPS and theoretically able to detect all chlamydial species) or species specific (directed against the MOMP of a single species such as *C. trachomatis*). A fluorescence microscope is required. These tests are sensitive but

are highly operator dependent: observer error or non-specific fluorescence creates false positives and reduces the specificity of the test. The expense and technical time required for DIF tests make them unsuitable for laboratories with a heavy diagnostic workload.

Enzyme Immunoassays

The development of enzyme immunoassays (EIA) allowed diagnostic facilities to become widely available. Several test formats exist, which use antibodies to detect the presence of an antigen, usually the group LPS, in clinical specimens. EIAs are comparatively cheap and are automated. Sensitivity is estimated at the order of 60–80% compared with that of NAATs (Taylor-Robinson and Tuffrey, 1987). A major problem of EIAs is specificity, and it is mandatory that all positives should be confirmed either with a blocking test (monoclonal anti-LPS used to block a repeated EIA) or with an independent test such as a DIF test. This increases specificity to over 99% (Moncada, Schachter and Bolan, 1990).

Rapid bedside test versions of the EIA have also been developed but have unacceptably low sensitivity when used in low-prevalence populations (Rani *et al.*, 2002).

Nucleic Acid Amplification Technology

Nucleic acid amplification technology (NAAT) has revolutionised the diagnosis of chlamydial infections. High-quality, commercially produced tests are now available for the diagnosis of *C. trachomatis* using PCR, ligase chain reaction (LCR), transcription-mediated amplification (TMA) and strand displacement assay (SDA) (Cherneskey, 2002). These assays amplify either the target nucleic acid or the probe after it has annealed to target nucleic acid. The major targets for NAATs are multiple-copy gene products such as ribosomal RNA or plasmid DNA, as the presence of multiple copies increases the sensitivity of the assay.

The main advantages of NAATs are their high sensitivity and specificity (Van Dyck *et al.*, 2001; Black *et al.*, 2002). They can be automated if required. The exquisite sensitivity of NAATs means that good laboratory practice is paramount if false positives are to be avoided (Furrows and Ridgway, 2001; Verhoeven *et al.*, 2002). NAATs are expensive of reagents, and pooling of samples is recommended by some authorities to reduce unit costs. This approach has

some merit in screening scenarios but is likely to be counterproductive in high-prevalence settings.

NAAT assays have demonstrated that the conventional tests, including culture, considerably underestimate the prevalence of *C. trachomatis*. It is now established that cell culture has, at best, a sensitivity of 90% compared with NAATs. The sensitivity of DIF, EIAs and DNA hybridisation tests was always felt to be inferior to that of cell culture in a field setting, giving an overall sensitivity for these tests of only 75%. There is a need to redefine the gold standard for chlamydial diagnosis because of the introduction of NAATs.

Serology

The diagnosis of chlamydial infection by estimating antibody response is far from satisfactory. The traditional complement fixation test, targeting LPS, is group reactive and cannot distinguish between species. Tests based on recombinant LPS in an enzyme-linked immunoadsorbent assay (ELISA) format also tend to be group specific. The technically demanding microimmunofluorescence (MIF) test, targeting the MOMP antigen, is the definitive test. This test is technically very demanding, requiring the use of serovar and species-specific antigens spotted onto slides and incubated with serum in dilutions. Although able to distinguish between species and serovars, the test is not widely available and difficult to standardise.

Chlamydial antibody is widely distributed in the population, much of it related to *C. pneumoniae* respiratory infection. Antibody in acute infection is late in appearing, and hence, paired sera are required at least 3 weeks apart, to demonstrate a significant (greater than fourfold) rise in IgG titre. IgM determination is useful in the diagnosis of neonatal infection and in adult respiratory infection but may not be seen in recurrent respiratory infection in adults. Persistence of serum IgA is regarded by some authorities as evidence of chronic chlamydial infection. Serology (greater than fourfold rise in IgG) may help in the confirmation of chlamydial PID but has no place in the diagnosis of lower chlamydial genital tract infection.

MANAGEMENT

Choice of Antibiotic

The intracellular habitat of chlamydiae restricts the classes of antibiotics that will be effective. In general, chlamydiae are not susceptible to antibiotics that do not penetrate cells efficiently, e.g. the aminoglycosides. The chlamydiae are sensitive to selected groups of antibiotics such as tetracyclines, macrolides and related compounds, rifampicin and more recent fluoroquinolones. The development of newer agents within these groups, such as the long-acting azalide macrolide, azithromycin, has brought new alternatives for therapy compared with traditional antibiotics. Choice of antibiotic, such as for the empirical treatment of genital or respiratory infection, must take into account all the likely causative organisms and their likely susceptibility, site affected, need for topical versus systemic therapy, cost and probable compliance.

β -Lactam antibiotics are not often recommended for routine chlamydial treatment. The chlamydial cell wall does not contain substantial amounts of peptidoglycan, although penicillin-binding proteins are present. Penicillins inhibit the differentiation of RBs to EBs and are reversibly bacteriostatic. Their use *in vivo* may have an inhibitory effect which precludes isolation of chlamydiae from a patient treated with β -lactams. Amoxicillin has a limited role in the treatment of chlamydial genital infection in pregnancy. Patients require careful follow-up to ensure eradication of the organism. Cephalosporins are not active against chlamydiae and should not be used.

The sulphonamides were extensively used to treat *C. trachomatis* before the introduction of tetracyclines. They act by competitively inhibiting the incorporation of *para*-amino benzoic acid in the folic acid pathway. They are now not commonly used, except in some treatment regimens for LGV, because they are poorly bactericidal. *Chlamydophila psittaci* and *C. pneumoniae* are resistant to sulphonamides because they derive their folic acid from the host cell pool. Trimethoprim is not active against chlamydiae.

The tetracyclines are highly active against chlamydiae and are therefore widely used to treat all chlamydial infections. There is considerable experience with their use, but they are not ideal. Gastrointestinal side effects, incompatibility with milk and milk products, multiple dosages and inability to use in pregnancy and for the treatment of paediatric infections are the main limitations. Doxycycline is the favoured preparation, because twice-daily dosage has the advantage over four-times-daily dosage of other forms.

Macrolides are a suitable alternative. There is most experience with erythromycin, but as with the tetracyclines, gastrointestinal side effects may be a problem. Azithromycin, which is an amino-substituted 15-membered azalide macrolide, penetrates extremely well into cells and has a long intracellular half-life. A single 1-g dose orally is effective against uncomplicated *C. trachomatis* genital infections, and a 5-day course of 500 mg daily is effective against chlamydial PID. Other macrolides such as clarithromycin, roxithromycin and josamycin are also effective, but their use has been largely superseded by azithromycin. This antibiotic is the only agent effective against lower genital tract chlamydial infection in a single dose.

Rifampicin is one of the most active antibiotics against chlamydiae *in vitro*. Unfortunately, as with other bacterial species, resistance is easily induced. Rifampicin is occasionally used to treat refractory chlamydial infections such as LGV or psittacosis, usually in combination with erythromycin.

Older fluorinated quinolones, including lomefloxacin, fleroxacin and ciprofloxacin, are moderately active *in vitro* but are not reliable agents *in vivo* and should not be used. Ofloxacin is effective clinically. The more recent quinolones such as gatifloxacin and moxifloxacin are highly active against chlamydiae *in vitro*. The role of fluoroquinolones in the treatment of chlamydial infections is not established owing to the impact of azithromycin on the treatment of acute lower genital tract chlamydial infection. Azithromycin is not as reliable for the treatment of gonorrhoea, and therefore, ofloxacin is favoured for the treatment of PID. Newer fluoroquinolones are being recommended increasingly for the treatment of community-acquired respiratory infections. Their *in vitro* activity against *C. pneumoniae* should ensure that they are clinically effective against respiratory infections with this organism. However, clinical trial data with specific definitive results against *C. pneumoniae* are still required. Resistance to ofloxacin has been demonstrated *in vitro* against *C. trachomatis* but not against *C. pneumoniae* (Morrissey *et al.*, 2002). The clinical significance of this finding is unclear.

Treatment Regimens

Several sets of guidelines on the management of chlamydial infections are available, including US guidelines (Centers for Disease Control and Prevention, 2002), European guidelines (Stary, 2001) and WHO guidelines (2001). WHO guidelines for treatment offer the alternatives of management based on a definite diagnosis or of syndromic management based on the identification of consistent groups of symptoms and easily recognised signs (syndromes). Syndromic management is particularly appropriate for trachoma and for sexually transmitted chlamydial infections in settings where laboratory facilities for diagnosis are limited. Where syndromic management is used, the choice of first-line drugs must cover all common pathogens causing the syndrome. For example, urethritis should be managed with drugs that cover *N. gonorrhoeae* as well as *C. trachomatis*.

Chlamydia trachomatis

Trachoma has been treated traditionally with topical sulphonamides or topical tetracyclines. Topical treatment is of limited use, and systemic oral therapy, usually with oxytetracycline or doxycycline, is preferred. Compliance is a problem, and tetracyclines are contraindicated in young children (Dawson and Schachter, 1985). Populations in hyperendemic areas require retreatment at twice-yearly intervals, in addition to education on hygiene and fly control. Trials of treatment with a single oral dose of azithromycin show 100% compliance and good control of disease for up to 12 months (Mabey *et al.*, 1998).

Genital infections are always treated systemically. For uncomplicated genital tract disease, several options exist: WHO recommend doxycycline for 7 days or a single dose of azithromycin. Alternative regimens include 7-day courses of erythromycin, ofloxacin or tetracycline. Ciprofloxacin is not reliable and should not be used to treat genital chlamydial infections.

Amoxicillin for 7 days is widely used in pregnancy, but careful follow-up is essential to avoid relapse. Erythromycin (if tolerated) is a suitable alternative. Tetracyclines should be avoided during pregnancy and lactation.

Resolution of SARA usually occurs without specific treatment, but relapse is common. A double-blind study comparing lymecycline (a tetracycline) with placebo in patients with reactive arthritis suggested that 3 months of treatment was effective in arthritis associated with chlamydial infection (Lauhio *et al.*, 1991). There is continuing uncertainty about the role, if any, of anti-chlamydial antibiotics in SARA.

Neonatal chlamydial infections are always treated with systemic antibiotics. Topical treatment of chlamydial ophthalmia will not eradicate chlamydiae from other sites such as the respiratory tract. Standard treatment is systemic erythromycin for 2–3 weeks, with local saline bathing if required. Topical silver nitrate (Crédés prophylaxis) is ineffective and may lead to a chemical conjunctivitis.

Early treatment of LGV is essential, before scarring complicates management. Current WHO recommendations are 2 weeks of doxycycline, with erythromycin or tetracycline as alternatives. Rifampicin has been used with good effect but should only be used as part of a multidrug regimen because resistance develops readily. Fluctuant buboes should be aspirated to prevent rupture and sinus tract formation. Scarring does not respond well to therapy.

Chlamydomphila pneumoniae

Symptomatic respiratory infections should be treated with a 2–3-week course of a macrolide/azalide or tetracycline. Treatment is usually started empirically before the diagnosis is confirmed. There is no evidence to support longer courses of treatment for chronic or persistent infections, including possible involvement in cardiovascular or neurological disease.

Chlamydomphila psittaci

Standard therapy is with oral tetracycline or doxycycline for 3 weeks. An alternative is erythromycin for 3 weeks. Shorter courses may lead to relapse (Schachter and Dawson, 1978). Without treatment, recovery takes 2–3 weeks, and the mortality is up to 20%.

PREVENTION AND CONTROL

Prevention of infection is always preferred to treatment. The vast clinical scope of infections due to chlamydial infection necessitates a different approach for each infection.

Trachoma control is a huge undertaking, involving education on hygiene and fly controls as well as mass treatment programmes, more recently with a single dose of azithromycin. Antibiotic therapy is

being combined with other factors, to provide a comprehensive attack on this disease. These treatment modalities are encompassed in the acronym SAFE. This stands for surgery (to eyelids to combat trichiasis), antibiotics (azithromycin), face (encouragement of improved personal hygiene, particularly face washing) and environment (improved provision of latrines and fly control) (Mabey, Solomon and Foster, 2003). Rapid reinfection occurs in endemic areas; therefore, treatment is needed twice a year. The hope is that the reservoir of infection will eventually be eliminated (Mecaskey *et al.*, 2003).

Patients with genital infection should be identified and treated promptly, and contact tracing of partners is an important control measure. There is ongoing debate over the role of screening within groups at risk, particularly in the 16–25-year group. Education about the use of barrier contraceptives and change in sexual behaviour is important.

There are no specific control measures against respiratory infections caused by *C. pneumoniae*. Respiratory infections caused by *C. psittaci* may be avoided by reducing contact with birds, particularly if they appear unwell.

Vaccination

Although there has been over 40 years of active research, an effective vaccine against human chlamydial infection is still not available. However, there is considerable activity in this field. Several approaches are being pursued (Brunham *et al.*, 2000; Stephens, 2000). Firstly, the pulsing of dendritic cells derived from mouse bone marrow cells *ex vivo* with chlamydiae may produce a Th1-type cell-mediated immune response, suggesting the possibility of using chlamydial components to stimulate a response. *In vivo* studies have so far proved disappointing. Vectors such as *Vibrio cholerae* ghosts are showing potential (Eko *et al.*, 1999). Putative DNA vaccines directed against MOMP are showing potential against respiratory but not genital infections in animal experiments. Techniques aimed at stimulating the mucosal response, including gene constructs or locally active gels, to allow slow release of stimulatory antigens and the use of carrier viruses are also promising. Sequencing of the chlamydial genome has identified further potential vaccine candidates. It is likely that, owing to the nature of chlamydial infections, vaccines that stimulate both a Th1 and Th2 response will be required.

A particularly exciting approach has been the development of a DNA vaccine utilising a cytomegalovirus (CMV) promoter virus, coding for MOMP or 60-kDa components, active against *C. pneumoniae* in a murine respiratory model (Penttila *et al.*, 2000).

Tropheryma whipplei

F. Fenollar and D. Raoult

Unité des Rickettsies, CNRS UMR 6020A, Université de la Méditerranée, Marseilles, France

INTRODUCTION

Tropheryma whipplei is the bacterium responsible for Whipple's disease (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). An American pathologist George Hoyt Whipple reported the first case in 1907 (Whipple, 1907). This was the case of a fatal disease in an anorexic patient with arthralgias, diarrhea, chronic cough and fever (Whipple, 1907). During the necropsy, abnormalities were principally observed in the intestine, the mesenterium, the heart and the lung (Whipple, 1907). Microorganisms were also detected in tissues by using silver staining. However, because of the observation of fats in the stools, the intestine and the mesenteric glands, a disorder of fat metabolism was suspected (Whipple, 1907) and named intestinal lipodystrophy. Whipple's disease is a rare systemic infection (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). We have been able to detect *T. whipplei* in biopsies from Dr Whipple's first patient (Dumler, Baisden and Raoult, 2003). The classical symptoms consist of weight loss, abdominal pains, diarrhea, arthralgias and lymphadenopathy (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). The symptomatology can be very protean and nonspecific. Cardiac, ocular or central nervous involvements can be observed (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). These manifestations are not always associated with digestive symptoms (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). For a long time, the diagnosis has been based on a small-bowel biopsy, which allows the observation of positive inclusions by using periodic acid–Schiff (PAS) staining (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). However, for patients without digestive symptoms, the results of the small-bowel biopsy could be negative, leading to delay in diagnosis. For 10 years, a new tool based on polymerase chain reaction (PCR) targeting the 16S rDNA followed by sequencing has been employed (Wilson *et al.*, 1991; Relman *et al.*, 1992). Since 1999, the culture of the bacterium has allowed new perspectives on the diagnosis (Raoult *et al.*, 2000). The progression of the disease without treatment is always fatal (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). Even with adequate treatment, relapses are possible (Misbah and Mapstone, 2000; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Maiwald and Relman, 2001). The isolation of *T. whipplei* has opened new perspectives on the characterization of the microorganism (La Scola *et al.*, 2001) and allowed the development of immunohistochemical tools for the diagnosis (Raoult *et al.*, 2001), the sequencing of the full genome and the introduction of studies on its physiopathology, *in vitro* antibiotic susceptibilities and serology.

DESCRIPTION OF THE ORGANISM

Morphology

When he described the disease for the first time, Whipple had noticed the presence of rod microorganisms 2 µm long, mainly in the vacuoles of macrophages of affected tissue (Whipple, 1907). In 1949, Black-Schaffer showed that the macrophages from the intestine and the lymphatic glands of patients with Whipple's disease contained PAS-positive material (Black-Schaffer, 1949). The PAS staining showed purple macrophages, but no bacteria were identified. He concluded that the macrophages must contain mucopolysaccharides. In 1960, a first observation with electron microscopy of structures such as bacteria was performed on an intestinal biopsy (Cohen *et al.*, 1960). This observation was confirmed 1 year later, and a bacterial etiology of Whipple's disease was highly suspected (Cheers and Ashworth, 1961; Yardley and Hendrix, 1961). Morphologically, the bacterium develops a characteristically trilamellar ultrastructure including a plasmic membrane surrounded by a thin wall, itself surrounded by a structure similar to a plasmic membrane (Silva, Macedo and Moura Nunes, 1961). This morphology is not typical of Gram-positive or Gram-negative bacteria.

Immunohistochemical Study

Antibodies directed against *Shigella* and *Streptococcus* A, B, C and G, when tested against intestinal biopsies from patients with Whipple's disease, have been shown to present cross-reactivity against the Whipple's disease bacterium (Ectors *et al.*, 1992; Alkan, Beals and Schnitzer, 2001). When using primary antibodies at optimal dilutions, only the cross-reactivity of antibodies directed against *Streptococcus* B persists (Du Boulay, 1982). This staining seems to be due to the presence of rhamnose-containing polysaccharides (Evans and Ali, 1985).

The culture of *T. whipplei* has been an elusive goal for many generations of microbiologists. Several attempts to cultivate *T. whipplei* have failed (Dutly and Altwegg, 2001) but have been reported with bacteria from the genera *Corynebacterium*, *Streptococcus*, *Propionibacterium*, *Bacteroides*, *Brucella*, *Escherichia*, *Clostridium*, *Klebsiella* and *Haemophilus* (Dobbins, 1987b; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). In 1997, two strains of *T. whipplei* were reported to have been isolated from cardiac valves of patients with endocarditis (Schoedon *et al.*, 1997). A macrophage system with its microbicidal functions deactivated by a combination of dexamethasone, interleukin-4 (IL-4) and IL-10 was used. Unfortunately, the findings of this work were not confirmed and no isolate could be subcultured (Schoedon *et al.*, 1997). Two years later, a

different approach was used for cultivating *T. whipplei*. The bacterium was isolated and established from a strain obtained from a cardiac valve of a patient with Whipple's disease endocarditis. *Tropheryma whipplei* has been propagated in human fibroblasts (HEL) in minimum essential medium (MEM) with 10% fetal serum calf and 2 mM glutamine (Raoult *et al.*, 2000). The use of an appropriate cellular system that can be conserved for several weeks, the high cell-to-bacterium ratio and the step of centrifugation to increase the adhesion of cells to bacteria have probably facilitated the isolation of the bacterium. At first, the bacterium multiplies slowly, and the doubling time has been estimated at 17 days. Currently, this time of multiplication is passed at 36 h (36 h passage). As of yet, culture of the bacterium in axenic medium has not been reported. The multiplication site of the bacterium is controversial. Some authors suggest that the bacterium multiplies in the digestive lumen and that they are phagocytosed and slowly degraded in the macrophages (Dobbins and Ruffin, 1967). *In vitro*, the bacteria apparently multiply in the monocytes with or without IL-4 (Schoedon *et al.*, 1997) (unpublished data). Later, they are released from the infected cells. Inside HeLa cells, *T. whipplei* multiplies actively in an acidic vacuole at pH 5 (Ghigo *et al.*, 2002). This acidic pH may inhibit the antibiotic activity (Street, Donoghue and Neild, 1999) and could then be responsible for the loss of activity of a high number of antibiotic regimens (Dutly and Altwegg, 2001). In a study that combined the use of *in situ* hybridization and confocal microscopy, the ribosomal RNA of the bacterium was localized to the extracellular spaces. This seems to indicate the presence of bacteria with an active metabolism outside the cells (Fredericks and Relman, 2001).

Molecular Characterization

In 1991, Wilson sequenced a fragment of 721 base pairs of the 16S rDNA (Wilson *et al.*, 1991). This sequence contained some ambiguous nucleotides, but it did not appear to be closely related to any known bacteria. One year later, sequencing of 1321 base pairs of the 16S rDNA (representing 90% of the sequence) from the biopsy of a patient and 384 base pairs from four biopsies from four other patients confirmed these data (Relman *et al.*, 1992). The sequence did not correspond to any microorganism characterized before. The bacterium was then named *Tropheryma whippelii*, from the Greek *trophē* (nourish) and *eryma* (barrier), linked to the malabsorption syndrome observed in the disease and in honor of George Hoyt Whipple. Following the culture and the description of the bacterium, and the deposit of a reference isolate, the name was corrected. The bacterium was officially named *Tropheryma whipplei* because the name of Whipple was not correctly Latinized in the original version (La Scola *et al.*, 2001).

Phylogenetic analysis based on the sequence of the 16S rDNA has shown that the bacterium associated with Whipple's disease could be classified among the group of the *Actinomyces* (class Actinobacteria), relatively close to two known species in human pathology, *Actinomyces pyogenes* and *Rothia dentocariosa*, and to bacteria principally found in the environment including the *Cellulomonadaceae* (Relman *et al.*, 1992; Maiwald *et al.*, 1996) (Figure 26.1). The molecular taxonomy classified *T. whipplei* close to bacteria with a high GC% which have in common the soil as a reservoir or a contamination source for humans. An analysis based on the complete sequence of the 16S rDNA (Maiwald *et al.*, 1996) places *T. whipplei* more precisely between the *Cellulomonadaceae* and the *Actinomyces*, compositing group B peptidoglycan. The sequence similarity of the 16S rDNA of *T. whipplei* with those of the two nearest species (*Cellulomonas cellasea* and *Corynebacterium aquaticum*) is only 90%.

The possibility of a second bacterial species being associated with Whipple's disease [Whipple's-disease-associated bacterial organism (WABO)], closer to *Nocardia*, has been suggested following PCR and

sequences obtained from an intestinal biopsy from a patient with a clinical and histological Whipple's disease (Harmsen *et al.*, 1994). Significant sequence differences (19 substitutions for 225 amplified and sequenced nucleotides) have been observed by using specific primers (Relman *et al.*, 1992). One case of co-infection with the two variants WABO and *T. whipplei* has been reported from a patient with a cerebral Whipple's disease (Neumann *et al.*, 1997). These data are difficult to interpret because they are based on a very short portion of the 16S rDNA sequence. The possibility of a second bacterial species being responsible for Whipple's disease is not excluded, but more data are necessary. Indeed, a variation of the 16S rDNA sequence of the bacterium responsible for the Whipple's disease cannot be definitely excluded, and this should be investigated in more patients. The variability of the 16S rDNA sequence with a difference of only one position among the 225 nucleotides analyzed has also been observed from two intestinal biopsies from two patients with a clinical and histological Whipple's disease (Harmsen *et al.*, 1994; Maiwald *et al.*, 2000). Phylogenetic analysis of *T. whipplei* based on the 23S and 5S rDNA sequences also places the bacterium in the class of *Actinobacteria*. However, the insufficient number of available sequences does not allow a precise comparison to be made between the analyzed sequences and the different species analyzed using 16S rDNA sequence (Maiwald *et al.*, 2000). *Tropheryma whipplei* shows a degree of heterogeneity that has been proven with the sequencing of the 16S–23S rDNA interregion (Maiwald *et al.*, 1996; Hinrikson, Dutly and Altwegg, 1999) and the 23S rDNA (Hinrikson, Dutly and Altwegg, 2000b). The interregion 16S–23S rDNA is known to be more variable than the structural flanking genes. This zone is considered as a tool for subtyping bacteria in various taxonomic groups (Gürtler and Stanisich, 1996). The sequences of the interregion 16S–23S rDNA and those of 200 nucleotides from the 23S rDNA of *T. whipplei* have been determined (Maiwald *et al.*, 1996). The reported length of the 16S–23S interregion of *T. whipplei* is 294 base pairs, without the coding sequences for the tDNA and the 5S rDNA. These data are comparable to the size and the structure of the 16S–23S interregion of most Gram-positive bacteria with high GC% (Gürtler and Stanisich, 1996). The research of similar sequences of the 16S–23S interregion of *T. whipplei* with those of other *Actinomyces* reveals globally a weak homology (Maiwald *et al.*, 1996). Nevertheless, several small zones with a high homology with other *Actinomyces* are present (Maiwald *et al.*, 1996). The first sequence of the 16S–23S interregion described by Maiwald *et al.* has been confirmed by the detection of homolog sequences in samples of nine Swiss patients with Whipple's disease (Hinrikson, Dutly and Altwegg, 1999). In a later study, the 16S–23S interregion of *T. whipplei* was studied by PCR, followed by sequencing in 38 samples from 28 patients with Whipple's disease (Hinrikson *et al.*, 1999). Sequence analysis revealed the existence of five dimorphic sites constituting three types of spacers (Hinrikson *et al.*, 1999) (Figure 26.2). The more common genotype, i.e. the type 1, corresponds perfectly with the original sequence described of 294 base pairs (Maiwald *et al.*, 1996). By comparison with this reference sequence, the spacer types 2 and 3 are different in only two and five nucleotide positions, respectively. Very recently, three genotypes have been identified among a series of 43 patients (Maiwald *et al.*, 2000). These spacers of types 4, 5 and 6 differ, respectively, in four, three and six nucleotide positions in comparison with type 1. Type 3 was not found in this study. The existence of different types of spacers has been confirmed by sequencing and through analysis with restriction enzymes (Maiwald *et al.*, 2000). The six different types of spacers are not found with the same frequency. Types 1 and 2 are the most common, whereas types 3–6 are only observed sporadically. In addition, the relative frequencies of types 1 and 2 differ between the studies of Hinrikson, Dutly and Altwegg (2000a, b) and Maiwald *et al.* (2000). Currently, differences cannot be attributed to a particular geographic origin because in all the studies most of the patients lived in central Europe. A possible bias could be that the Swiss studies (Hinrikson, Dutly and Altwegg, 2000a)

Figure 26.1 Phylogenetic taxonomy of *Tropheryma whipplei* based on DNA 16S ribosomal sequences.

included not only patients with Whipple's disease but also patients with a positive PCR but with no symptoms of Whipple's disease. When several samples were available for the same patient, the same spacer type was found in each sample from the same patient (Hinrikson *et al.*, 1999; Dutly *et al.*, 2000; Maiwald *et al.*, 2000). Nevertheless, one exception existed – a patient seemed to present a possible double infection (Maiwald *et al.*, 2000). On the basis of these data, each patient seemed then to be infected with only one strain (Gürtler and Stanisich, 1996). The variations found in the 16S–23S interregion raise the question of the possible existence of six different species or subspecies. The 16S rDNA partial sequences determined in

most of the studies have not revealed differences with the reference sequence. However, as for the other bacteria, even a complete identity of 16S rDNA sequences does not prove species identity (Fox, Wisotzkey and Jurtschuk, 1992) but suggests only a very close relation (Stackebrandt and Goebel, 1994). To resolve the problem, DNA–DNA hybridization studies are necessary. Currently, these six types are considered as subtypes of only one species, because of a weak number of variable nucleotides, similar to or less than the variations observed in other species.

For the *Actinobacteria*, one insertion in domain III of the 23S rDNA sequence of approximately 100 nucleotides has been described

Nucleotides of the interregion of the *T. whipplei* 16S–23S DNA. (The base numeration corresponds to those of the reference sequence (X99636). P = position)

and does not seem to be present in any other bacterial group (Roller, Ludwig and Schleifer, 1992). This insertion is more variable between species than the other parts of the 23S rDNA and 16S rDNA sequences. A part of this domain III of *T. whipplei* has been amplified from clinical samples by using primers targeting the flanking region (Hinrikson, Dutly and Altwegg, 2000a). Analysis of the sequence has revealed an insertion of 80 nucleotides (Hinrikson, Dutly and Altwegg, 2000b; Maiwald *et al.*, 2000), confirming the classification of *T. whipplei* in the *Actinobacteria*. Among the 28 studied patients, 27 carried this identical insertion sequence (type A), whereas the other patient had a different insertion sequence (type B), which differed in only one position (Hinrikson, Dutly and Altwegg, 2000a). The similarity of the sequences with those of other *Actinobacteria* was high (greater than 90%) for the region immediately upstream, but only moderate (approximately 70%) for the region downstream of the insertion (Hinrikson, Dutly and Altwegg, 2000b). Compared to other *Actinobacteria*, the insertion sequence itself of *T. whipplei* is smaller (80 nucleotides compared with 86–116 nucleotides), and its similarity

to other sequences is low (Roller, Ludwig and Schleifer, 1992; Hinrikson, Dutly and Altwegg, 2000b; Maiwald *et al.*, 2000). In addition, it does not contain specific elements of the group (Roller, Ludwig and Schleifer, 1992), and more particularly, there is no similarity with the insertion sequences found for the *Cellulomonadaceae* and the *Actinomyces* of group B peptidoglycan, i.e. the groups close to *T. whipplei*, based on 16S rDNA sequence comparisons (Maiwald *et al.*, 1996). Until now, a link between the different genotypes and the symptomatology has not been demonstrated. Some authors suggested that some specific strains may not have a pathogenic role, that others could be responsible for typical Whipple's disease and that others could be responsible for atypical Whipple's disease such as blood culture-negative endocarditis, but this is not yet demonstrated (Maiwald *et al.*, 1998; Hinrikson *et al.*, 1999; Dutly and Altwegg, 2001). Very recently, the genome of *T. whipplei* has been entirely sequenced and deposited in GenBank. *Tropheryma whipplei* has a unique circular chromosome and a small genome size (925 kb), with a GC content of 47%.

EPIDEMIOLOGY OF WHIPPLE'S DISEASE

Whipple's disease is considered rare, and there is no real estimation of the prevalence of the disease. In 1985, Dobbins estimated that 2000 cases have been reported since 1907 (Dobbins, 1987b). The disease seems to be more common in farmers (Dobbins, 1987b). In 1987, an analysis of 696 cases demonstrated that approximately 55% of cases had been reported in Europe and 38% in the north of America (Dobbins, 1987b) and that 97% of the patients were Caucasian (Dobbins, 1987b). The disease has not been frequently reported in Asiatic, black, Indian or Hispanic people. Whipple's disease has been rarely diagnosed in children, but it can be observed in anyone irrespective of the age (Dobbins, 1987b). Few familial cases have been described (brothers, father/daughter), but analysis has not shown particular risk factors (Dobbins, 1987b; Fenollar and Raoult, 2001b). No epidemic or inter-human transmissions have been described (Dutly and Altwegg, 2001). Of note, few grouped cases have been reported (Dobbins, 1987b). Whipple's disease involves principally men with a mean age of 50 years, and there is a man-to-woman sex ratio of 8:1 (Dobbins, 1987b). New studies seem to show a higher prevalence in women than previously supposed (von Herbay *et al.*, 1997b). A prevalence of approximately 26% in HLA-B27-positive patients has been observed in patients with Whipple's disease, i.e. three or four times more frequent than in a normal population (Dobbins, 1987a, b). However, a direct association between an HLA-B27-positive type and a diminution of resistance to infection has never been observed. In addition, these data have not been confirmed in other populations, principally in Italy and in Argentina (Bai *et al.*, 1991; Olivieri *et al.*, 2001). The source of *T. whipplei* and its transmission are presently unknown. The bacterium seems to be present in the environment: studies based on PCR have shown the presence of *T. whipplei* DNA in sewage water (Maiwald *et al.*, 1998) and in human stools (Gross, Jung and Zoller, 1999; Dutly and Altwegg, 2001; Maibach, Dutly and Altwegg, 2002). *Tropheryma whipplei* could therefore be ingested orally (Fenollar and Raoult, 2001b; Maiwald *et al.*, 2001). PCR-based studies have found that the *T. whipplei* DNA can be detected in saliva, duodenal biopsies, gastric liquids and stools of subjects without Whipple's disease (Ehrbar *et al.*, 1999; Street, Donoghue and Neild, 1999; Dutly *et al.*, 2000). Indeed, a study of 40 healthy subjects has detected the presence of *T. whipplei* DNA in 35% (Street, Donoghue and Neild, 1999). Another PCR-based study has shown the presence of *T. whipplei* DNA in 4.8% of duodenal biopsies and 13% of gastric liquids from 105 patients without clinical suspicion of Whipple's disease (Ehrbar *et al.*, 1999). These data suggest that *T. whipplei* could be a commensal bacterium of the gut. However, these data should be interpreted with caution because they are based on 'home-made' PCR and they may not be confirmed (Dutly and Altwegg, 2001). Indeed, *T. whipplei* could have a particular geographic distribution. This hypothesis is supported by a study that investigated the presence of *T. whipplei* DNA in duodenal biopsies and gastric liquid from Swiss and Malaysian patients without clinical suspicion of Whipple's disease (Dutly and Altwegg, 2001). The presence of *T. whipplei* DNA was detected in 14 of 105 Swiss patients (Ehrbar *et al.*, 1999), whereas none was detected in 108 Malaysian patients (Dutly and Altwegg, 2001). These preliminary data should be substantiated to conclude on the existence of a heterogeneity of geographic distribution for *T. whipplei*. New PCR-based studies did not find *T. whipplei* DNA in the duodenal biopsies of control patients. The demonstration of *T. whipplei* in duodenal biopsies of patients with an extraintestinal Whipple's disease without clinical, endoscopic or histologic evidence of digestive involvement suggests the existence of an intestinal entry for *T. whipplei* (Müller *et al.*, 1997).

EPIDEMIOLOGY AND PATHOGENESIS

The epidemiology and physiopathology of Whipple's disease are still obscure. The distribution of the disease is not well defined. It is

currently difficult to determine any difference between the importance of risk factors (genetic factors and presence of immune defect) and the existence of different strains of *T. whipplei* in the physiopathology of Whipple's disease.

IMMUNOLOGY AND PATHOLOGY

Different immunological abnormalities have been observed in patients with Whipple's disease, and it was often difficult to make distinctions between the primary and the secondary causes. This is probably due to the small number of patients with Whipple's disease and to the several clinical manifestations. The supposed immunological defect must probably be subtle and specific to *T. whipplei*. Indeed, patients with Whipple's disease are not usually predisposed to other infections. Only a few cases of co-infections with HIV-positive patients or patients with nocardiosis or giardiasis have been described (Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). In patients with Whipple's disease, the lamina propria often presents a massive infiltration of macrophages and a relative poverty of infiltration by the plasma cells and the lymphocytes (Maxwell *et al.*, 1968). The number of B lymphocytes is diminished, and the T lymphocytes are lost, suggesting a defect in B cells and/or T cells in response to the causative agent (Dutly and Altwegg, 2001). This could also reflect a secondary loss of the lymphocytes because of lymphangiectasis. A study has found a diminution of immunoglobulin A (IgA) B cells but an augmentation of the number of IgM B cells in the lamina propria (Eck *et al.*, 1997). However, the level of secretory IgA determined from intestinal aspirations is normal (Dobbins, 1981). The humoral response to *T. whipplei* is not currently measurable in patients. Some studies reported a normal level of IgG and a normal or often diminished level of IgM, whereas the level of IgA appeared slightly increased before treatment and was normal after treatment (Dobbins, 1981, 1987b). For several patients with Whipple's disease, a study has shown a diminution of the level of IgG2 subclass. This subclass of IgG is usually produced in response to infections caused by encapsulated bacteria. Its synthesis is regulated by an immune response based on cellular mediation and interferon- γ (IFN- γ) (Marth *et al.*, 1997). The circulating T-cell population and those of the lamina propria can be characterized by a reduced CD4-to-CD8 ratio of T cells (i.e. augmentation of the number of positive T8 cells), associated with a shift in the T-cell subpopulations to an increased expression of CD45RO, a marker of memory on T cells (Marth *et al.*, 1994). These changes are present in ill patients and also in patients with residual PAS-positive cells but are not observed in patients in complete remission (Marth *et al.*, 1994). These changes are accompanied by a reduced *in vitro* response of T-cell proliferation to mitogens or other stimuli such as phytohemagglutinin (PHA), concanavalin A (ConA) and anti-CD2 and anti-CD3 antibodies (Dobbins, 1981, 1987b; Marth *et al.*, 1994). These alterations and an impaired delayed-type hypersensitivity are present not only in patients with an acute disease but also in patients with a long period of remission (Dobbins, 1981; Marth *et al.*, 1994). Studies of macrophages in Whipple's disease have shown dysfunctions: they have an incapacity to degrade the bacterial antigens (proteins and DNA derived from *E. coli* and *Streptococcus pyogenes*). Even so, phagocytosis and intracellular killing do not seem to be decreased (Bjerknes *et al.*, 1988). In patients with Whipple's disease, this deficiency of macrophages in degrading the intracellular microorganisms is persistent (Bjerknes *et al.*, 1988; Marth *et al.*, 1994). Another study has shown that the intestinal macrophages equally presented reduced phagocytosis (Lukacs, Dobi and Szabo, 1978). A diminution of production of IL-12 and IFN- γ by monocytes has been shown in patients with Whipple's disease, compared to controls, not only during the acute phase but also in the remission phase (Marth *et al.*, 1997). These results, therefore, suggest that the macrophages and not the T cells are directly implicated in the immune defect. IL-12 is a cytokine and a pivotal mediator of cellular immunity.

The granulocytes, the monocytes, the macrophages and the dendritic cells, which are the first cells to encounter a foreign antigen during infection, produce it. IL-12 activates the natural killer (NK) cells plus the T cells and induces the production of IFN- γ by T-helper type 1 cells. The low production of IL-12 lowers IFN- γ production by T cells and consequently controls the microbicidal effect of macrophages. Diminished levels of IL-12p40 have been observed in patients' sera (Marth *et al.*, 2002). These data suggest that Whipple's disease could be associated with a primary defect in the production of IL-12 by monocytes (Ramaiah and Boynton, 1998). In addition, the secretion of this defective cytokine is also associated with low secretions of serum IgG2, a subclass of IgG dependent on IFN- γ . A deficit in IL-12 production is correlated with chronic infections or relapses due to microorganisms of low virulence, such as *Mycobacterium avium* (Levin *et al.*, 1995). An IL-12 defect, but less severe than those observed in patients with Whipple's disease, has been found in two related persons (one sister and one brother of two different patients with Whipple's disease) (Marth *et al.*, 1997). These data suggest the existence of a genetic base to these abnormalities. It has also been demonstrated that patients with Whipple's disease have a reduced expression of CD11b markers, the α -chain of complement receptor 3 (CR3) (Marth *et al.*, 1994). CR3 is a member of the integrin family and facilitates microbial phagocytosis (Marth *et al.*, 1994), playing a role in antigen presentation and mediating the intracellular death induced by the IFN- γ , produced in response to ingested bacteria (Marth *et al.*, 1994). Indeed, a study has reported the case of a patient with Whipple's disease refractory to all antibiotic therapies and with reduced rates of IFN- γ *in vitro*, for whom a treatment with antibiotics and recombinant IFN- γ allowed a cure (Schneider *et al.*, 1998). The recent improvement in the treatment of infections due to intracellular bacteria such as those of the *M. avium* complex has shown that immunotherapy with IFN- γ , which leads to monocyte activation, can have a complementary therapeutic use for patients resistant to antibiotics (Holland *et al.*, 1994).

Two types of granulomatous reactions are observed. In mesenteric adenopathy, granulomas such as those observed in the presence of a lipid-associated foreign body are observed. In the other tissues, epithelioid granulomas with or without giant cells, similar to those observed in sarcoidosis, are observed (Rouillon *et al.*, 1993). The presence of systematic granulomatous inflammation in adenopathy, the liver or spleen in 9% of patients with Whipple's disease leads to a possible confusion with the diagnosis of sarcoidosis (Dobbins, 1987b). Any kidney involvement, such as glomerulonephritis and interstitial or granulomatous nephritis, is not common and usually appears late during the disease (Dobbins, 1987b; Marie, Lecomte and Levesque, 2000). Hypothyroiditis has been rarely described (Dobbins, 1987b). Despite improvements in diagnostic tools, most case reports underline the difficulty of Whipple's disease diagnosis in cases of various and atypical presentations.

CLINICAL FEATURES OF WHIPPLE'S DISEASE

Whipple's disease is often diagnosed late in its evolution. For a long time, Whipple's disease has been considered as a mainly digestive disease. However, it is currently estimated that 15% of diagnosed patients have no digestive symptoms (Misbah *et al.*, 1997). Indeed, the clinical manifestations are several and not specific, depending on the implicated organs (Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). No major organ is spared by the *T. whipplei* infection. The various clinical manifestations of Whipple's disease are described in Table 26.1. Weight loss, diarrhea, malabsorption and abdominal pains are the most frequent symptoms observed at the time of diagnosis (Marth and Raoult, in press). In very rare cases, constipation is observed instead of diarrhea (Mur Villacampa, 1987). Splenomegaly and hepatomegaly are observed in 15% of patients (Marth, 1999). Very rare cases of hepatitis have also been observed (Schultz *et al.*,

Table 26.1 Clinical manifestations in Whipple's disease

Manifestations
<i>Classic manifestations</i>
Diarrhea
Arthralgias
Weight loss
Abdominal pain
Polyadenopathy
Cutaneous pigmentation
Unknown fever
Sarcoidosis
<i>Central nervous system involvement</i>
Dementia
Abnormal ocular movement
<i>Ophthalmologic manifestations</i>
Uveitis
<i>Cardiovascular manifestations</i>
Blood culture negative endocarditis
Pericarditis
Myocarditis

2002). Ascites has been found in 5% of patients (Ramaiah and Boynton, 1998). Arthralgias are classical symptoms in Whipple's disease. Three-quarters of patients have joint complaints before the diagnosis of the disease (Puéchal, 2001). Arthralgias consist usually in the involvement of peripheral joints and are migratory, non-deformed and non-deforming (Dobbins, 1987b; Puéchal, 2001). Large joints are usually involved and less frequently the small joints. The diagnosis of rheumatic disease is often considered before the diagnosis of Whipple's disease. Vertebral localization of Whipple's disease is rare, but the diagnosis should be considered in any case of HLA-B27-negative spondylarthropathy (Varvöli *et al.*, 2002) or spondylodiscitis (Altwegg *et al.*, 1996). The involvement of the Whipple's bacterium in a knee prosthesis infection of a patient with systemic Whipple's disease has been confirmed by PCR techniques targeting the 16S rDNA sequence (Frésard, 1996). The neurological involvement of *T. whipplei* infection has been estimated at 6–43% (Maizel, Ruffin and Dobbins, 1970; Dobbins, 1987b; Fleming, Wiesner and Shorter, 1988; Fantry and James, 1995; Vital-Durand *et al.*, 1997; Gerard *et al.*, 2002).

All patients with Whipple's disease have a neurological localization (Dobbins, 1988; von Herbay *et al.*, 1997a; Schneider *et al.*, 2002). This localization may correspond to a sanctuary of the bacterium responsible for relapses of the disease with central nervous system involvement. Currently, clinical neurological symptoms are estimated at more than 15% (Marth and Raoult, in press). These signs may or may not be associated with digestive symptoms (Dobbins, 1987b; Louis *et al.*, 1996; Gerard *et al.*, 2002). The classical signs are facial myoclonus, external ophthalmoplegia and dementia (Dobbins, 1987b; Louis *et al.*, 1996; Gerard *et al.*, 2002). The neurological manifestations are diverse: cephalgia, ataxia, hypoacusia, personality changes, seizures, memory loss, somnolence, dysarthria and pyramidal signs have been described (Dobbins, 1987b; Louis *et al.*, 1996; Gerard *et al.*, 2002). Hypothalamic involvements causing insomnia, hypersomnia, polyuria and polydipsia are less common (Dobbins, 1987b; Louis *et al.*, 1996; Gerard *et al.*, 2002). Hypothalamopituitary involvement could be responsible for the deterioration of the secretion of sex hormones and hypogonadism (Di Stefano *et al.*, 1998). More rarely, parkinsonian syndrome, meningitis, myopathies and myoclonus have been observed in Whipple's disease (Louis *et al.*, 1996; Gerard *et al.*, 2002). An abnormal movement called oculo-facio-cervical myorhythmia, considered by some as pathognomonic of Whipple's disease, has been also described (Louis *et al.*, 1996). Cardiac involvement is observed for at least one-third of patients (Fenollar, Lepidi and Raoult, 2001) and is more and more frequently observed in patients without digestive symptoms (Elkins, Shuman and Pirolo, 1999; Wolfert and Wright, 1999; Fenollar, Lepidi and Raoult, 2001).

The manifestations could be cardiac murmur, pericardiac friction rub, nonspecific electrocardiogram modification, congestive heart failure, sudden death, valvular insufficiency, coronary arteritis, myocardial fibrosis, lymphocystis myocarditis, pericarditis and blood culture-negative endocarditis (McAllister and Fenoglio, 1975; Khairy and Graham, 1996; Fenollar, Lepidi and Raoult, 2001). Hypotension is also frequently observed (McAllister and Fenoglio, 1975; Khairy and Graham, 1996). The ocular involvement is rare, estimated to affect 2–3% of patients with Whipple’s disease, and is only rarely observed in patients without digestive symptoms (Dobbins, 1987b). The manifestations usually include blurred vision, uveitis, retinitis, retinal hemorrhages, choroiditis, papillary edema, optical atrophy, retrobulbar neuritis and keratitis (Selsky *et al.*, 1984; Williams *et al.*, 1998; Misbah and Mapstone, 2000; Fenollar and Raoult, 2001b). The neuroocular manifestations include ophthalmoplegia, supranuclear paralysis, nystagmus, myoclonia and ptosis (Adams *et al.*, 1987; Chan, Yannuzzi and Foster, 2001). In 1987, Dobbins estimated that pulmonary involvement could be observed in 30–40% of patients with Whipple’s disease (Dobbins, 1987b). Cough is a frequently observed symptom and is found in approximately 50% of patients (Enzinger and Helwig, 1963). Chronic cough, thoracic pain or dyspnea secondary to a pleural or parenchyma involvement or a pulmonary emboli could be observed (Enzinger and Helwig, 1963; Wimberg, Rose and Rappaport, 1978; Dobbins, 1987b). Peripheral lymphadenopathies are observed in half of the patients with Whipple’s disease (Alkan, Beals and Schnitzer, 2001). Very rare cases of mediastinal lymphadenopathy have also been described (MacDermott *et al.*, 1997).

Cutaneous involvement is rare and various. Hyperpigmentation is the most common manifestation described in approximately one-third of reported cases (Keren, 1981).

DIAGNOSIS

In the absence of clinical and radiological indicators for establishing a diagnosis of Whipple’s disease, laboratory techniques play a crucial role. The different tools are summarized in Figure 26.3 and Table 26.2.

Table 26.2 Diagnostic tools for the diagnosis of Whipple’s disease

Technique	Sample	Inconvenience	Advantage
Electron microscopy	Biopsy, aspirate fluid	Necessity to have an apparatus	Unknown sensitivity
Periodic acid–Schiff staining	Biopsy, aspirate fluid	Low specificity	Easy to perform Retrospective
Genomic detection	Biopsy, aspirate fluid Blood	Unknown specificity	Available in most laboratories
Immunodetection	Biopsy, aspirate fluid Blood	Non-commercialized antibodies	Specificity Sensitivity Retrospective
Culture	Biopsy, aspirate fluid, blood	Cell-culture technology Long time for the primary isolation	New strain isolation
Serology	Serum	Low specificity Presently experimental	Noninvasive procedure

Nonspecific Diagnosis

Blood

The blood may show inconstant leucocytosis, hypochromic anemia and a very inconstant thrombocytosis (Dobbins, 1987b).

For unknown reasons, a significant percentage of patients develop hypereosinophilia (Dobbins, 1987b). An inflammatory syndrome can also be observed (Dobbins, 1987b; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). Malabsorption signs (hypoalbuminemia, hypocholesterolemia, vitaminic defects and hypocalcemia) could be present (Dobbins, 1987b; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). Abnormalities of Ig levels are sometimes present. The fat excretion in stools can be increased (Dobbins, 1987b) and the D-xylose absorption reduced (Dobbins, 1987b).

Histological Diagnosis

Electron Microscopy Diagnosis

Electron microscopy can be performed on various biopsies (Fenollar and Raoult, 2001b). The analysis allows the detection of bacteria in the macrophages (Fenollar and Raoult, 2001b). This technique is not available in most laboratories, and there have been no studies concerning the sensitivity of this technique in comparison with histology or PCR and therefore cannot be considered as an established tool for the diagnosis of the disease.

Specific Staining

Histology was the first tool used for the diagnosis of Whipple’s disease. Classically, the diagnosis is performed with a duodenal (or jejunal) biopsy, with the observation, using PAS staining, in the mucosa, of spumous macrophages containing purple material. Owing to a sparse involvement, several duodenal biopsies may be necessary to establish the diagnosis. Since the organisms are localized to the submucosa, the diagnosis could be missed if the biopsies are too superficial (Fenollar and Raoult, 2001b). Depending on the clinical manifestation, other samples could be tested, such as cardiac valves, adenopathies, muscle, lung, liver, spleen, synovial biopsies, synovial liquid, bone marrow or cerebrospinal fluid (CSF) (Fleming, Wiesner

Figure 26.3 Samples, transport means and techniques for the diagnosis of Whipple’s disease.

and Shorter, 1988; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). However, PAS staining, which has been considered for a long time as diagnostic in Whipple's disease, is not completely specific. Patients with infections due to *Actinomyces*, *Mycobacterium avium-intracellulare*, *Rhodococcus equi*, *Bacillus cereus*, *Corynebacterium* sp., *Histoplasma* or *Fungi* could have PAS-positive macrophages in their samples (Dobbins, 1987b; Misbah and Mapstone, 2000; Fenollar and Raoult, 2001b). The diagnosis of Whipple's disease can be excluded when a positive Ziehl-Neelsen staining is obtained. In patients suffering from melanosis coli, histiocytosis, macroglobulinemia and Crohn's disease, the diagnosis can be confused with Whipple's disease (Marth and Raoult, in press; Dobbins, 1987b; Misbah and Mapstone, 2000; Fenollar and Raoult, 2001b). Gastric or rectal biopsies are not adequate for the diagnosis of Whipple's disease. Indeed, weakly PAS-positive macrophages can be observed in the stomach and the rectum of healthy people (Dutly and Altwegg, 2001). Furthermore, mononuclear cells from tissues and synovial liquid may also contain nonspecific PAS-positive cells (O'Duffy *et al.*, 1999). The involvement of lymphatic tissues, gastrointestinal tract and other organs such as the liver or lungs could be associated with the presence of granulomas composed of non-caseous epithelioid cells. Of note, these granulomas associated with Whipple's disease can be PAS negative (Cho *et al.*, 1984). In these latter cases, electron microscopy, immunohistochemistry or PCR is then necessary to confirm the diagnosis of Whipple's disease. These data suggest that the diagnosis of Whipple's disease should not be exclusively based on the presence of PAS-positive macrophages and should not be completely excluded because of the negativity of the PAS staining.

Specific Diagnosis

Immunohistochemical Diagnosis

Immunohistochemistry performed using rabbit polyclonal antibodies directed against *T. whipplei* can be performed on various biopsies (duodenum, cardiac valve, adenopathy and brain), on various liquid puncture (aqueous humor) and blood monocytes (Raoult *et al.*, 2000, 2001; Raoult, Lepidi and Harlé, 2001; Baisden *et al.*, 2002; Lepidi *et al.*, 2002; Dumler, Baisden and Raoult, 2003). The use of polyclonal and monoclonal antibodies (Liang, La Scola and Raoult, 2002) has demonstrated good results. This technique is sensitive and specific for the diagnosis of Whipple's disease. The technique can be performed with previously fixed samples. We stained biopsies from Dr Whipple's patient nearly one century later (Dumler, Baisden and Raoult, 2003). However, it is necessary to possess the specific antibodies, which are not commercially available. This method offers added advantage in terms of specificity over PCR methods, owing to the direct visualization of bacilli and antigens within cells in tissue sections, and offers increased sensitivity and specificity over the traditional PAS method.

Molecular Biology

Because physicians do not often consider Whipple's disease in their differential diagnosis, PCR targeting broad-spectrum 16S rDNA is useful. PCR can be performed on various biopsies (adenopathy, cardiac valve, kidney, brain and synovial) and samples (CSF, articular liquid and aqueous humor blood). PCR on duodenum saliva or stools uses primers targeting different genes of the bacterium (Fenollar and Raoult, 2001a). The hypothesis that the diagnostic PCR of the Whipple's disease could be performed exclusively using DNA extracted from blood has been raised (Lowsky *et al.*, 1994; Marth *et al.*, 1996). However, blood does not appear to be a good sample for this technique because of the likely presence of PCR inhibitors (Lowsky *et al.*, 1994; Marth *et al.*, 1996). For example, Marth *et al.* (1996)

did not succeed in finding some evidence of *T. whipplei* DNA in the blood of four patients with active Whipple's disease (confirmed by a PAS positive on intestinal biopsies). However, this technique has at times contributed to disease diagnosis (Messori *et al.*, 2001; Peters, du Plessi and Humphrey, 2002). It has notably allowed the diagnosis of Whipple's disease in a patient with neurological disease without digestive involvement (Jiménez Carmena *et al.*, 2000). The utility of saliva and stool samples remains to be determined (Gross *et al.*, 1959; Gross, Jung and Zoller, 1999; Dutly *et al.*, 2000; Maibach, Dutly and Altwegg, 2002).

The DNA extraction is a key step, and different protocols have been proposed (Fenollar and Raoult, 2001a). These protocols can be applied using a fresh sample or one fixed in paraffin. The sequence targets presently used for the molecular diagnosis of Whipple's disease are the 16S rDNA, the intergenic region 16S-23S, the 23S rDNA, the *rpoB* gene and the *hsp65* gene (Fenollar and Raoult, 2001a). The availability of the full genome of the bacterium should allow the optimization of the PCR diagnosis. Currently, if an amplification product is obtained by PCR, it should then be confirmed by sequencing. The PCR sensitivity depends on the primers used and on the number of cycles (Fenollar and Raoult, 2001a, b). The amplification of short fragments, compared to long fragments, seems to be more sensitive (Rickman *et al.*, 1995; Lynch *et al.*, 1997; Ramzan *et al.*, 1997). The use of fresh clinical samples obtains better results in comparison with fixed samples comprising partially degraded DNA (Ramzan *et al.*, 1997). Some studies have shown that PCR performed in intestinal samples is more sensitive than the histological studies. A greater sensitivity has also been reported in CSF (von Herbay *et al.*, 1997a). The main problem with PCR is specificity, due notably to the problem of contamination, depending on the technique used and the samples studied. PCR seemed to be a technique full of promise. Positive results have been reported in saliva, gastric liquids and duodenal biopsies in patients without suspicion of Whipple's disease (Ehrbar *et al.*, 1999; Street, Donoghue and Neild, 1999; Dutly *et al.*, 2000), but these results have not been confirmed by others (Maiwald *et al.*, 2001; Fenollar *et al.*, 2002). The utilization of PCR has simplified the laboratory diagnosis, principally for patients with neurological involvement. The PAS staining could necessitate invasive procedures such as a cerebral biopsy to confirm the diagnosis, whereas PCR can be more simply performed on the CSF (Cohen *et al.*, 1996; von Herbay *et al.*, 1997a). The number of patients with atypical Whipple's disease is rising (Rickman *et al.*, 1995; Misbah *et al.*, 1997; Averbuch-Heller *et al.*, 1999; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b; Akar *et al.*, 2002; Peters, du Plessi and Humphrey, 2002). For a definite molecular diagnosis of Whipple's disease, especially with atypical cases, we suggest that at least two sequenced amplicons from two pairs of primers be obtained from two different genes to avoid false-positive results due to contamination.

Culture

Cell cultures from diverse biopsies, puncture liquids or blood can be performed using human fibroblasts with MEM with 10% fetal calf serum and 2 mM glutamine incubated at 37°C under a 5% CO₂ atmosphere (La Scola *et al.*, 2001). However, the culture cannot become a tool for the diagnosis unless there is an improvement in culture conditions. One of the major problems is the delay in primary isolation. The first isolate of *T. whipplei* was obtained from a cardiac valve. It demonstrated a cytopathic effect after 2 months. Indeed, the bacterium multiplies slowly in human fibroblasts (MRC5 and HEL cells), HeLa cells and peripheral blood monocytes (Relman *et al.*, 1992). In addition, the culture of the bacterium from contaminated samples such as duodenal biopsies requires the use of a mix of antibiotics (Raoult *et al.*, 2001). Its limitations are the long generation time of these bacteria, the necessity to have qualified personnel and the capacities of cell-culture techniques.

Serology

The recent culture of *T. whipplei* has allowed preliminary testing of serologic techniques, based on indirect immunofluorescence, on a series of patients with Whipple's disease and a control group (Raoult *et al.*, 2000). IgG antibodies greater than or equal to 1/100 were observed so frequently in the control subjects that they were not useful for diagnosis. The presence of IgG in most subjects, independent of the presence or the absence of Whipple's disease, suggests the spread of the microorganism or the frequency of cross-reactivity (Ehrbar *et al.*, 1999; Street, Donoghue and Neild, 1999; Dutly *et al.*, 2000; Hinrikson, Dutly and Altwegg, 2000b). IgM antibodies are more specific. Titers greater than or equal to 1/50 were present in 5 of 7 patients with a classical Whipple's disease, in 2 patients with Whipple's disease endocarditis, in none of 10 patients with an endocarditis other than those of Whipple's disease, in 2 of 9 patients with an autoimmune disease and, lastly, in 1 of 20 blood donors. However, after several subcultures, there was an antigenic modification of the bacterium, leading to a loss of specificity (Marth and Raoult, in press).

For the serological diagnosis of Whipple's disease, another approach has been reported with a recombinant protein *hsp65* by using an enzyme-linked immunosorbent assay (ELISA) (Morgenegg *et al.*, 2001). Unfortunately, the results observed for 10 patients with Whipple's disease and 89 control subjects did not show significant differences (Morgenegg *et al.*, 2001). Whipple's disease serology is not presently achievable, but only experimental.

TREATMENT

Whipple's disease was always fatal before the use of antibiotic therapy. However, after the introduction of an antibiotic therapy, a rapid improvement in the patient's clinical state was observed. Diarrhea and fever disappear in less than 1 week, and the arthralgia and the other symptoms improve within several weeks (Marth and Raoult, in press). The neurological disturbances take a longer time to regress. The treatment of Whipple's disease has been established empirically, in the absence of data concerning the *in vitro* antibiotic susceptibilities of *T. whipplei*. The rarity of the disease has notably not allowed randomized trials to determine the best drugs to use and the optimal length of treatment. In 1952, the first antibiotic used, chloramphenicol, was responsible for a regression of the symptoms, with the disappearance of histological abnormalities. Since then, several antibiotic treatments have been prescribed with success, including penicillin, penicillin in combination with streptomycin, ampicillin, chloramphenicol, tetracycline and trimethoprim-sulfamethoxazole (Dobbins, 1987b; Fleming, Wiesner and Shorter, 1988; Vital-Durand *et al.*, 1997). Until 1970, the antibiotic regimen used most frequently was a combination of penicillin and streptomycin using parenteral administration, at the initiation of treatment, followed by per os tetracyclines. However, the evidence of relapses, which could occur late and involve the CNS despite prolonged antibiotic therapy, demonstrated a limitation of tetracycline-based treatment (Dutly and Altwegg, 2001). The treatment has been reoriented toward antibiotics, with good penetration into the brain (Dutly and Altwegg, 2001), and the prescription of trimethoprim-sulfamethoxazole was suggested (Wang and Prober, 1983). The rate of relapse, after antibiotic therapy, is estimated to be from 2 to 33%, depending on the initial treatment (Dutly and Altwegg, 2001). When performing a synthesis of several studies, the rate of relapse can be more precisely evaluated at 2% (1 of 46) for patients treated with trimethoprim-sulfamethoxazole and at 25% (33 of 133) for patients treated with tetracycline (Fleming, Wiesner and Shorter, 1988; Keinath *et al.*, 1985; Feurle and Marth, 1994; Vital-Durand *et al.*, 1997). The rate of clinical relapse seems to be lower after treatment based on trimethoprim-sulfamethoxazole. Currently, the recommended treatment is a per os trimethoprim (160 mg) and sulfamethoxazole (800 mg) two times per day, preceded with an intra-

venous treatment of 14 days based either on streptomycin (1 g/d) and benzylpenicillin (penicillin G: 1.2 million U/day) or on trimethoprim-sulfamethoxazole for a duration of 1–2 years (Keinath *et al.*, 1985; Dobbins, 1987b; Fleming, Wiesner and Shorter, 1988; Feurle and Marth, 1994; Fantry and James, 1995). The optimum length of treatment duration has not been determined. Antibiotic therapies of short duration (few weeks to few months) are thought to be sufficient by some authors (Fleming, Wiesner and Shorter, 1988; Dutly and Altwegg, 2001), and the recommendations for a longer treatment are based on prudence rather than on evidence base. The objective of treatment is to avoid neurological relapses described after short treatment durations (Dutly and Altwegg, 2001). For patients allergic to trimethoprim-sulfamethoxazole or for those with no response to the treatment, chloramphenicol, cefixime or ceftriaxone could be used (Vital-Durand *et al.*, 1997; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b).

The follow-up strategy for patients with Whipple's disease is not yet established. At the end of the antibiotic therapy, PCR and PAS staining of affected tissues could be useful for detecting a possible relapse (Marth and Strober, 1996; von Herbay *et al.*, 1997a; Dutly and Altwegg, 2001; Fenollar and Raoult, 2001b). If a good clinical response is observed, it is sufficient to follow the patient by performing a duodenal biopsy at 6 months and 1 year after the diagnosis, and the antibiotic treatment can be stopped if no PAS-positive material is observed. In a few cases, where the PAS-positive material persists, treatment must be continued or an alternative therapy could be considered. An increase in PAS-positive material may be an indicator of relapse (Geboes *et al.*, 1992). The results of PCR after the onset of antibiotic treatment can quickly become negative (Müller *et al.*, 1997; Ramzan *et al.*, 1997; Pron *et al.*, 1999). These results are probably linked to the degradation of bacterial DNA before the resolution of the rigid wall of Gram-positive bacteria (von Herbay, Ditton and Maiwald, 1996; von Herbay *et al.*, 1996, 1997a; Petrides *et al.*, 1998). However, the value of the PCR following treatment is controversial (von Herbay, Ditton and Maiwald, 1996; Müller *et al.*, 1997; Ramzan *et al.*, 1997; Brändle *et al.*, 1999). If PCR becomes negative a few weeks after the initiation of the treatment, then it seems to suggest the efficiency of the treatment but not the eradication of the microorganism. The neurological manifestations of Whipple's disease have become the most common symptoms during relapses and have a bad prognosis. The follow-up of patients includes CSF analysis every 6 months.

The recent discovery of a possible defect in cellular immunity in Whipple's disease could lead to a search for new therapeutic approaches. Indeed, it should be possible to combine antibiotic therapy with immunotherapy using IFN- γ . IFN- γ plays an important role in the control of bacterial infection (Gallin *et al.*, 1995). This therapeutic option has yet to be applied. IFN- γ has been used with success in the treatment of a patient with Whipple's disease presenting resistance to presumed efficacious antibiotics (Schneider *et al.*, 1998). The choice of IFN- γ as a therapeutic agent is based on the observation of a deficit in the production of IFN- γ and IL-12 *in vitro* by the monocytes of patients with Whipple's disease (Marth *et al.*, 1997), and it has been employed successfully in the treatment of other infections due to intracellular microorganisms (Holland *et al.*, 1994; Gallin *et al.*, 1995). It is suggested that the utilization of IFN- γ in association with antibiotics could then diminish the number of relapses, but more studies are necessary to prove the real efficacy of the treatment.

Identification of Enterobacteriaceae

Peter M. Hawkey

Division of Immunity and Infection, The Medical School, Edgbaston, Birmingham, UK

The family Enterobacteriaceae is the most widely studied family of organisms in the world. They have a worldwide distribution, and while largely found in animals, medical microbiologists are inclined to gain a distorted view of the family as they only encounter species associated with human disease, such as *Escherichia coli*, *Proteus mirabilis*, *Salmonella* spp. and *Klebsiella* spp. The genera *Erwinia* and *Pectobacteria* are major plant pathogens causing blights, wilts and rots in many different crops. *Yersinia ruckeri* is a major pathogen of farmed salmon, and the salmonellae are pathogens of cattle, sheep and poultry. Various species of Enterobacteriaceae have been isolated from the gut contents of animals ranging from fleas to elephants, some being adapted to very specific hosts, e.g. *P. myxofaciens* in the gut of gypsy moth larvae.

The family is numerically important to the medical microbiologist, as they may account for 80% of clinically significant Gram-negative bacilli and about 50% of isolates from cases of septicaemia. The family now has over 20 genera and more than 100 species, of which about 50 are definitely or probably associated with human disease (Farmer *et al.*, 1985). Taxonomy now makes use of formation on the relationship of isolates from examining a wide range of semantides (large information-bearing molecules). These are DNA, both in terms of sequences of genes and DNA/DNA hybridization studies, RNA, particularly 16S rRNA phylogenetic trees, and proteins both as functional enzymes and as electrophoretic cellular protein patterns. The synthesis of this information has led to the development of a clear and scientifically robust taxonomy of the Enterobacteriaceae. These developments are comprehensively and authoritatively reviewed by Farmer and colleagues (1985) in a review which, although now 20 years old, is still the most useful. Changes in taxonomy are often reluctantly accepted by medical microbiologists, but this is an evolving area and much of that which is familiar remains. I urge the reader to embrace the newer names and use them – they will become familiar in time. Although there appears to be a number of unfamiliar genera, such as *Ewingella*, *Obesumbacterium* and *Xenorhabdus*, these organisms are very rarely encountered. In clinical material 99% of isolates are represented by 23 species, whereas the remaining 1% belongs to 74 species (Farmer *et al.*, 1985). The adage from the authors, ‘when you hear hoof beats, think horses, not zebras’, is indeed true.

There are four reasons why clinical microbiologists may wish to identify microorganisms:

1. to help predict the likely outcome of the infection;
2. to identify potential cross-infection risks and cross-infection, retrospectively;
3. to attempt to predict likely sensitivity to antimicrobials;
4. to obtain research information on new disease associations with microorganisms.

The level to which an identification is made is very much a question of the clinical significance of the cultured bacteria. In the

case of a moist, noninflamed surgical wound from which a mixture of faecal bacteria, such as enterococci, *E. coli*, *Klebsiella* spp., *P. mirabilis* and *Pseudomonas aeruginosa* are cultured, identification of the individual isolates of Enterobacteriaceae is inappropriate and a report of mixed faecal flora should be made. Isolates of Enterobacteriaceae from blood cultures, normally sterile sites (e.g., cerebrospinal fluid, peritoneum and deep tissues), infections at different sites requiring linking (e.g., isolates from a blood culture and urine), enteric pathogens (e.g. *Salmonella enteritidis* and *Shigella sonnei*) and if epidemiologically important (e.g., multi-resistant *K. pneumoniae*) should be identified to species level.

With the development of newer technologies the utilization of identification as a predictor of pathogenicity, for example, identification of *Shigella dysenteriae*, can be replaced by identification of the genes responsible for pathogenicity, regardless of the host background. Thus isolates of *E. coli* carrying Shiga toxin genes can be identified in 3 h with a greater sensitivity than biochemical methods (Iijima *et al.*, 2004). Species identification of some Enterobacteriaceae combined with antimicrobial sensitivity data may predict responses to certain agents. This is true of the use of cefotaxime/ceftazidime to treat bacteraemia and pneumonia caused by *Enterobacter* spp. because of the selection of derepressed mutants expressing the chromosomal gene *ampC* encoded by the β -lactamase found in that species (Stearne *et al.*, 2004).

There are other species-specific β -lactamase associations which have been reviewed elsewhere (Livermore, 1995). These predictions are not confined to β -lactams: *Serratia marcescens* was found to be the only species of Enterobacteriaceae that carries the *aac(6')*-Ic that encodes the aminoglycoside-inactivating enzyme AAC(6')-Ic, when 186 strains of 10 species of *Serratia* were probed with a specific DNA probe (Snelling *et al.*, 1993). The enzyme confers broad resistance to aminoglycosides, and aminoglycoside-sensitive strains of *S. marcescens* can express the gene fully after exposure, leading to treatment failure. Some species of Enterobacteriaceae are intrinsically resistant to certain antimicrobials, and this can be used to help in the presumptive identification of isolates in the clinical laboratory. Table 27.1 lists this information.

Suspicion that an isolate cultured from a clinical specimen belongs to the Enterobacteriaceae arises from the following characteristics:

- Gram-negative bacillus 0.5–2 × 2–4 μ m;
- cytochrome oxidase negative;
- ferments glucose;
- nitrates reduced to nitrites;
- facultative anaerobe.

Some species have characteristic appearances on solid media which may give a clue to identity: swarming – *Proteus* spp.; pronounced mucoid capsule – *Klebsiella/Enterobacter* spp. Definitive identification

Table 27.1 Intrinsic antimicrobial resistance encountered in clinically significant Enterobacteriaceae

Species	Agents to which most strains are resistant	Common chromosomal β -lactamase ^a
<i>Citrobacter diversus</i>	Ampicillin ^b , cefuroxime, cephalothin ^c , cefoxitin (piperacillin ^d , ticarcillin ^e)	K1 type ^f
<i>Citrobacter freundii</i>	Ampicillin, cephalothin, cefoxitin (piperacillin, cefotaxime, ceftazidime, aztreonam)	AmpC
<i>Enterobacter</i> spp.	Ampicillin, cephalothin, cefoxitin (piperacillin, cefotaxime, ceftazidime, aztreonam)	AmpC
<i>Klebsiella pneumoniae</i>	Ampicillin, ticarcillin	SHV-1
<i>Klebsiella oxytoca</i>	Ampicillin, ticarcillin (piperacillin, cefuroxime, cefotaxime, aztreonam) ^g	K1
<i>Morganella morganii</i>	Polymyxins, nitrofurantoin, ampicillin, cephalothin, cefuroxime (ticarcillin, piperacillin, cefotaxime, ceftazidime)	AmpC
<i>Proteus mirabilis</i>	Polymyxins, tetracycline, nitrofurantoin	
<i>Proteus vulgaris/penneri</i>	Polymyxins, nitrofurantoin, ampicillin, cefuroxime, cephalothin, cefoxitin (piperacillin, ticarcillin)	K1 type ^h
<i>Providencia stuartii/rettgeri</i>	As <i>M. morganii</i> , plus tetracycline except <i>Prov. stuartii</i> resistant to gentamicin/tobramycin	AmpC
<i>Serratia marcescens</i>	Polymyxins ⁱ , ampicillin, cephalothin, cefuroxime (ticarcillin, piperacillin, cefotaxime)	AmpC

Resistance to agents shown in parentheses is only seen in hyperproducers of β -lactamase.

^a Expression of these genes varies; so resistance in individual strains may vary according to induction or mutation to hyperproduction.

^b Representative of amoxicillin.

^c Representative of cephalexin, cefazolin and cephadrine.

^d Representative of azlocillin/mezlocillin.

^e Representative of carbenicillin.

^f Some strains have AmpC-like enzymes (Jones *et al.*, 1994).

^g Hyperproduction of K1 only occurs in 10–20% of isolates, rarer than *Enterobacter* spp. AmpC.

^h Cefuroximes classified by Bush, Jacoby and Medeiros (1995) as 2e.

ⁱ Frequently forms target zones around disc.

relies on the use of the fermentation of carbohydrate tests and a number of other tests to identify the presence or absence of specific enzymes, e.g. amino acid decarboxylases, urease and phenylalanine deaminase. Microbiologists at the end of the nineteenth century, such as Escherich and Gartner (who discovered *Salmonella enteritidis* in 1888) relied heavily on the use of agglutination tests to differentiate Enterobacteriaceae. It was the work of Theobald Smith and Herbert Durham, at the University of Cambridge, who appreciated the value of carbohydrate fermentation tests in identification (Durham, 1900). Using a range of fermentable vegetable extracts, as well as other tests, Durham recognized ten distinct types which accord broadly with many of the genera now recognized in the Enterobacteriaceae. Initially, laboratories prepared their own identification media, and the choice and quality control were highly individualistic. In the late 1960s, miniaturized, disposable, commercially prepared systems such as the API and Enterotube systems became available. These offered rapid, reliable identification and in the case of the API20E system used freeze-dried reagents that were rehydrated by inoculation with a bacterial suspension. Laboratories relied on either flow charts or tables for translating test results into a species identification (Barrow and Feltham, 1993). The widely used API20E system for the identification of Enterobacteriaceae translates the results from 21 individual tests into an octal number. The tests are arranged in groups of three and the positive and negative results for each are converted into a single octal, representing the results for that group of three tests, as summarized in Table 27.2. A 7 digit number is generated, which can be searched for on a computer database. The database can be derived from a large number of isolates, and a probability of correct identifica-

tion can be given, taking into account unusual biochemical properties of biotypes of species. The API20E system has been in use for 30 years and, in a recent evaluation, was still found to provide a good level of accuracy of identification (78.7% at 24 h) which although slightly lower than earlier evaluations is acceptable (O'Hara, Rhoden and Miller, 1992).

Because of the special requirements for the identification of enteric pathogens, such as *Salmonella* spp. (Chapter 29) and *Shigella* spp. (Chapter 28), shortened sets of biochemical tests are used to screen isolates. These are described in the relevant chapter and range from single tubes of media, like triple sugar iron agar, to disposable cupule systems to detect preformed enzymes, such as APIZ. The practical details of using these various systems for identification are described in detail elsewhere (Pedler, 2004).

More recently, the principles enshrined in packaged disposable kits have been further developed into automated systems. Generally, these use pre-prepared cartridges of freeze-dried reagents which, after rehydration and inoculation, are incubated and continuously monitored by an automated spectrophotometer. Most systems use conventional biochemical tests with colour changes or release of fluorophores, but growth inhibition by antibiotics and dyes is also included. A number of different approaches have been developed, for example, the Biolog system determines carbon source utilization profiles and the Midi microbial identification system utilizes an automated high-resolution gas chromatography system coupled to a computer (Stager and Davis, 1992). The most widely used systems are VITEK (BioMerieux Marcy l'Etoile, France) and PHOENIX (Becton and Dickinson Franklin Lakes, New Jersey, USA) which combine identification with antimicrobial susceptibility testing. The VITEK2 system incorporates an expert system to match MIC results with identification which had a 95.7% correlation with human review of results, thus greatly reducing laboratory interpretative input (Sanders *et al.*, 2001). The combination of VITEK2 with direct inoculation from an automated blood culture system has the potential to save 1 or 2 days in reporting the antimicrobial sensitivity and identification of Enterobacteriaceae causing septicaemia, although polymicrobial disease will give an erroneous result (Ling, Liu and Cheng, 2003). It is easy for microbiologists to lose sight of the basic biochemical characteristics of the species of the Enterobacteriaceae when using automated systems. Should problems arise, back-up systems should be available and the microbiologist should be aware of the key biochemical properties of the commonly encountered and clinically significant Enterobacteriaceae, which are summarized in Table 27.3.

Table 27.2 Octal conversion of binary code

Binary	Conversion formula	Octal
---	0+0+0 =	0
+-	0+0+1 =	1

ONPG, o-nitrophenyl-β-D-galactopyranoside; +, >90% positive; V, 10–90% positive; -, <10% positive, after 48 h incubation at 37 °C.

Bacterial identification by sequencing the 16S rRNA gene is a universal bacterial identification method which has been used in combination with whole-genome DNA/DNA hybridization by bacterial taxonomists. Because the first 500 bp of this highly conserved gene have the greatest heterogeneity, this sequence, which can be generated using PCR and automated DNA sequencing, has been used in the clinical laboratory (particularly for *Mycobacterium* spp.) to identify unknown isolates (Patel, 2001). Consensus primers can be used, and DNA sequenced in-house or commercial systems are available (e.g., MicroSeq – www.appliedbiosystems.com). The technique is extremely powerful as illustrated by the reclassification of the causative agent of granuloma inguinale. 16S rRNA sequencing has reclassified *Calymmatobacterium granulomatis* which cannot be cultured on conventional media, as *Klebsiella granulomatis* (Kharsany *et al.*, 1999). The costs for 16S rRNA identification are relatively high, and a balance must be made between the clinical value of the identification and cost. Individual molecular tests for the rapid identification of some species or Enterobacteriaceae have been developed, for example, *Yersinia pestis* in relation to bioterrorism (McAvin *et al.*, 2003).

ESCHERICHIA COLI

INTRODUCTION

Since its first description by Dr Theodore Escherich in 1885, *Escherichia coli* is the most extensively studied bacterial species. Much of our knowledge of bacteria at a molecular and cellular level has been obtained through studies with *E. coli*, particularly using the strain K12, isolated in 1922 from a patient with diphtheria. The complete genome sequence of a strain of *E. coli* K12 has been published, revealing the degree of genome plasticity, as indicated by the presence of phage remnants and insertion elements (Blattner *et al.*, 1997).

DESCRIPTION OF THE ORGANISM

The genus *Escherichia* includes motile and non-motile bacteria which belong to the family Enterobacteriaceae (Edwards and Ewing, 1972). They are Gram-negative, oxidase negative, non-spore-forming, rod-shaped bacteria, facultative anaerobes, which are often motile by peritrichously arranged flagella. They are capable of fermenting a wide variety of carbohydrates with production of both acid and gas, although anaerogenic biotypes exist. Rapid fermentation of lactose is a characteristic feature of many strains, particularly those of *E. coli*, whilst other *Escherichia* species, including strains of enteroinvasive *E. coli* (EIEC), as well as some *E. coli* (metabolically inactive) strains ferment it slowly or fail to utilise this substrate at all. Other genera within the family Enterobacteriaceae (*Klebsiella*, *Enterobacter*, *Serratia* and *Citrobacter*), which share this ability to ferment lactose rapidly (typically within 24h), are collectively termed coliform bacteria. Besides *E. coli*, other species belonging to the genus *Escherichia* are *Escherichia blattae*, *Escherichia fergusonii*, *Escherichia hermannii* and *Escherichia vulneris*. The species *Escherichia adecarboxylata* has since been assigned to the genus *Lecercia*, and a new species, *Escherichia albertii*, has been described (Abbott *et al.*, 2003). The biochemical characteristics of the genus *Escherichia* are given in Table 28.1.

With the exception of *E. blattae*, which has been isolated from the cockroach intestine, but not from human clinical specimens, the primary habitat of *E. coli* and the other species is the gastrointestinal tract of humans and other warm-blooded animals where they generally exist as harmless commensal organisms. They can also occur in water, food and soil, but this is invariably the result of faecal contamination.

Although most *E. coli* strains are harmless, there are others that cause disease in humans and animals that have evolved to become important pathogens in their own right. Clinically, two distinct types of pathogenic *E. coli* are recognised. One group commonly called extraintestinal pathogenic *E. coli* (ExPEC) includes those *E. coli* associated with newborn meningitis (NBM) or sepsis and urinary tract infections (UTIs). The second group termed intestinal pathogenic *E. coli* (IPEC) includes *E. coli* responsible for a range of distinct classes of diarrhoeal disease.

Escherichia coli is a genetically diverse species that includes many intestinal and extraintestinal pathotypes. Many of these have highly efficient and specialised mechanisms of colonisation and pathogenicity, developed through the acquisition of virulence-associated genes and adaptation to their changing surroundings aided by mutations and natural selection. Many virulence-associated genes are localised on mobile genetic elements such as plasmids, bacteriophages and pathogenicity islands (PAIs). First described in uropathogenic *E. coli*, and now recognised in other pathotypes, notably enteropathogenic *E. coli* (EPEC) and enterohaemorrhagic *E. coli* (EHEC), PAIs are distinct types of genetic element thought to have evolved from mobile genetic elements by horizontal gene transfer. Characterised by their large size (>10 kb), presence of virulence-associated genes and a G+C content that is different from that of the rest of the genome, they are often flanked by repeat structures carrying fragments of other mobile and accessory genetic elements such as plasmids, bacteriophages and insertion sequence (IS). It is this exchange of virulence genes between different bacteria that is largely responsible for the evolution of different bacterial pathotypes, and horizontal transfer plays a major role in the creation of new virulent clones (Johnson, 2002).

Multilocus enzyme electrophoresis (MLEE) and sequencing of the *malate dehydrogenase* gene (*mdh*) indicate that pathogenic strains of *E. coli* have arisen many times and that they do not have a single evolutionary origin within the species (Pupo *et al.*, 1997). Many prophage elements present in the *E. coli* O157 Sakai genome indicate that bacteriophages have played an important role in the emergence of this pathogen and, possibly, other pathotypes of *E. coli* (Ohnishi, Kurokawa and Hayashi, 2001). Although thought to be uncommon, genome rearrangements within species have been reported to be very frequent in human clinical isolates (Hughes, 2000). Comparison of genome size within a species also enables the degree of divergence between strains to be assessed. In strain MG1655 of *E. coli* K12 the chromosome is 4.6 Mb (Blattner *et al.*, 1997), whereas genome sizes of 5.4 Mb and 5.5 Mb have been reported for *E. coli* O157:H7 strain

Data from Farmer *et al.* (1985) with the exception of *E. albertii*, which was derived from Abbott *et al.* (2003). Figures represent percentage positive reactions after incubation at 36 °C for 2 days except for those indicated by an asterisk, which were incubated at 35 °C. ONPG, *ortho*-nitrophenyl- β -D-galactopyranoside.

EDL933 (Perna *et al.*, 2001) and the O157:H7 Sakai strain (Hayashi *et al.*, 2001), respectively.

The complete genome sequence of *E. coli* K12 strain MG1655 has provided a benchmark against which other *E. coli* strains have been compared. Comparison of *E. coli* O157:H7 EDL933 against this K12 strain has highlighted that lateral gene transfer in this O157:H7 strain has been more extensive than was initially expected (Perna *et al.*, 2001). DNA sequences found in MG1655 but not EDL933 were designated K islands (KI) and DNA sequences in EDL933 but not MG1655, O islands (OI). There are 177 OI and 234 KI greater than 50 bp in length. Whilst they both share a common 'backbone' sequence of 4.1 Mb (Perna *et al.*, 2001), since the divergence of O157:H7 from K12 about 4.5 million years ago (Reid *et al.*, 2000), this O157:H7 strain has acquired 1387 new genes (Perna *et al.*, 2001). Many of these are putative virulence factors, while others are genes encoding alternative metabolic capacities as well as several prophages (Perna *et al.*, 2002). Whilst the amount of apparent horizontal transfer in MG1655 is not as high as that observed in EDL933, there is evidence that the genome of MG1655 also contains DNA obtained through horizontal transfer (Blattner *et al.*, 1997).

PATHOTYPES OF *E. COLI* AND CLINICAL FEATURES OF INFECTIONS

Extraintestinal Pathogenic *E. coli*

Unlike *E. coli* responsible for diarrhoeal disease and life-threatening infections, ExPEC can either behave as harmless inhabitants of the human intestine or become serious pathogens when they enter the blood, cerebrospinal fluid (CSF) or urinary tract. Certain *E. coli* strains are responsible for classic syndromes such as UTIs, bacteraemia and neonatal meningitis. This has given rise to particular strains, often characterised by specific O:K:H serotypes being classified as uropathogenic *E. coli* (UPEC) or meningitis-associated *E. coli* (MAEC). Some strains differ from commensal *E. coli* by the presence of pathogenicity-associated genes and particular clones of *E. coli* such as strains of O4:H5 which appear to show a greater propensity to cause UTI. The high-affinity iron-uptake system mediated by the hydroxamate siderophore aerobactin, which can be chromosomally or plasmid encoded, is

reported to be particularly prevalent among ExPEC, including those that cause septicemia, pyelonephritis and meningitis (Carbonetti *et al.*, 1986). However, *E. coli* is capable of infecting many anatomical sites and some strains demonstrate pathogenic versatility and the ability to cause infections other than the classic syndromes (Johnson and Russo, 2002).

Urinary Tract Infections

Escherichia coli which generally originate from faeces or the periurethral flora are responsible for most UTIs. After colonising the periurethral area, these organisms may ascend the urinary tract from the urethra meatus or from the insertion of catheters and infect the bladder. In some cases, these organisms continue to progress through the ureters and cause acute pyelonephritis, involving one or both kidneys. Patients with acute pyelonephritis present with a range of symptoms including fever, flank pain and bacteriuria with or without diaphoresis, rigors, groin or abdominal pain and nausea and vomiting. Abdominal tenderness of one or both kidneys may be elicited on examination. In a small proportion of cases, including those with pyelonephritis, the bacteria may spread beyond the urinary tract and enter the blood.

The group of *E. coli*, often called UPEC, which are responsible for acute and chronic UTIs are distinct from the commensal *E. coli* found in the colon of humans and are represented by a few serogroups (O1, O2, O4, O6, O7 and O75). They often possess genes encoding many pathogenicity-associated factors including adhesins, siderophores (i.e. aerobactin), capsule and toxins implicated in UTI pathogenesis. PAIs as a distinct type of genetic element were first described for UPEC strain 536 (O6:K15:H31), which has become a model organism to study ExPEC pathogenesis. The published complete genome sequence of UPEC strain CFT073 reveals the presence of numerous pathogenicity-associated genes in UPEC, especially genes encoding potential fimbrial adhesins, autotransporter iron sequestration systems as well as showing the acquisition of PAIs by horizontal gene transfer (Welch *et al.*, 2002). Unlike *E. coli* O157:H7 and other EHEC strains, the UPEC CFT073 genome contained no genes for type III secretion system, phage or plasmid-encoded virulence genes.

Individual pathogenicity-associated factors found in UPEC strains include adhesins, particularly fimbriae, which facilitate adherence and bacterial colonisation. Many fimbriae, with different host receptor

specificity, are expressed by UPEC strains. These include the mannose-resistant P, M, S, F1C and Dr fimbriae, which haemagglutinate erythrocytes in the presence of mannose. The type 1 fimbriae are common among Enterobacteriaceae, although in UPEC, the presence of type 1 fimbriae may increase their virulence for the urinary tract by promoting bacterial persistence and by enhancing the inflammatory response to infection (Wullt, 2003). The earliest described and most commonly associated adhesin in UPEC are P fimbriae, particularly the PapG adhesin. These fimbriae, encoded by the *pap* (pyelonephritis-associated pili) operon, recognise the disaccharide α -D-galactosyl-(1–4) β -D-galactose receptor, which is a very common P blood group antigen. This enables it to bind to red cells, but also to uroepithelial cells in most of the population. There exists a strong relationship between the presence of P fimbriae and severity of infection, especially pyelonephritis. Also in UPEC are P-related sequences (Prs) which are closely related to P fimbriae but possess the F or PrsG adhesin which bind to galactosyl-*N*-acetyl(α 1–3)-galactosyl-*N*-acetyl.

Toxins produced by UPEC include haemolysin and cytotoxic necrotizing factor 1 (CNF1) and secreted autotransporter toxin (Sat) which has been shown to have a cytopathic effect on various bladder and kidney cell lines (Bahrani-Mougeot *et al.*, 2002). A high percentage of *E. coli* isolated from patients with pyelonephritis secrete haemolysin, which can be plasmid or chromosomally encoded. Additionally, on the chromosome of UPEC strains, the *hly* operon (*hlyCABD*) is often located near the P fimbrial genes on the same PAI. In strain 536, four PAIs have been characterised which carry many pathogenicity-associated genes including two α -haemolysin gene clusters (PAI I₅₃₆ and PAI II₅₃₆), P-related fimbriae (PAI II₅₃₆), S fimbriae (PAI II₅₃₆) and the salmochelin (PAI III₅₃₆) and yersiniabactin (PAI IV₅₃₆) siderophore systems (Dobrindt *et al.*, 2002). The K15 capsule determinant of UPEC strain 536 is also found on a PAI (PAI V₅₃₆) (Schneider *et al.*, 2004). Whilst the role of capsular antigens in UTI remains controversial, it is possible that they enable the bacteria to resist phagocytosis and survive in human serum or aid adherence of the bacteria to host cells. Interestingly, PAIs show considerable variability in their composition and structural organisation. Some PAIs show genetic instability, having a tendency to be deleted from the chromosome, which can be influenced by environmental conditions, whereas others appear to be relatively stable (Middendorf *et al.*, 2004).

Escherichia coli* Bacteraemia and Meningitis-Associated *E. coli

Although *E. coli* are able to colonise and infect the gastrointestinal and urinary tracts of humans, septicaemia remains a relatively rare complication of *E. coli* infections. Nevertheless, *E. coli* is one of the most common Gram-negative bacteria responsible for bacteraemia in humans. Isolates of *E. coli* that infect the bloodstream often possess virulence factors that enable the organisms to circumvent the normal clearance mechanisms and evade the host immune response. These include a range of adhesins (P, S and M), the siderophore aerobactin and haemolysin which are found in other ExPEC. The lipopolysaccharide (LPS) of *E. coli*, as with other Gram-negative bacteria, is an important pathogenicity factor which may cause fatal septic shock and disseminated intravascular coagulation. In response to the presence of *E. coli*, epithelial cells and cells of the host immune system have been shown to secrete many host-cell factors including interleukins (IL), tumour necrosis factor (TNF) and activators of the complement cascade. Epithelial cells are capable of producing a variety of cytokines in response to bacterial stimuli. Epithelial cells originating from the human urinary tract have been shown to produce IL-6, IL-1 α and IL-8, whereas human peripheral blood monocytes additionally produce IL-1 β and TNF- α in response to the presence of *E. coli* (Agace *et al.*, 1993). Whilst *E. coli* bacteraemia can occur in UTI, especially when the tract is obstructed, studies suggest a relationship between the magnitude of *E. coli* bacteraemia and the development of meningitis.

The most common Gram-negative organism responsible for meningitis during the neonatal period is *E. coli*. Sepsis and NBM are often associated with *E. coli* belonging to a limited number of serotypes, particularly those expressing the K1 capsular antigen (Korhonen *et al.*, 1985), e.g. O83:K1 and O7:K1 and especially O18:K1. Whilst few specific pathogenic determinants have been described for *E. coli* causing NBM, isolates have been shown to possess many factors, some of which are also found in UPEC strains and others that appear to be specific to this group. The polysialic acid homopolymer K1 capsule is believed to increase serum survival by blocking complement activation (Pluschke *et al.*, 1983), and expression of this, together with production of aerobactin, is believed to be important for blood stream dissemination. Adherence is a critical step in the pathogenesis of *E. coli* meningitis. Factors involved in the binding of *E. coli* to brain microvascular endothelial cells (BMECs) include S fimbriae which are also important in UPEC pathogenesis. Subsequent invasion is facilitated by various microbial determinants including invasion of brain endothelium (Ibe) proteins, which may promote the crossing of the blood–brain barrier. A primary determinant of this event is a high density of bacteraemia, but how circulating *E. coli* cross the blood–brain barrier is not fully understood: one mechanism might involve transcytosis through the endothelial cells aided by specific pathogen–host-cell interactions. Another factor which may contribute or enhance invasion of BMEC by *E. coli* is outer membrane protein A (OmpA), which shows structural similarities to *Neisseria* outer membrane protein (Opa) and surface protein PIII (Prasadarao *et al.*, 1996). Another candidate protein necessary for the invasion of BMEC is a novel *ibe10* protein found in CSF isolates of *E. coli*, which has been shown to interact with endothelial cells, thus enhancing invasion by *E. coli* cells (Prasadarao *et al.*, 1999). Whilst possession of P fimbriae is important in *E. coli* causing pyelonephritis, it is not thought to be relevant in strains responsible for NBM. Furthermore, whereas α -haemolysin and CNF-1 are less common in NBM strains, *ibe10* and *sfa* genes are reported to be more commonly associated with meningitis strains compared with blood or commensal *E. coli*.

Intestinal Pathogenic *E. coli*

Six distinct groups have been defined within IPEC commonly associated with intestinal disease: EIEC, enterotoxigenic *E. coli* (ETEC), EPEC, EHEC, enteroaggregative *E. coli* (EA_ggEC) and the diffusely adherent *E. coli* (DAEC). These diarrhoeagenic *E. coli* are described in more detail, along with aspects of the associated pathogenesis and their epidemiology (Donnenberg, 2002; Kaper, Nataro and Mobley, 2004).

Some of the virulence-associated genes and key features of the different pathotypes are presented in Table 28.2. In the past, pathogenic *E. coli* were defined by their serotype on the basis of somatic O and flagella H antigens and to a lesser extent the K antigens. Although this practice continues, it has become more common to define individual pathotypes based on their pathogenetic characteristics. This is particularly important because of the existence of strains with the same serotype that belong to different pathotypes based on their pathology and complement of specific virulence determinants, which is apparent with some strains of EPEC and EHEC.

Enteroinvasive *E. coli*

Strains belonging to this group are biochemically, genetically and pathogenically closely related to *Shigella* spp. Compared with most *E. coli* strains, EIEC are atypical. They are generally lysine decarboxylase negative and non-motile and 70% are unable to ferment lactose (Silva *et al.*, 1980). These characteristics are shared with *Shigella*, although some strains of *Shigella sonnei* can ferment lactose slowly. Genetically, *Shigella* spp. and *E. coli* are very closely related and it has been proposed that *Shigella* spp. have evolved from *E. coli* and

Table 28.2 Summary of pathogenicity-related characteristics of intestinal pathotypes of *E. coli*

Pathotype	Pathogenicity-associated genes or factors	Mechanism	Clinical features
Enteroinvasive <i>E. coli</i>	140 MDa plasmid (pINV) chromosomal genes	Bacterial attachment and invasion of colonic enterocytes via endocytosis, multiplication causing host-cell death and inflammation, accompanied by necrosis and ulceration of large bowel	Ulceration of bowel, watery diarrhoea, dysenteric stools (bacillary dysentery)
Enterotoxigenic <i>E. coli</i>	Plasmid-encoded CFAs: CFA-I (rigid rod-like fimbriae), CFA-III (bundle-forming group), CFA-II and CFA-IV (flexible fimbriae) and type IV-related longus pili Labile toxins: LTI, LTII (plasmid encoded) Heat-stable toxins: STa, STb (plasmid and transposon encoded)	Colonisation of surface of small-bowel mucosa (CFA I-IV) and production of enterotoxins LTI, LTII, STa, STb ADP ribosylation of G proteins → adenylate cyclase activation → increased cAMP secretion → reduced Na absorption/Cl secretion → diarrhoea Guanylate cyclase (G C-C) activation → increased cGMP secretion → chloride secretion and/or inhibition of NaCl absorption → diarrhoea	Acute watery diarrhoea, usually without blood mucus or pus
Enteroaggregative <i>E. coli</i>	Plasmid (60 MDa) encoded: Aggregative adherence fimbriae (AAF/I and AAF/II), transcriptional regulator (AggR) <i>E. coli</i> heat-stable-like toxin-1 (EAST-1) ShET1 is Shigella enterotoxin-1 Plasmid-encoded toxin (Pet)	Adherence and colonisation of intestinal mucosa facilitated by AAF/I and AAF/II Release of toxins and damage to host epithelial cells	Aggregative adherence (AA) phenotype Persistent diarrhoea
Diffusely adherent <i>E. coli</i>	Afa/Dr family adhesins (AIDA) EAST-1 <i>set</i> genes (enterotoxins) Possible TTSS with <i>esc</i>	DA phenotype facilitated by surface fimbriae, e.g. F1845 encoded via <i>daaC</i> gene, or by other related adhesins which are plasmid or chromosomally encoded Events in pathogenesis remain unclear	Diffusely adherent (DA) phenotype Watery diarrhoea, usually without blood
Enteropathogenic <i>E. coli</i>	50–70 MDa plasmid (EAF) encodes: bundle-forming pilus (BFP), plasmid-encoded regulator (Per) and LEE-encoded regulator (Ier) Chromosomal PAI (LEE) TTSS comprising: intimin (<i>eaeA</i>), secreted proteins; Tir, EspA, EspB, EspD, EspF, EspG and mitochondria-associated protein (MAP) EAST-1 Cytolethal distending toxin (CDT)	Localised adherence (LA) via BFP A/E histopathology; cytoskeletal rearrangement of host epithelial cells involving TTSS Intimate effacing adherence mediated by intimin Destruction of microvilli and interference with host-cell signalling cascades	A/E lesions Acute diarrhoea
Enterohaemorrhagic <i>E. coli</i>	Large (60 MDa) plasmid encodes: enterohaemolysin (Ehx), LCT, EspP Chromosomal PAI (LEE)	A/E histopathology and intimate adherence similar to EPEC. Alternative adherence mechanisms (besides <i>eae</i>) known. TTSS aids pathogenesis, toxins (Stx/VT) inhibit protein synthesis of host cells and mediate different pathological effects	Bloody diarrhoea (haemorrhagic colitis) Haemolytic uraemic syndrome (HUS) TTP
Verocytotoxin-producing <i>E. coli</i>	Chromosomal (prophage) encoded Shiga toxins (Stx)/verocytotoxin (VT) VT1, VT2 and VT2v		

A/E, attaching and effacing; CFA, colonisation factor antigen; EAF, EPEC adherence factor; EAST, enteroaggregative heat-stable toxin; EPEC, enteropathogenic *E. coli*; Esp, *E. coli* secreted protein; LCT, large clostridial toxins; LEE, locus of enterocyte effacement; TTP, thrombotic thrombocytopenic purpura; TTSS, type III protein secretion system.

that they constitute a single species. This has been supported by a recent publication comparing the genome sequence of *Shigella flexneri* 2a with the genomes of *E. coli* K12 and O157 (Jin *et al.*, 2002).

Both *Shigella* and EIEC are responsible for bacillary dysentery, a disease that has had a major impact on society throughout history. Transmission is via the faecal–oral route, with contaminated food and water being the main sources of infection, but person-to-person transmission can also occur. The syndrome produced by EIEC infection can be indistinguishable from *Shigella* infection. In both cases the site

of infection is predominantly the colon. The most common symptom is watery diarrhoea which may precede dysenteric stools containing mucus and blood. In severe cases the bacteria may attack the colonic mucosa, invading epithelial cells, multiplying and causing ulceration of the bowel. In EIEC, genes necessary for invasiveness are carried on a 140-MDa plasmid (pINV). These genes encoding a range of invasion plasmid antigens (IpaA to IpaD) are necessary for strains to be fully pathogenic. Serotypes associated with the EIEC pathotype include O159:H2 and O143:H⁻.

Enterotoxigenic *E. coli*

Strains belonging to the ETEC pathotype are characterised by the production of at least one of two types of enterotoxin: LT (oligomeric heat-labile enterotoxin) and ST (monomeric heat-stable enterotoxin). The LT is classified into type I (LTI) and type II (LTII). LTI is a plasmid-encoded periplasmic protein resembling cholera toxin (CT) expressed by *Vibrio cholerae*, and LTII is chromosomally encoded but is similar to LTI both structurally and in its mode of action (Nair and Takeda, 1997). The pathway used by LT within the host cell is similar to that used by other AB₅ toxins including CT and Shiga toxin

(Stx)/verocytotoxin (Sandvig and Van Deurs, 2005; Lencer and Tsai, 2003). These pathways are described in Figure 28.1. In contrast, STs are peptides that stimulate guanylate cyclase in intestinal epithelial cells, resulting in intracellular accumulation of cyclic guanylate monophosphate (cGMP), leading to net fluid secretion and diarrhoea (Figure 28.1). They are classified into two distinct groups (STa and STb) or STI and STII (Nair and Takeda, 1997), and genes for ST are found on plasmids, although some have been found on transposons. Human infections are more commonly associated with STa, which is also found in *Yersinia enterocolitica* and *V. cholerae*, and it shares 50% protein identity with EAST-1 found in EAaggEC. Some strains of ETEC

Figure 28.1 Molecular pathogenesis of three *E. coli* toxins. (ST) Binding of the 18–19 amino acid peptide, heat-stable enterotoxin (ST), to an extracellular domain of membrane-spanning enzyme guanylate cyclase (GC-C) increases accumulation of cyclic GMP (cGMP) which activates G kinase. This leads to altered sodium and chloride transport via phosphorylation of membrane proteins, leading to net fluid secretion and diarrhoea. (LT) Analogous to cholera toxin, *E. coli* heat-labile toxin (LT) binds at the cell surface to a monosialoganglioside receptor (GM1) via its pentameric B subunit. The single A subunit comprises two functional domains: A1 peptide which exhibits the toxins ADP ribosyltransferase activity and A2 peptide which tethers A and B subunits together and contains the endoplasmic reticulum (ER) targeting motif K(R)DEL. Upon receptor binding the toxin–receptor complex enters the cell via endocytosis. It then carries retrogradely from the plasma membrane (PM) to the trans Golgi network (TGN), Golgi apparatus and the ER where proteolytic cleavage releases the B subunit from the two A subunits, which remain covalently linked via a disulphide bond. This bond is subsequently reduced, and the A1 peptide is released into the cytosol where this enzymatically active peptide translocates back to the PM where it catalyses the dissolution of NAD to nicotinamide and ADP ribose, thus enabling access to its substrate G_{sα} which undergoes toxin-induced ADP ribosylation. This results in the dissociation of the G_{sβγ} subunit from the G_{sα} subunit, which activates adenylate cyclase which catalyses the formation of cyclic AMP. Raised levels of cAMP elicit a Cl⁻ secretory response in intestinal crypt epithelial cells and water efflux in the gut. (VT) Most verocytotoxins (VT) bind to a globotriosyl ceramide (Gb₃) receptor via the pentameric B subunits of the toxin molecule. The toxin molecule can then be internalised by two distinct mechanisms depending on the cell type. The receptor–toxin complex is endocytosed, via clathrin-coated pits or by another endocytosis mechanism. Cleavage of the A1 and A2 subunits by furin can occur in endosomes, the TGN or in the Golgi. The toxin molecule is transported retrogradely to the Golgi apparatus and ER where ER-resident chaperons and enzymes may facilitate reduction of disulphide bonds between the A1 and A2 subunits. The destination of the B fragment and A2 subunit is not yet fully understood. The A1 subunit is transported into the cytosol where it facilitates the removal of an adenine at position 4324 in the 28S rRNA of the 60S ribosomal subunit, resulting in the inhibition of protein synthesis.

have been shown to carry enterotoxin genes formerly characterised in *Shigella* species, for example the ShET1 toxin gene which is described in more detail with other virulence determinants found in EAggEC.

Another characteristic feature of ETEC is their ability to adhere to the intestinal epithelium mediated by adhesive fimbriae, also called *colonisation factors* (CFs), *colonisation factor antigens* (CFAs), *coli surface antigens* (CSAs) or *putative colonisation factors* (PCFs) (Elsinghorst, 2002). Depending on their structure, CFAs can be classified as fimbrial (rigid, filamentous, rod-like structures) or fibrillar (thinner, more flexible) or nonfimbrial if they lack these structures. Like the toxins, the CFAs are also plasmid encoded and associations are reported to exist between the toxin type and CFA carried on a single plasmid. For example, ST has been associated with CFA-I and CFA-IV, and LT and ST together have been associated with CFA-II (Wolf, 1997). The CFs also confer host specificity on the strain because they require the presence of specific host receptors for colonisation to occur. Consequently, ETEC strains are often host specific.

In developing and tropical countries, ETEC are particularly prevalent. They are often associated with travellers' diarrhoea, and in developing countries, ETEC-mediated diarrhoea is primarily a disease of young children, but high prevalence also occurs among infants and older children. The onset is usually abrupt and characterised by watery diarrhoea, usually without blood or mucus, and vomiting is only present in few cases. Whilst ETEC diarrhoea may be mild and self-limiting, in severe cases, dehydration and electrolyte imbalance can become life-threatening.

Infections are acquired through consumption of contaminated food or drink. The organisms colonise the proximal small intestine with the aid of many CFAs. These include those belonging to CFA I group (rigid rod-like fimbriae), CFA-III (bundle-forming group) and CFA-II and CFA-IV (flexible fimbriae). Following colonisation of the intestinal mucosa, localised delivery of enterotoxins occurs, resulting in diarrhoea.

Enteroaggregative *E. coli*

In certain developing countries, EAggEC (or EAEC) are a major cause of chronic infantile diarrhoea and they have also emerged as a cause of diarrhoeal disease in adults and children in developed countries. Currently, EAggEC are defined as *E. coli* strains that do not secrete enterotoxins LT or ST and which adhere to HEp-2 cells in a distinct pattern termed aggregative adherence (AA). This is characterised by the layering of the bacteria in a stacked-brick configuration on the surface of the host cells, which is associated with the carriage of a 60-MDa plasmid (Baudry *et al.*, 1990).

Strains of EAggEC appear to express putative pathogenic determinants, which include aggregative adhesion fimbriae I (AAF/I) and AAF/II that are plasmid encoded, and which have been shown to mediate adhesion to HEp-2 cells by certain strains of EAggEC (Nataro, Steiner and Guerrant, 1998). Expression of AAF genes requires the transcriptional regulator AggR. DNA probes for AAF/I and AAF/II have enabled the screening of strains for these surface structures. It has been reported that only a minority of EAggEC strains carry the genes for AAF (Czeczulin *et al.*, 1997), whilst genes homologous to AggR are found in most of the strains (Nataro and Steiner, 2002), suggesting that other yet-undiscovered adhesins exist. Some strains of EAggEC are reported to express nonfimbrial surface-exposed proteins which mediate adhesion to HEp-2 cells by charge (Chart, Smith and Rowe, 1995), but again, only a proportion of EAggEC strains adhere by means of these surface proteins.

Toxins that have also been associated with strains of EAggEC include an *E. coli* heat-stable-like enterotoxin termed enteroaggregative heat-stable toxin-1 (EAST-1) and a heat-labile toxin termed plasmid-encoded toxin (Pet). However, in one small study the prevalence of Pet in EAggEC strains was reported to be low (Vila *et al.*, 2000). Furthermore, EAST-1 is not exclusive to EAggEC but is also found in other *E. coli*, notably ETEC, EPEC and EHEC strains, including O157:H7 and other VTEC (Nataro, Steiner and Guerrant,

1998), and has also been reported in DAEC (Vila *et al.*, 2000). However, EAST alone may not be sufficient to cause diarrhoea without the presence of other virulence determinants. One candidate for the regulation of virulence genes in EAggEC is AggR (Sheikh *et al.*, 2002). Many EAggEC strains elaborate the *Shigella* enterotoxin (ShET1), first identified in *Shigella flexneri* 2a strains, and ShET2 found in other *Shigella* strains. In *Shigella flexneri* 2a, ShET1 is encoded by the *set1* chromosomal gene, whereas ShET2 is encoded in the *sen* gene located on the invasion-associated (140 MDa) plasmid (Vargas *et al.*, 1999). The ShET1 toxin gene was reported in ETEC expressing ST and LT, in DAEC and in *E. coli* not belonging to any diarrhoeagenic category, although not all strains carrying the *set* genes expressed the toxin (Vila *et al.*, 2000). ShET1 production was reported to be common in diarrhoea patients, regardless of pathotype, whereas the ShET2 gene (*sen*) was found in EAEC, ETEC-ST and *E. coli*, not belonging to any diarrhoeagenic group.

Pathogenesis is thought to involve adherence to the intestinal mucosa and colonisation, probably facilitated by AAF/I and AAF/II. A functional class of colonisation factor in EAggEC termed dispersin could also aid colonisation by facilitating bacterial dispersal (Sheikh *et al.*, 2002). Colonisation is followed by enhanced mucus production which may promote persistent colonisation, followed by the release of toxins that results in damage to the host's epithelial cells. A flagellar protein in EAEC (FlhC-EAEC) has been shown to interact with epithelial cells, leading to IL-8 secretion (Steiner *et al.*, 2000). This protein shows amino acid sequence similarity to a flagellin found in *Shigella dysenteriae*, which, although phenotypically non-motile, have retained some flagellar operons; however, these are commonly non-functional in shigellae (Al Mamun, Tominaga and Enomoto, 1996). Flagella in EAggEC may therefore be responsible for inflammation and could play a role in pathogenesis alone or together with EAEC toxins.

Diffusely Adherent *E. coli*

This relatively recently described pathotype of *E. coli* is characterised by three features: ability to adhere to HEp-2 cells in a diffuse pattern (Nataro and Steiner, 2002), presence of the Afa/Dr family or adhesin involved in diffuse adherence (AIDA) adhesins (Peiffer *et al.*, 2000) and absence of virulence genes typical of other *E. coli* pathotypes. This diffusely adherent (DA) phenotype is believed to be mediated by fimbrial structures. This adhesion pattern is also exhibited by some EPEC strains. One surface fimbria (F1845) encoded via the *daaC* gene has been characterised (Bilge *et al.*, 1989), and this, together with other genetically related adhesins, may provide potential targets for detection and diagnosis of DAEC. Little is known about the clinical characteristics of DAEC, except that they are capable of causing watery diarrhoea without blood and that DAEC strains are able to induce finger-like projections extending from the surface of infected HEp-2 or Caco-2 cells. One recent report has provided evidence of a type III secretion system in DAEC with similar secreted protein (*esc*) genes to those found in EPEC and EHEC (Kyaw *et al.*, 2003). There is evidence that DAECs also produce the EAST toxin which is common in EPEC and EAggEC strains and that they can possess *set* genes which encode enterotoxins found in *Shigella* spp. (Vila *et al.*, 2000). Furthermore, *in vitro* studies show that Afa/Dr DAEC may have a marked proinflammatory effect on colonic epithelial cells, inducing secretion of IL-8 which promotes polymorphonuclear leukocyte (PMNL) migration across the epithelium (Bétis *et al.*, 2003).

Enteropathogenic *E. coli*

The EPECs, together with the closely related EHEC, are perhaps the most extensively studied group of pathogenic *E. coli*. The terminology and the assigned role of specific proteins and putative virulence determinants in EPEC and EHEC pathogenesis have changed. For recent reviews, see Donnenberg (2002) and Kenny (2002).

The first stage in EPEC pathogenesis is localised non-intimate attachment of the organism to the intestinal epithelium via the inducible bundle-forming pilus (BFP) encoded by the *bfp* operon on a 50–70-MDa plasmid, designated the EPEC adherence factor (EAF) plasmid. The BFP, a member of the type IV class of fimbriae produced by other pathogenic bacteria, facilitates interbacterial aggregation, leading to a characteristic local adherence (LA) pattern. EPEC strains not possessing the EAF plasmid are commonly termed atypical EPEC and appear to be closely related to Verocytotoxin-producing *E. coli* (VTEC). Whereas humans appear to be the only reservoir for 'typical EPEC', atypical EPECs have been isolated from both humans and animals.

Adherence of EPECs to the epithelial cells induces a variety of signal transduction pathways in the host cell, mediated by various bacterial proteins. One of the most important characteristics of EPEC is attaching and effacing (A/E) demonstrated histologically, characterised by the local effacement of the microvilli and intimate adherence between the bacterium and the host's epithelial cell membrane. This lesion is often characterised by the polymerisation of actin in the host cell, which results in a pedestal-like structure beneath the adherent bacteria (Knutton *et al.*, 1989). Although the EAF plasmid may be not essential for the formation of A/E lesions, its presence may enhance colonisation (Trabulsi, Keller and Gomes, 2002). A simple diagnostic assay for the A/E lesion and confirmatory test for EPEC is the fluorescence actin staining (FAS) technique (Shariff *et al.*, 1993).

Several genes implicated in A/E lesion formation are located on large (35.6kb) PAI termed the locus of enterocyte effacement (LEE) (McDaniel *et al.*, 1995). This chromosomal locus encodes four distinct elements involved in EPEC pathogenesis. Firstly, there is the type III protein secretion system (TTSS) which is capable of transporting proteins across the cytoplasmic and outer membrane of the bacterial pathogen and the membrane of the host cell where they interfere with host-cell signalling cascades.

Secondly, there are several secreted proteins, including many *E. coli* secreted proteins (Esp), which serve as substrates for the LEE-encoded TTSS. Thirdly, there is the adhesin intimin, a 94-kDa outer membrane protein encoded by the *E. coli* attaching and effacing (*eaeA*) gene in the LEE which is required for intimate adherence of EPEC to host cells at the site of A/E lesions. This protein shows sequence similarity to invasins found in *Yersinia* (Jerse *et al.*, 1990) and plays an important role in virulence and host-cell invasion, including activation of signal transduction pathways induced by products of the TTSS and subsequent pedestal formation (Phillips *et al.*, 2000). The fourth component, termed the translocated intimin receptor (Tir), is a bacterial protein that acts as the receptor for intimin. This too is translocated into the plasma membrane of the host cell via the bacterial TTSS (Kenny *et al.*, 1997).

Proteins reported to be essential for A/E lesion formation are themselves components of the extracellular translocation apparatus. These include EspA (25 kDa), EspB (38 kDa) and EspD (40 kDa). The EspA protein is a major component of a filamentous sheath-like structure, sometimes called a needle complex (NC) or EspA filament which is a characteristic feature of TTSS (Büttner and Bonas, 2002). This NC connects the bacteria to the host cells to form a pore or translocon through which other LEE-encoded effector proteins are secreted. These translocated effector proteins which include Tir, EspF, EspG and MAP (mitochondria-associated protein) perform specific functions or attack specific targets after introduction into and sub-localisation in the host cell. The translocation apparatus protein EspB (formerly called EaeB) may also serve as an effector protein. Besides these proteins there are also many chaperone proteins encoded by the *ces* genes of the LEE. These interact specifically with certain effector or translocator proteins of the TTSS (Crawford, Blank and Kaper, 2002). Although their exact function is not fully understood, they are believed to play a role in providing stability to the secreted cognate protein or participate in the regulation of the transcription of type III substrates (Feldman and Cornelis, 2003).

Besides the *bfp* operon, the BFP plasmid also encodes other genes involved in the regulation of the LEE. These include the plasmid-encoded regulator (Per) transcriptional activator (Gómez-Duarte and

Kaper, 1995) which activates transcription of the chromosomal regulator protein LEE-encoded regulator (*ler*). This in turn upregulates the transcription of other LEE genes including *EspA*, *EspB* and *EspD* (Mellies *et al.*, 1999) and increases the expression of chromosomal *eae*. *ler* has been shown to be essential for the formation of A/E lesions in EPEC and EHEC O157:H7, since all the genes known to be important for A/E lesion formation are regulated by *ler*, as well as potentially activating other genes or even the entire LEE (Elliott *et al.*, 2000).

Although there are similarities, it is now known that there are important differences between the regulatory proteins involved in pedestal formation by EPEC and EHEC O157:H7 (Campellone and Leong, 2003). Whereas both EPEC and EHEC Tir bind intimin and focus cytoskeletal rearrangement of the host cell, there are also other regulatory proteins with as-yet-undefined roles in pedestal formation that are present in EPEC but absent from EHEC (Campellone and Leong, 2003). Besides the virulence determinant already described, EPEC strains may also possess genes for the production of EAST-1 and cytolethal distending toxin (CDT), although the role of these toxins in diarrhoeal disease remains unclear and not all EPECs encode these toxins (Blank, Nougayrède and Donnenberg, 2002).

Enterohaemorrhagic and other Verocytotoxin-Producing *E. coli*

EHECs have emerged as one of the most important threats to human health (Kaper, Nataro and Mobley, 2004). Strains belonging to serotype O157:H7 are now regarded as model EHEC based on their phylogenetic profiles and histopathology. Since it was first identified in 1983 (Riley *et al.*, 1983) as the cause of two outbreaks of gastroenteritis in the United States, the previously 'rare serotype' *E. coli* O157:H7 has become responsible for an increasing number of large food- and waterborne outbreaks of haemorrhagic colitis throughout the world including the United States, Canada, United Kingdom and Japan (Kaper and O'Brien, 1998).

The term EHEC was originally used to describe strains causing distinct clinical manifestations such as haemorrhagic colitis (HC) and haemolytic uraemic syndrome (HUS) in humans. EHECs are characterised by the production of a distinct group of prophage-encoded toxins, their ability to cause A/E lesions on epithelial cells using mechanisms similar to those found in EPEC and the possession of a 60-MDa plasmid carrying other virulence determinants that may contribute to pathogenesis. Besides O157:H7 and O157:H⁻, *E. coli* strains traditionally belonging to common EPEC serogroups, e.g. O111 and O26 strains, which have acquired the genes and ability to produce these toxins now also belong to the EHEC group. Genetically, it has been proposed that *E. coli* O157:H7 originally evolved in a step-wise manner from an ancestral strain of EPEC O55:H7 (Feng *et al.*, 1998). The close relationship between O157:H7 and O55:H7 is supported by numerous studies showing genetic similarities between these serotypes (Perna *et al.*, 1998; Shaikh and Tarr, 2003), including evidence that the H7 *fliC* genes of O55:H7 and O157:H7 are almost identical (Reid, Selander and Whittam, 1998). However, *E. coli* O157:H7 and O157:H⁻ strains appear to belong to a unique clonal lineage with various phenotypic characteristics that distinguish these strains from other *E. coli*. These include the lack of β -glucuronidase (GUD) activity and the inability of most strains to ferment sorbitol in 24h, which have been used as diagnostic features to aid methods for their detection and isolation.

Carriage of the toxin genes is, however, evident in over 200 serotypes of *E. coli*, some of which do not possess the additional virulence genes found in EHEC and have not yet been associated with human infection. Other serotypes have been responsible for sporadic cases of infection and outbreaks (Goldwater and Bettelheim, 1994; Johnson *et al.*, 1996). Therefore, EHECs can be regarded as a subgroup of a larger group of toxin-producing *E. coli* which are collectively termed VTEC or Stx-producing *E. coli* (STEC). These bacteria are present in the intestinal tract of a wide range of domestic and wild animals, but farm animals, particularly cattle and sheep, are major reservoirs of these pathogens (Chapman *et al.*, 1993; Blanco *et al.*, 2001). They have also been isolated

from a range of non-ruminant animals, including birds, horses, dogs and cats (Beutin, 1999; Wasteson, 2001). Persistent carriage and host associations between particular serotypes and certain animals exist, but others appear to be carried transiently. VTEC infections have been linked to a diverse range of food types, although many are linked directly or indirectly to animal reservoirs, e.g. undercooked beef, unpasteurised milk and cheese. Infection can also occur via contaminated water, contact with animals and their faeces and secondary person-to-person transmission.

The ability of some *E. coli* strains to produce this range of toxins with potent cytotoxicity against Vero cells was first described in 1977 (Konowalchuk, Spiers and Stavic, 1977). These toxins, termed Verotoxins or Verocytotoxins (VT), were later shown to be structurally and functionally similar to the Stx produced by *S. dysenteriae* 1 (O'Brien and Holmes, 1987). Consequently, they are now commonly called Stx. Two major antigenically distinct forms of toxin, termed VT1 (Stx1) and VT2 (Stx2), are produced by VTEC, and strains may carry genes (*vtx/stx*) for the production of either VT1 or VT2 alone or both together.

Both toxins consist of an enzymatically active A subunit (32 kDa) and a pentameric B subunit (7.7 kDa monomers). The B subunits form a ring which mediates binding to a neutral glycolipid receptor. Most of the VT types recognise and bind to globotriaosylceramide (Gb₃) receptors (Lingwood, 1996). These receptors are found in many different eukaryotic cells but are particularly abundant in the cortex of the human kidney. The exception to this is the VT2 variant toxin VT2e that preferentially binds to globotetraosylceramide (Gb₄). Structurally, VT1 is identical to Stx from *S. dysenteriae* type 1, differing by only a single amino acid in the A polypeptide (Strockbine *et al.*, 1988).

The VT2 group shows substantial sequence heterogeneity, especially in the B subunit where amino acid exchanges give rise to many VT2 variant forms. These include VT2c and VT2d, which are produced by VTEC from both animals and humans (Piérard *et al.*, 1998; Ramachandran *et al.*, 2001; Eklund, Leino and Siitonen, 2002), VT2e, which is found in VTEC commonly associated with oedema disease in pigs (Wasteson, 2001), and VT2f, which is associated with VTEC isolated from pigeons (Morabito *et al.*, 2001). In contrast, the VT1 family appears homogeneous, although variant forms of the *vtx1* gene have been recently reported (Zhang *et al.*, 2002; Bürk *et al.*, 2003). Furthermore, expression of *vtx1* is also increased under iron-restricted conditions, by as much as a fivefold increase in VT1 production (Wagner *et al.*, 2002). Under these conditions, toxin expression but not lysis is stimulated, resulting in the accumulation of intracellular and not extracellular VT1.

Despite detecting antibodies against VT in the serum of patients with HUS, the route taken by VT from the intestine to the kidneys or other target organs remained unknown for some time. Recent studies report that VT is possibly transported in the blood by PMNLs, which have been shown to bind both VT1 and VT2 (te Loo *et al.*, 2001). The pathway used by these toxins, by which they exert their action, is similar to that used by the plant toxin ricin and is shown in Figure 28.1. Although the A subunit appears to be the active component, the B pentamer may also induce apoptosis in certain cell lines independently of A subunit activity (Marcato, Mulvey and Armstrong, 2002).

The effects of VTs on intestinal epithelium cells are not completely understood, but animal models of VTEC infection suggest that, in the gut, VT may participate in both immune activation and induction of apoptosis as well as causing proinflammatory responses by host cells, stimulating the influx of acute inflammatory cells, contributing to intestinal tissue damage (Thorpe *et al.*, 2001). Localised production of the host proinflammatory cytokines, TNF- α and IL-1, may also exacerbate toxin-mediated vascular damage (Tesh, Ramegowda and Samuel, 1994).

Although VT2e is thought to be chromosomally encoded, the *vtx* (*stx*) genes of VTEC are encoded by prophages of the lambda (λ) family. As well as facilitating horizontal transfer of toxin and other virulence-associated genes in *E. coli*, the phage cycle and phage induction play a central role in regulating the expression and production of VT. Toxin production has been linked to prophage induction associated with the activity of RecA protease which is part of the bacterial SOS DNA repair system (Schmidt, 2001). Induction of prophage can occur spontaneously upon exposure to certain agents that damage DNA.

These can include ultraviolet (UV) irradiation, mitomycin C and certain fluoroquinolone antibiotics that can induce both the SOS response and high levels of phage induction with subsequent increased production of VT (Kimmitt, Harwood and Barer, 2000; Teel *et al.*, 2002).

VTECs are responsible for a range of clinical conditions and syndromes in humans. An important feature of VTEC infections, particularly those by *E. coli* O157:H7, is the low infectious dose, which is reported to be as low as less than 100 cells (Willshaw *et al.*, 1994). Besides outbreaks and sporadic infection, asymptomatic carriage is another important feature of these organisms that probably contributes to secondary spread of infection. The incubation period is typically 1–14 days, with diarrhoea being the most common clinical feature. This can be mild, non-bloody or bloody diarrhoea accompanied by severe abdominal cramps. Vomiting may occur in 50% of patients, but fever is uncommon. The presence of visible blood in the stool is one feature strongly associated with *E. coli* O157:H7 infections (Slutsker *et al.*, 1997). The quantity of blood in the faeces may be as little as a few streaks, but the condition can progress to HC, which is characterised by bloody diarrhoea in which the stool is almost entirely comprised of blood. This severe condition can be life threatening, especially in patients at the extremes of age.

In its severest form, infection can progress to diseases such as HUS, a cause of acute renal failure in children, characterised by a triad of microangiopathic haemolytic anaemia, thrombocytopenia and acute renal impairment. Approximately 90% of HUS cases are reported to be VTEC associated (Rose and Chant, 1998). Also involving features characteristic of HUS, but with the additional involvement of the central nervous system and neurological problems, is thrombotic thrombocytopenic purpura (TTP) which, although rare, is more common in adults, especially the elderly. Complete HUS/TTP is commonly established 6 days after the onset of the gastrointestinal symptoms. The mortality rate is often higher in infants and the elderly where infection may lead to clinical complications, and mortality rates as high as 35% have been reported (Carter *et al.*, 1987). The number of cases of VTEC infection developing into HUS depends on the age of the patient and is often dependent on the serotype and toxin type expressed by the infecting organism. Significant risk factors for HUS include age less than 15 years or greater than 65 years (Dundas *et al.*, 2001). Severity of infection in humans, particularly the likelihood of HUS and bloody diarrhoea, has been linked to the carriage of *vtx2* (Eklund, Leino and Siitonen, 2002). Epidemiological evidence from human infections also implicates VT2 as a significant predictive risk factor for HUS. In the longer term, whilst many patients infected with VTEC recover, 15–40% of survivors have renal sequelae (Fitzpatrick, 1999). Production of VT1 is commonly associated with strains found in animals and milder forms of infection.

Besides VT, strains of EHEC and other VTEC carry a varied repertoire of additional putative virulence determinants (Law, 2000) that may or may not play a direct role in pathogenicity. Some genes, e.g. the LEE, have been fully characterised and extensively studied in EPEC as well as VTEC, while the role of others remains unclear. Functional and regulatory differences exist between the LEE of EPEC and EHEC, although the LEE of *E. coli* O157 and other VTEC have the same distinct regions and genes found in EPEC. A strong association between severe human disease, particularly HC and HUS, and the capacity of VTEC to produce intimin-mediated A/E lesions has been reported. However, HUS has occurred in patients infected by *eaeA*-negative VTEC (Paton and Paton, 1998). Other adhesins and attachment mechanisms facilitating cellular attachment besides intimin have been reported (Paton and Paton, 2002; Jenkins *et al.*, 2003), but their role in colonisation and pathogenesis has yet to be fully elucidated.

Most *E. coli* O157:H7 and other EHEC strains possess a large (60 MDa) plasmid (pO157) encoding many putative virulence genes and several IS elements (Burland *et al.*, 1998). Among these is an EHEC-specific plasmid-encoded haemolysin termed enterohaemolysin (Ehx), which is genetically related to α -haemolysin except that it does not show activity against lymphocytes (Bauer and Welch, 1996). Although there is good association (89%) between VT and Ehx production (Beutin *et al.*, 1989), the precise role of Ehx in disease is not fully

understood. Several other haemolysins (cytolysins) have been described for *E. coli* from different pathotypes, of which the chromosomally encoded α -haemolysin is probably the best characterised (Beutin, 1991). Also on pO157 are many putative virulence factors, including EHEC catalase peroxidase, sequences with similarity to a family of toxins termed large clostridial toxins (LCT) and an extracellular serine protease (EspP). The latter may contribute to the mucosal haemorrhage in patients with EHEC-associated HC (Karch, Schmidt and Brunder, 1998). DNA sequences homologous to the gene encoding EAST-1 (*astA*) found in EAggEC are also found in the chromosome in many EHEC strains, including O157:H7 as well as other VTEC (Kaper *et al.*, 1998).

LABORATORY METHODS FOR ISOLATION AND DETECTION OF PATHOGENIC *E. COLI*

Whilst most strains of *E. coli* grow well on a range of microbiological culture media, the growth and isolation of some pathogenic strains requires specific methodology. Strains of pathogenic *E. coli* can be phenotypically identical to commensal *E. coli* strains, whereas others may give rise to atypical reactions with particular biochemical tests which aid the identification of *E. coli*. Rapid lactose fermentation remains a key diagnostic feature of media used for the initial isolation or subsequent confirmation of *E. coli*. MacConkey agar and *E. coli* broth are widely used for the initial isolation and confirmation of suspect *E. coli*, respectively. Strains of *E. coli* are commonly distinguished from other faecal coliforms by their ability to grow and produce gas from lactose at 44 °C and indole production from tryptophan. However, these two tests are not always exclusive to *E. coli* as other bacteria, e.g. *Klebsiella*, can give rise to false-positive results. Furthermore, strains of EIEC often ferment lactose slowly or not at all, which together with the absence of indole production and synthesis of lysine decarboxylase, can mean that they are not recognised as *E. coli*.

The presumptive identification of *E. coli* has been improved by the introduction of chromogenic media that provide better diagnostic characteristics mediated by specific enzyme activity which yields colonies of a distinct colour. Most chromogenic substrates used in *E. coli* specific media rely upon the activity of GUD which is prevalent in approximately 95% of *E. coli* strains. A notable exception, however, is *E. coli* O157:H7, which is largely GUD negative. Another common enzyme exploited in chromogenic media is β -D-galactosidase which is responsible for lactose fermentation and common in coliform bacteria, including *E. coli*. Some media contain individual chromogenic substrates to enable specific identification of the target organism, whereas others contain more than one substrate, which enables a differential count or presumptive identification to be made. Fluorogenic substrates that follow the same principle are also available, although they are now less popular because of the requirement to observe plates under long-wave UV light and the problems caused by diffusion of fluorescence through the medium.

Lactose fermentation remains a useful diagnostic feature of media for the isolation of urinary pathogens, including *E. coli*. A good example of such a medium is cysteine lactose electrolyte-deficient (CLED) agar which is used for routine diagnostic urinary bacteriology. This medium is recommended because it is reported that 1.5% of *E. coli* isolated from urine require cysteine and that subsequent broths used for their identification will require cysteine supplementation (McIver and Tapsall, 1990). The non-selective medium CLED supports the growth of a wide range of urinary pathogens whilst preventing swarming of *Proteus* spp. Lactose-fermenting organisms, including *E. coli*, lower the pH of the medium, which turns from green to yellow. The development of chromogenic media combining the basal CLED medium with various chromogenic substrates has the potential to improve presumptive identification of urinary isolates (Fallon *et al.*, 2003).

The correlation between specific O and H antigens with different pathotypes of *E. coli* has led to serotyping being used for identification purposes. Whilst this remains useful for certain pathotypes associated with infection, especially those that comprise limited serotypes

and strains belonging to distinct clonal lineages, this becomes less reliable when the pathogenicity-associated genes are located on mobile genetic elements. Consequently, there is no longer a clear distinction between certain pathotypes of *E. coli* based on serotyping. Detection of specific antigens or toxins associated with a particular *E. coli* pathotype using appropriate immunological methods such as ELISA can improve detection and identification of these strains. This approach has been used to confirm ETEC colonies using a GM1 ganglioside ELISA to detect LT and ST, which compared favourably against a gene probe (Sommerfelt *et al.*, 1988). Numerous commercial assays are available for the detection of the somatic O antigen of *E. coli* O157 and also for the detection of VT from culture supernatants or directly from sample enrichments, thus enabling detection of all VTEC in clinical samples and foods (Bettelheim and Beutin, 2003).

Although phenotypic tests remain useful for the presumptive identification of pathogenic *E. coli*, the introduction of rapid molecular-based technologies has revolutionised clinical diagnosis. Detection and confirmation of specific DNA sequences associated with known pathogenicity-associated genes or conserved regions unique to a particular pathotype can be used to aid confirmation of the presence or identity of these bacteria. DNA probes and techniques such as polymerase chain reaction (PCR) can be applied directly to clinical samples and foods. Alternatively, PCR can be applied directly to suspect colonies to confirm the presence of specific gene sequences. For the detection of ETEC, this has included using non-radioactively labelled oligonucleotide DNA probes and PCR targeted against the genes encoding LT and ST (Yavzori *et al.*, 1998) and EAST-1 (Yamamoto and Echeverria, 1996). Popular targets for probe and PCR-based detection of EPEC strains include the EAF plasmid (Franke *et al.*, 1994) and the gene encoding BFP (*bfpA*) (Gunzburg, Tornieporth and Riley, 1995). Demonstrating AA pattern in the HEp-2 assay is used to confirm the presence of EAggEC, but this has been improved by the development of an EAggEC-specific probe (Baudry *et al.*, 1990). Detection of EAggEC and DAEC strains has been improved by using PCR primers targeted against various plasmid and chromosomally encoded genes associated with adherence and colonisation.

Detection of EHEC strains, particularly *E. coli* O157:H7, has received much attention recently owing to the risks posed by these bacteria and the severity of the infection they cause. Unlike typical *E. coli*, including other VTEC strains, most O157:H7 strains share the inability to ferment sorbitol in 24 h, which is exploited in selective plating media, the most commonly used medium being sorbitol MacConkey agar (SMAC). Since it was described for the differentiation of *E. coli* O157:H7 from other *E. coli* in clinical samples (March and Ratnam, 1986), SMAC and modified versions of this medium have been universally adopted as the medium of choice for the isolation of *E. coli* O157. A limitation of relying solely on the lack of sorbitol fermentation for the isolation of *E. coli* O157 is the existence of sorbitol-fermenting (SF) strains (Fratamico, Buchanan and Cooke, 1993) and O157 strains that display both SF and GUD activity (Gunzer *et al.*, 1992). Alternatives to SMAC for O157 isolation include chromogenic media (Restaino *et al.*, 1999), including some that allow isolation and recognition of other VTEC (Bettelheim, 1998) and blood agar containing washed sheep red cells, which allows recognition of Ehx production (Beutin *et al.*, 1989).

Detection of nucleotide sequences related to the toxin (*stx/vtx*) genes including *vtx2* variants using the PCR technique has become a popular method for detecting VTEC in foods and clinical samples (Lin *et al.*, 1993). DNA probes have also been developed for the confirmation of suspect isolates (Samadpour, Ongerth and Liston, 1994). Alternative targets for DNA probes and PCR include the haemolysin (*hlyA*) gene (Lehmacher *et al.*, 1998), the *E. coli* attaching and effacing (*eae*) gene (Louie *et al.*, 1994), the GUD (*uidA*) gene (Feng, 1993), the 60-MDa plasmid found in O157:H7 and other VTEC (Levine *et al.*, 1987) and the O157 *fliC* (flagellin) gene (Gannon *et al.*, 1997).

Multiplex PCR has been used to simultaneously detect EHEC, EPEC and ETEC in faecal samples from patients with watery diarrhoea, HC and HUS using primers targeted against *eae*, *bfp*, *stx1*, *stx2*, *lt* and *st* (Vidal *et al.*, 2004).

ANTIBIOTIC RESISTANCE

Most *E. coli* are sensitive to antimicrobial agents active against Gram-negative bacteria, although resistance among enteric bacteria, including *E. coli*, has increased markedly over the past 50 years since of the widespread use of antibiotics (Houndt and Ochman, 2000).

Multiple antibiotic resistance can be acquired via plasmids or drug efflux systems. The chromosomal multiple antibiotic resistance locus in *E. coli*, designated *marA*, influences the expression of the *acrAB* efflux pump and other chromosomal genes, resulting in resistance to a range of antibiotics including tetracycline and many unrelated antibiotics including chloramphenicol, β -lactams and nalidixic acid (George and Levy, 1983). Susceptibility of *E. coli* strains to amoxicillin has decreased over recent years owing to the presence of TEM-1 and TEM-2 β -lactamase. The effectiveness of cotrimoxazole and trimethoprim has been reduced by frequent carriage on plasmids and integrons of *dhfr* resistance genes (Yu *et al.*, 2003). Because resistance is high, a fluoroquinolone or nitrofurantoin should be considered for empirical treatment. One study of *E. coli* urinary isolates from females in the United States from 1995 to 2001 revealed resistance rates to be constant for ampicillin (36–37%) and co-trimoxazole (15–17%), with increasing resistance to ciprofloxacin (0.7–2.5%) and low resistance to nitrofurantoin (0.4–0.8%) (Karlowsky *et al.*, 2002), which together with fosfomycin-trometamol remain highly active against urinary Enterobacteriaceae with over 90% of *E. coli* reported to be susceptible (Chomarat, 2000). One prospective study has identified prior UTI as a common risk factor for resistance to different antibiotics use to treat UTI (Sotto *et al.*, 2001).

In a study of the incidence of antibiotic resistance in *E. coli* isolates from blood and CSF between 1991 and 1996 in England and Wales, a significant increase in the incidence of strains resistant to ampicillin and ciprofloxacin was reported (Threlfall *et al.*, 1998). Between 1990 and 1999, ciprofloxacin resistance in *E. coli* from bacteraemias rose from 0.8% to 3.7% in England and Wales (Livermore *et al.*, 2002). Fluoroquinolone resistance is normally acquired by a single mutation in *gyrA*, with high-level resistance probably the result of a second mutation in *gyrA* and *parC*, but mutations in other genes may play a role (Kern *et al.*, 2000). Resistance to β -lactam antibiotics is most frequently due to the production of β -lactamases with some variants able to inactivate the newer cephalosporins. These variants, termed extended-spectrum β -lactamases (ESBL), are predominantly plasmid mediated and arose through single mutations in the progenitor enzymes TEM-1,2 and SHV-1 (Gniadkowski, 2001). Recently, a chromosomal β -lactamase (CTX-M) from *Kluyvera* spp. has become mobilised onto plasmids. Some variants are particularly common in *E. coli* both in the United Kingdom (Woodford *et al.*, 2004) and elsewhere (Munday *et al.*, 2004). Strains of EHEC O157 have developed resistance to antibiotics (Meng *et al.*, 1998), but their use in the treatment of EHEC infections remains controversial. The spread of ESBLs, together with the emergence of broad-spectrum resistance among *E. coli* populations, will pose a significant clinical problem in the future.

MANAGEMENT OF *E. COLI* INFECTION

Most infections caused by *E. coli* respond to treatment with appropriate antibiotics, although higher mortality rates are associated with septicæmia, especially in immunocompromised and elderly patients. In cases of UTI, antibiotic treatment must often be started before antimicrobial susceptibilities are known, and if CTX-M ESBL-producing strains are common, a carbapenem is the preferred choice. Antimicrobial susceptibility testing is important both to confirm whether the correct empirical choice has been made and to detect resistance. As *E. coli* is generally spread via the faecal–oral route, IPEC infections can be prevented by good hygiene and the provision of clean water and good food handling practices, especially avoiding

cross-contamination from raw to cooked foods and ensuring adequate cooking and proper storage of foods. This also applies to hospitals where handwashing by nursing staff and environmental cleaning are important in controlling outbreaks.

In cases of VTEC infection, early recognition of the disease and appropriate clinical management of the patient are critical. Patients with acute gastroenteritis should receive supportive measures that ensure maintenance of fluid and electrolyte balance. Antimotility and antidiarrhoeal agents may be inappropriate as these may lead to the progression of the disease to HUS/TTP along with the use of certain antibiotics (Todd, Duncan and Coia, 2001). Previous reports have warned that antibiotic treatment of children with *E. coli* O157:H7 infection increases the risk of HUS (Wong *et al.*, 2000). This observation conflicts with the findings of a retrospective study of the 1996 Sakai City outbreak which reported that early use of fosfomycin reduced the risk of HUS in children (Takeda *et al.*, 1998). However, *in vitro* evidence suggests that treatment with four quinolones increases the risk of toxin release (Kimmitt, Harwood and Barer, 1999) and that certain fluoroquinolone antibiotics such as ciprofloxacin induce VT prophages and enhance toxin production by VTEC (Zhang *et al.*, 2000). Patients who develop HUS are commonly treated by dialysis, and in extreme cases renal transplantation may be necessary. Current clinical management relies on maintenance of the patient and supportive care. Various novel approaches, including vaccines and other experimental therapies, have been developed and are undergoing evaluation in clinical trials (Kaper and O'Brien, 1998), although currently no alternative approaches have been routinely adopted for the treatment of VTEC infections.

SHIGELLA

INTRODUCTION

The disease caused by *Shigella* spp., dysentery, was recognised by Hippocrates as a condition characterised by the frequent passage of stools containing blood and mucus. He also recognised some aspects of the epidemiology, noting that after a dry winter and a wet spring the number of cases became more frequent in the summer. It was not until 1875 when the cause of amoebic dysentery was discovered and later when Shiga isolated the organism that was later known as *Shigella dysenteriae* that the two dysenteric illnesses could be clearly differentiated.

Dysentery has always played an important part in human history, influencing the course of military campaigns. Although the mortality rate among soldiers with bacillary dysentery was approximately 2.5%, the high attack rate meant that as many men died of this cause as the effects of battle. At crucial times, many soldiers were infected and incapable of performing military duties. When people are herded together in gaols or on ships, epidemic dysentery may sweep through the population with devastating effect. Dysenteric disease remains an ever-present danger in the refugee camps of modern times.

The first of the genus to be identified was *S. dysenteriae*, which for many years was known as Shiga's bacillus (Shiga, 1898). *Shigella flexneri* was originally described by Flexner in 1900 (Flexner, 1990). *Shigella sonnei* was first isolated in 1904, but it was not until 1915 that its pathogenic potential was recognised by Sonne (Sonne, 1915).

DESCRIPTION OF THE ORGANISM

Shigellae are small Gram-negative rods, non- or late lactose fermenters, fermenting sugars without gas production. Although non-motile using conventional tests, recent studies have shown the presence of flagellar genes and expression of a motile phenotype under certain conditions (Giron, 1995). For details of the biochemical features of *Shigella* spp., see Table 28.3.

Shigellae do not survive as well as salmonellas in clinical specimens and so should be plated onto isolation medium as quickly as possible. Some selective media, deoxycholate citrate agar (DCA) or Wilson and Blair designed for the isolation of Salmonella, can be too inhibitory for Shigella; thus, it is useful to use a non-inhibitory medium such as MacConkey, *Salmonella-Shigella* (SS) or xylose-lysine-deoxycholate (XLD) in parallel (see below).

CLASSIFICATION

The genus *Shigella* is part of the Enterobacteriaceae, which have been classified together on the basis of the disease they cause. The shigellae have been shown to be closely related to *E. coli* by DNA hybridisation, isoenzyme analysis and the presence of Shiga-like toxin (Brenner *et al.*, 1969; Crosa *et al.*, 1973; Goulet, 1980). Recently, the full genome of *Shigella flexneri* 2a was sequenced and comparisons with *E. coli* K12 showed that *Shigella* were phylogenetically indistinguishable from *E. coli* (Jin *et al.*, 2002; Wei *et al.*, 2003). It has been suggested that *Shigella* spp. should be reclassified and new nomenclature introduced to clarify the relationship between these two species (Lan and Reeves, 2002). They are most closely related to the EIEC, which also are capable of producing a dysenteric illness.

The genus *Shigella* contains four species: *S. dysenteriae*, *S. flexneri*, *Shigella boydii* and *S. sonnei*. The species are differentiated on the basis of simple biochemical tests and serology of their LPSs: *S. dysenteriae* are non-mannitol fermenters and their O-polysaccharide LPS is unrelated antigenically to the other shigellas. *Shigella flexneri* and *S. boydii* ferment mannitol, but the latter are antigenically distinct from *S. flexneri*. All *S. flexneri* O-specific polysaccharides of the LPS antigens have a common rhamnose-containing tetrasaccharide (Robbins, Chu and Schneerson, 1992). Included among the *S. boydii* are variants, some of which are capable of producing gas from glucose. *Shigella sonnei* differs from the other members of the genus in that it is a late lactose fermenter, which can be detected with ONPG, unlike other members of the genus which are non-lactase fermenting (Tabe 28.3). The O-side chain is composed of a repeating disaccharide containing an unusual monosaccharide altruronic acid (Robbins, Chu and Schneerson, 1992). This antigen is identical to that of *Plesiomonas shigelloides* 017 which make up most human isolates (see Chapter 16) and is the source of the cross-reactions between these two species.

The O-polysaccharide of the LPS is used to divide the species into serotypes as follows: *S. dysenteriae* into 12 serotypes, *S. flexneri* into 13, *S. boydii* into 18 and a single serotype of *S. sonnei*.

PATHOGENESIS

Shigella spp. are largely limited to mucosal infection of the distal ileum and colon; intestinal perforation, although rare, has been reported (Azad, Islam and Butler, 1986); toxic megacolon may occur

in up to 3% of patients in developing countries (Bennish, 1991). Bacteraemia is the most important lethal complication (Struelens *et al.*, 1990); meningitis and pneumonia due to general spread are rare (Bennish, 1991). Seizures are common especially with *S. dysenteriae* infection, and these resemble febrile seizures, although they occur in children over 5 years old (Rawashdeh, Ababneh and Shurman, 1994; Thapa *et al.*, 1995).

To establish an infection, *Shigella* must invade the enteric epithelium via the basolateral epithelial surface. The organisms gain access to the basolateral side via M-cells, the specialised antigen-presenting cells of the lymphoid follicles (Wassef, Keren and Mailloux, 1989; Perdomo *et al.*, 1994). Subsequent killing of macrophages in the submucosa leads to the release of cytokines (Zychlinsky, Prevost and Sansonetti, 1992; Zychlinsky *et al.*, 1994), which attracts many PMNLs. A path for *Shigella* invasion is opened via the tight junctions which are broken down by the PMNLs (Perdomo, Gounon and Sansonetti, 1994) (Figure 12b.1). Recent research has shown that *S. flexneri* can also invade the colonic epithelial layer by manipulation of the epithelial cell tight junction proteins in an M-cell/PMN-independent manner (Sakaguchi *et al.*, 2002).

Once inside the submucosa, *S. flexneri* makes contact with the basolateral membrane of the epithelial cells (Tran Van Nhieu *et al.*, 1999). Shigellae have a virulence plasmid that encodes two loci required for invasion: the *ipa* locus and the *mxi-spa* locus (Jennison and Verma, 2004). The *ipa* operon encodes the invasion plasmid antigens IpaA, IpaB, IpaC and IpaD, whereas the *mxi-spa* operon encodes the components of a type III secretion system that delivers the Ipa proteins from the bacterial cytoplasm to the cytoplasmic membrane or cytosol of the host cell (Menard, Sansonetti and Parsot, 1993; Menard *et al.*, 1994). Bacterial proteins are secreted into the epithelial cell's cytoplasm through a pore formed by IpaB and IpaC (Blocker *et al.*, 1999; Harrington *et al.*, 2003). IpaC and IpgD polymerise actin within the host cell and create cell-surface extensions which form around the bacterium, inducing the epithelial cell to take up *S. flexneri* into a vacuole (Bourdet-Sicard *et al.*, 1999; Tran Van Nhieu *et al.*, 1999; Niebuhr *et al.*, 2002). IpaB, and possibly IpaC, lyses the vacuole, releasing the bacteria into the epithelial cytoplasm, where they replicate (High *et al.*, 1992; De Geyter *et al.*, 1997). The epithelial cells lyse, probably because of the host inflammatory response to the replicating bacteria (Jennison and Verma, 2004).

Shigella exploits the host-cell actin via the outer membrane protein, IcsA, to move through the host-cell cytoplasm and into adjacent epithelial cells (Bernardini *et al.*, 1989; Purdy, Hong and Payne, 2002). It does this by creating a polymerisation actin tail behind the bacterium, by expressing IcsA on one pole of the bacterium, and propelling *S. flexneri* through the cytoplasm until it contacts the cytoplasmic membrane. The force of the contact creates a protrusion into the neighbouring epithelial cell. Both membranes are lysed, thus releasing *S. flexneri* into the neighbouring epithelial cell (Jennison and Verma, 2004).

Shigella dysenteriae type 1 produces a potent exotoxin (Stx) which enhances local vascular damage. It is structurally closely related to the Shiga-like toxins of *E. coli*. It produces fluid accumulation in the rabbit ileal loop model but does not appear to be necessary for intracellular killing of mucosal epithelial cells. Systemic distribution of the toxin results in microangiopathic renal damage with subsequent development of the HUS (Obrig *et al.*, 1988). The Stx is a bipartite molecule with an enzymatic A subunit activated by proteolytic cleavage and a multimeric receptor-binding B subunit (O'Brien *et al.*, 1992). The binding subunits, like CT, bind to a host-cell-surface glycolipid, in this case Gb₃, which possesses a Gala-1,4-Gal as the carbohydrate moiety. Stx exerts its lethal effect by inhibiting the host-cell 60S ribosomal subunit by cleaving a specific adenosine residue of the 28S rRNA. Recent studies have shown that Stx can cause apoptosis in certain cell types (Cherla, Lee and Tesh, 2003).

Table 28.3 Typical biochemical reactions of *Shigella* spp. and *E. coli*

	Indole	LDC	ODC	Motility	Glucose with gas	ONPG	D-Mannitol
<i>S. sonnei</i>	–	–	+	–	–	+	+
<i>S. dysenteriae</i>	– ^a	–	–	–	–	–	–
<i>S. boydii</i>	–	–	–	–	–	–	+
<i>S. flexneri</i>	–	–	–	–	–	–	+
<i>E. coli</i>	+	+	+	+	+	+	+

LDC, lysine decarboxylase; ODC, ornithine decarboxylase; ONPG, *ortho*-nitrophenyl-β-D-galactopyranoside.

^a*Shigella dysenteriae* type 2 is positive.

EPIDEMIOLOGY

It is estimated that there are 164.7 million cases of bacillary dysentery annually, of which 163.2 million are in developed countries and 1.5 million in industrialised countries (Kotloff *et al.*, 1999). Approximately 1.1 million people die from shigellosis each year – 61% of these are children under 5 years old (Kotloff *et al.*, 1999). Infection is spread by the faecal–oral route with great ease, as the infective dose is low (10^2 – 10^3 cfu). *Shigella* spp. are obligate human pathogens and do not infect other hosts, although experimental infection can be achieved in primates. Most cases of bacillary dysentery spread from person to person, and this may occur rapidly, especially in closed communities and when individuals are brought together in large numbers and sanitary arrangements are inadequate. Dysentery is a disease of poverty, and the incidence of infection can be correlated with poor housing and sanitary facilities and when large populations are suddenly displaced through war or natural disaster. Epidemics of disease may be both water and food borne and can be associated with faecally contaminated wells.

Shigellosis is a disease of children under 5 years old in developing countries, reaching a peak at between 18 and 23 months (Henry, 1991). Disease is more severe in children who are malnourished (Bennish, 1991). In one study, all of the fatal cases were severely malnourished (Thapa *et al.*, 1995). Patients suffered convulsions, bacteraemia, renal failure, intestinal perforation and toxic megacolon (Rawashdeh, Ababneh and Shurman, 1994; Thapa *et al.*, 1995). *Shigella* dysentery has a significant effect on childhood mortality and on growth in excess of dysenteric illnesses of other aetiologies (Bennish, 1991; Henry, 1991).

In developing countries, *S. flexneri* and *S. dysenteriae* are most frequently isolated, whereas *S. sonnei* and *S. flexneri* predominate in developed countries (Kotloff *et al.*, 1999). The change in pattern of infection occurred in industrialised countries more than 50 years ago and resulted in a fall in mortality from dysentery as the more virulent forms became less common (Figure 12b.2). Haemolytic uraemic syndrome is associated with infection with *S. dysenteriae*.

Between 2000 and 2004, the annual number of cases per 100 000 population per year in the United Kingdom varied between 1.6 and 1.1 (data from the Health Protection Agency, Communicable Disease Surveillance Centre, London). A study of infectious intestinal disease among cases in the community in England, carried out between August 1993 and January 1996, showed that *Shigella* spp. was isolated in 0.8% of faecal samples from cases and none of the controls (Tompkins *et al.*, 1999). However, in many industrialised countries the scale of bacillary dysentery is not clearly established as many cases do not come to medical attention or are neither investigated bacteriologically nor notified to public health authorities. Infection is more common in children than in adults. *Shigella* is an important cause of travellers' diarrhoea, especially in individuals returned from developing countries (Vila *et al.*, 1994). Data from the Health Protection Agency on *Shigella* isolates received between April and June 2004 showed that 24% of all reports of *Shigella* infection recorded recent travel abroad, 63% of which specified travel to the Indian subcontinent, 19 of those were due to *S. sonnei* (Health Protection Agency, 2004).

CLINICAL FEATURES

Dysentery is an infection, not a toxæmia, and symptoms result from changes in the bowel wall, caused by multiplication of the organisms after ingestion. The incubation period appears to be 2–3 days on average.

Clinical features vary markedly among the different types of shigellae, sonne dysentery being the mildest. Diarrhoea is frequently the only symptom in sonne dysentery and consists of several loose stools in the first 24 h. This acute stage passes off rapidly, and in most cases, by the second day, the condition largely subsides. From then on, the frequent bowel movement is more of a social inconvenience. In some, the infection can be a mild and trivial affair; for others the

symptoms are more severe and vomiting can lead to dehydration, especially among the young. Fever is usually absent, but sometimes, at the onset, there is a sharp rise in temperature and general signs and symptoms may suggest meningeal involvement. Isolation of *Shigella* from blood and CSF specimens is rare (Struelens *et al.*, 1990; Langman, 1996). *Shigella* septicaemia is most common in infants and in people with malnutrition or in the immunocompromised (Huebner *et al.*, 1993; Huskins *et al.*, 1994). Data published by Gupta *et al.* (2004) identified infants and elderly patients (>80 years) as having the highest rates of *Shigella* bacteraemia. *Shigella dysenteriae*, *S. flexneri* and *S. boydii* were isolated from blood cultures more frequently than *S. sonnei*, raising the possibility that these serotypes may be more invasive (Gupta *et al.*, 2004).

Abdominal pain is not usually a prominent symptom, although the illness may mimic appendicitis or even intussusception in babies. In some severe cases, the onset may be sudden, with vomiting, headache, rigors, severe colic and exhausting diarrhoea. This may lead to dehydration, tetany and meningeal signs.

While the illness caused by *S. flexneri* and *S. dysenteriae* may be no worse than sonne dysentery, in most cases the patient is more acutely ill with constitutional upset. Diarrhoea is severe and persistent. Faecal material soon gives way to mucus and blood, and it is some days before faecal material returns. Abdominal pain and tenderness are frequent features, and the patient is toxic and febrile. The pulse is rapid and weak, and the patient becomes feeble, the skin punched, the tongue coated and urine scanty. The patient suffers from great thirst and cramps in the limbs; confusion or delirium may ensue. Generally, symptoms gradually subside over a period of 10–14 days, but relapses do occur, with a flare-up of the dysenteric diarrhoea and rapid death. Fulminant choleraic or gangrenous forms are usually due to *S. dysenteriae*. Bacteraemia, pneumonia, meningitis, seizures and HUS are recognised complications.

During the acute stage of the disease, *Shigella* organisms are excreted in large numbers in the faeces, but during recovery the numbers fall, although the organism may remain in the faeces for several weeks after the symptoms have subsided.

LABORATORY DIAGNOSIS

The organisms are usually present in large numbers in the intestinal mucus or the faeces in the early stages. Freshly passed stools should be examined, although rectal swabs showing marked faecal staining may be used. If the specimen includes blood and mucus, these should be plated directly. When faeces are kept alkaline, shigellae may survive for days, but in acid stools they die in a few hours. If there is likely to be much of a delay, it may be useful to collect faeces into buffered 30% glycerol saline solution. Nothing is to be gained by culturing urine or blood, since these are invariably negative. Numerous waterborne epidemics are on record, and in several instances, shigellas have been isolated from water itself.

Microscopic examination of the mucus in the early stages of acute bacillary dysentery shows a marked predominance of polymorphonuclear cells and red cells.

Faecal material is plated out directly onto deoxycholate citrate agar (DCA), *Salmonella*–*Shigella* (SS) agar or xylose–lysine–deoxycholate (XLD) medium. Shigellae appear as small colourless or slightly pink colonies on DCA and as a pink or red colonies with, in some cases, a pink or yellow periphery on XLD. A few strains grow poorly on inhibitory media, and it is advisable to use MacConkey agar and to examine any non-lactose-fermenting colonies after overnight incubation. A preliminary identification can often be made by slide agglutination with specific antisera from the growth on the primary plate. In any event, full biochemical and serological tests must be performed on subcultures that have been checked for purity.

The biochemical identification of *Shigella* is complicated by the similarity of some strains of other genera, in particular strains of *Hafnia*,

Providencia, *Aeromonas* and atypical *E. coli*; non-lactose-fermenting or anaerogenic strains of *E. coli* are a common problem.

The PCR can be used to identify *Shigellae* either from a cultured isolate or directly from faeces. The *ipaH* gene is a good target for PCR as it is a multiple-copy element found on the large invasion plasmid (pINV) and the chromosome (Islam *et al.*, 1998; Dutta *et al.*, 2001). This PCR test also detects EIEC, as this group of diarrhoeagenic *E. coli* also harbours pINV. Molecular typing techniques, such as pulsed-field gel electrophoresis (PFGE), can be used to investigate outbreaks of *Shigella* infection and to trace the source of infection (Chen *et al.*, 2003; Surdeanu *et al.*, 2003).

Safety

Most potential isolates belong to Advisory Committee on Dangerous Pathogens (ACDP) Group 2, and good laboratory practice is all that is required. Should *S. dysenteriae* be suspected, then all manipulations should be carried out in a class I microbiological safety cabinet in the containment level 3 laboratory. Since the infectious dose is between 10 and 100 cfu, great care must be taken to avoid environmental contamination. Gloves should be worn and the bench surfaces disinfected (e.g. with clear phenol) before removing the used gloves, followed by careful handwashing. Aerosolisation is also a problem – avoid splashes.

Antimicrobial Sensitivities

The earliest reports described *Shigella* spp. as susceptible to sulphonamides, but within a few years resistant strains began to appear. Between 1947 and 1950, antibiotic-resistant strains became predominant in many countries. In 1992, it was recommended that should antibiotic therapy be needed for the treatment of shigellosis in developed countries, children should be treated with ampicillin or trimethoprim plus sulphamethoxazole and adults should be treated with one of the fluoroquinolone antimicrobials (Bennish and Salam, 1992). However, 46% of isolates of *S. dysenteriae*, *S. flexneri* and *S. boydii* received by the reference laboratory at the Health Protection Agency in London between 1995 and 1996 were resistant to ampicillin and trimethoprim (Cheasty *et al.*, 1998). Fifteen per cent of *S. sonnei* isolates were resistant to both these antimicrobials and 50% were resistant to one or the other (Cheasty *et al.*, 1998). Resistance to fluoroquinolones has been rarely reported, and nearly all *Shigella* isolates are susceptible to these agents (Ashkenazi *et al.*, 2003). Therefore, if treatment must be commenced before laboratory-based tests are available, it is still recommended that fluoroquinolone antibiotics, such as ciprofloxacin, should be used to treat adults but that nalidixic acid should be used to treat children (Cheasty *et al.*, 1998; Ashkenazi *et al.*, 2003; Phavichitr and Catto-Smith, 2003). Fluoroquinolones are not currently approved for children.

Most cases of shigellosis, especially those caused by *S. sonnei*, are mild and do not require antibiotic therapy. Symptomatic treatment with the maintenance of hydration is all that is required. However, treatment with a suitable antibiotic is necessary in the very young, the aged or the debilitated and in severe infections. Because of the high incidence of the antibiotic resistance among shigellae, it is necessary to determine the resistance pattern of the strains before starting treatment where possible.

MANAGEMENT OF INFECTION

Oral Rehydration Therapy

Oral rehydration therapy (ORT) is the cornerstone of worldwide efforts to reduce mortality from acute diarrhoea, and while toxæmia plays a major role in the severity of illness in shigellosis, dehydration

has to be corrected. The World Health Organization (WHO)/United Nations Children's Fund (UNICEF) oral rehydration formula (ORS) contains glucose and sodium in a molar ratio of 1.2:1. Potassium chloride is added to replace potassium lost in the stool. Trisodium citrate dihydrate (or sodium bicarbonate) corrects metabolic acidosis caused by faecal loss of bicarbonate. ORT has proved to be a simple, safe and cost-effective means of preventing and managing dehydration in the community (Bhattacharya and Sur, 2003).

When patients, especially babies and elderly persons, are acutely ill, there is much loss of fluids and salts in vomit and in stools, and replacement of fluids may need to be controlled by electrolyte estimations. Intravenous administration seldom needs to be continued for more than 24 h, but children suffering from HUS may require dialysis. Patients with tetany may respond to intravenous normal saline alone or with the addition of 20% calcium gluconate.

On clinical grounds, antibiotics are not required for mild or moderate cases; this applies to virtually every case of dysentery seen in Britain, where 94% of cases are due to *S. sonnei* (Crowley, Ryan and Wall, 1997). In severe form of dysentery due to *S. dysenteriae* and *S. flexneri* where shigellae have penetrated intestinal epithelial cells in large numbers, the use of antibiotics such as ciprofloxacin, pivmecillinam or ceftriaxone (Bennish and Salam, 1992) to kill these intracellular organisms may prevent severe destruction of the intestinal wall. Persistent hiccough or the passage of sloughs in the stools are ominous signs. The choleraic and gangrenous types of bacillary dysentery are almost invariably fatal.

Biotherapy is the use of live organisms or their metabolic products for treatment. The most commonly available sources are fermented milk products such as yoghurt, kefir and buttermilk. Unless pasteurised, these products contain live bacteria, and they have been used for the prevention and treatment of gastrointestinal complaints. Kefir is traditionally made from goats' milk by the addition of kefir granules consisting of *Lactobacillus* spp. and a yeast (*Torula kefir*). *Saccharomyces boulardii* is a non-pathogenic yeast which is sometimes used to treat diarrhoea. It does not multiply in the gut, and there is no permanent colonisation of the bowel (Roffe, 1996).

Antimicrobial Therapy

During the last decade, quinolones such as norfloxacin, ciprofloxacin, ofloxacin and fleroxacin have emerged as drugs of choice for the treatment of various bacterial enteric infections, including shigellosis (Bhattacharya and Sur, 2003). Controlled trials have shown that quinolones in varying regimens, from a single dose (Salam *et al.*, 1994) to 5 days of treatment, significantly reduce the intensity and severity of traveller's diarrhoea as well as shigellosis (Wistrom and Norrby, 1995). Quinolone resistance is presently uncommon among shigellae, but it is inevitable that resistance will develop from increased usage of these agents.

Antimotility drugs such as diphenoxylate (Lomotil) are not recommended in the treatment of diarrhoea, although loperamide, a synthetic antidiarrhoeal agent, has been shown to decrease the number of unformed stools and shortens the duration of diarrhoea caused by *Shigella* in adults treated with ciprofloxacin (Murphy *et al.*, 1993; Bhattacharya and Sur, 2003).

INFECTION CONTROL

The mild and often fleeting nature of the clinical illness associated with sonne dysentery means that patients, often children, remain ambulant and are free to continue their daily activities and act as dispersers of the organism. When the arrangements for the disposal of human faeces are crude or non-existent, heavy contamination of the environment is inevitable, and even with modern sanitation the disease can spread easily and rapidly if there is a break in hygiene standards. The dose of *Shigella* needed to cause infection is very

small (less than 200 organisms), and given moist, alkaline, cool and shady conditions, large numbers will survive for many days. Even on dried linen, organisms will survive in the dark for long periods. Environmental contamination, particularly in and around toilet facilities, remains an important focus for continuing outbreaks of dysentery.

Shigellae are sensitive to heat and are killed in 1 hour at 55 °C. At laboratory temperatures below this level, they survive for varying periods of time, and unless strict care is exercised, a laboratory bench will remain a rich source of contamination. Shigellae are readily killed by disinfectants: in 6 h by 0.5% clear phenolics or in 15–30 min by 1% phenol. A handwash of 1% benzalkonium chloride will kill *S. sonnei* in 1 min in a dilution of 1:64. A solution of 3% (1:30) is a useful hand decontamination fluid, which is safe to use on children's hands and has been used to control outbreaks of sonne dysentery in preschool institutions.

Drinking water should be protected and kept well away from toilet facilities as shigella can survive in tap or sterilised water for as long as 4–6 weeks. Waterborne outbreaks tend to be explosive, especially in developing countries. Handwashing, although very important, cannot be guaranteed to remove all dysentery bacilli from hands, which readily become recolonised from inanimate objects.

Given the low infectious dose, cases with diarrhoea should stay at home. Infection is rarely spread in the absence of diarrhoea, and cases with no diarrhoea need not be excluded from work or school. Exceptions to this include those working in the food industry, health-care or nursery staff and children at nursery, who should be excluded or isolated until free from diarrhoea and three consecutive faeces specimens collected at intervals of at least 24 h are negative (PHLS Salmonella Sub-committee, 1990).

Spread by Personal Contact

Sonne dysentery spreads by direct contact and is largely a disease of young children. This reflects the intimate nature of contact between young children and decreases with age as the standard of hygiene increases. Symptomless excretors play a much less important role in the spread of disease than in the acute case. Although splashing occurs with the contamination of the toilet area, door-handles and so on, it is likely that hand-to-hand contact facilitates spread among young children. Likewise, staff-to-patient and patient-to-staff transmission can occur.

Adequate toilet facilities in schools and nurseries, supervised handwashing for young children and separate nappy changing areas in nurseries are simple preventative measures to minimise transmission (Crowley, Ryan and Wall, 1997). Children without symptoms can be allowed to stay at school, provided their hygiene is supervised. The use of antibiotics prophylactically in an attempt to limit the spread should be avoided.

Vaccines

Serum antibodies do not seem to be protective against intestinal shigella infection. Killed shigellae induced humoral immunity only, and research and clinical trials are underway with live attenuated strains. The growing understanding of the mechanisms of pathogenicity involved in *Shigellosis* has contributed to improvements in vaccine development. Mutations in the *S. flexneri* chromosome and the virulence plasmid (pINV) have been used to generate non-invasive live vaccine strains (Jennison and Verma, 2004). Invasive vaccine strains, attenuated by mutations in either virulence or metabolic genes, have also been produced and have been shown to induce a strong immune response (Kotloff *et al.*, 1996). *Shigella* LPS can be complexed to proteosomes and delivered intranasally, producing a safe subunit vaccine that can also induce a strong serum response (Fries *et al.*, 2001).

Immunity to *S. flexneri* is serotype specific, and vaccination against one serotype will only provide protection to infection by the homologous serotype. Studies have shown that mixing many different serotypes into a vaccine cocktail can result in a cross-reactive immune response (Noriga *et al.*, 1999). Novel approaches include the development of a vaccine strain able to express the O-antigen of more than one serotype (Guan and Verma, 1998).

Salmonella spp.

Claire Jenkins¹ and Stephen H. Gillespie²

¹Department of Medical Microbiology, Royal Free Hospital NHS Trust, London, UK; and, ²Centre for Medical Microbiology, Royal Free and University College Medical School, Hampstead Campus, London, UK

INTRODUCTION

Infection with organisms of the *Salmonella* spp. is an important public health problem throughout the world. Non-typhoidal Salmonellosis is a common cause of food-borne infection, and typhoid continues to exact a considerable death toll in developing countries.

DESCRIPTION OF THE ORGANISM

Classification

Salmonella are fermentative facultatively anaerobic, oxidase-negative Gram-negative rods. They are generally motile, aerogenic, nonlactose fermenting, urease negative, citrate utilizing and acetyl methyl carbinol negative.

Taxonomists, it appears, cut their teeth on the Enterobacteriaceae. They were simple to cultivate and submitted themselves readily to biochemical testing (Barrow and Feltham, 1992). The consequence of this early enthusiasm is a proliferation of genera and species which in the modern age, dominated as it is by the results of molecular studies, would never be dignified with genus or species designation. Comparisons of the *Salmonella* genome with other enteric bacteria, such as *Escherichia coli*, highlight large regions of DNA showing a high degree of conservation between species (70–80% of the chromosome) (McClland *et al.*, 2001) – sufficiently similar to cause them to be classified as the same species. Although this has been proposed, it is unlikely to happen as the genus *Salmonella* has an important clinical identity giving the name utility in day-to-day microbiological practice.

Historically, the classification of *Salmonella* was based on host specificity, serotyping the lipopolysaccharide (LPS) and flagella antigens and phage typing, resulting in more than 2500 different, often imaginatively named, serovars (Kauffmann, 1957). However, molecular methods, such as DNA hybridization, protein isozyme analysis, and DNA sequence similarity, show that *Salmonella* serovars are sufficiently similar at the genomic level to be regarded as the same species. The genus *Salmonella* consists of two species, *Salmonella enterica* and *S. bongori*. Within the species *S. enterica* there are six subspecies differentiated by biochemical variations, namely *enterica*, *salamae*, *arizonae*, *diarizonae*, *houtenae* and *indica* (Barrow and Feltham, 1992, Old and Threlfall, 1998). Using this system the designation for *S. enteritidis* phage type (PT4) is *S. enterica* subsp. *enterica* serotype Enteritidis PT4, although this can be abbreviated to *S. enteritidis* (Old and Threlfall, 1998). Serovars within the subspecies

other than subsp. *enterica* are designated by their antigenic formulae, for example, *S. enterica* subsp. *arizonae* 61:k:1,5,7.

Population Structure of *Salmonella* spp.

The population structure of *Salmonella* spp. has been studied by a number of techniques including multilocus sequence typing (Kidgell *et al.*, 2002), genome sequencing (McClland *et al.*, 2001, Wain *et al.*, 2002) and DNA microarrays. Comparison of the housekeeping genes, involved in DNA replication and central metabolism, indicate that the *Salmonella* serovars are very similar (97.6–99.5%). Despite their overall similarity, comparative genomics show that each serovar has many insertions and deletions relative to other serovars (Edwards, Olsen and Maloy, 2002). These unique regions represent 10–12% of their 5-Mb genome and probably encode gene products responsible for the ability of the serovars to infect different hosts (for example, *S. enterica* subsp. *arizonae* 61:k:1,5,7 infect sheep) and cause a range of diseases (for example, *S. typhi*).

PATHOGENICITY

Salmonella cause localized infection of the gastrointestinal tract but can also multiply in the reticuloendothelial system resulting in systemic infection and death. *Salmonella* invade host cells by subverting host-cell signal transduction pathways and promoting cytoskeletal rearrangements. This results in the uptake of the microorganism via large vesicles or macropinosomes. To avoid the intracellular environment of the host, *Salmonella* invade macrophages, where they proliferate within a membrane-bound vacuole.

Non-*Salmonella typhi* serotypes

Invasion

Salmonella cross the small intestine epithelium by translocating through the M cells of the Peyer's patches, resulting in the destruction of the M cells and the adjacent epithelium. The *Salmonella* genome contains five large insertions, or pathogenicity islands, absent from *E. coli*. Most of the genes controlling entry into the M cells are located on *Salmonella* pathogenicity island-1 (SPI-1) and encode a type III secretion system responsible for exporting proteins from the bacterium to the host-cell cytosol. Four proteins encoded by genes on SPI-1, SopE, SipA, SipC and StpP are injected into the host cell in this way and, once inside, initiate cytoskeletal rearrangements, membrane ruffling and, ultimately, bacterial internalization.

Intracellular Survival

Once inside the macrophage, *Salmonella* remains inside a phagosome or *Salmonella*-containing vacuole (SCV). Proteins encoded for by genes on SPI-2, such as SpiC, inhibit fusion of the SCV with the microbiocidal contents of the host-cell lysosomes and endosomes. Other SPI-2 proteins may interfere with the intracellular trafficking of the host cell to increase the chances of survival of *Salmonella* within the phagosome. For example, SPI-2 proteins may reduce the amounts of NADPH oxidase in the macrophage which is essential for the production of microbiocidal compounds, such as reactive oxygen and nitrogen intermediates.

Virulence Plasmids

Jones *et al.* (1982) originally identified a cryptic plasmid capable of conferring a virulent phenotype on *S. typhimurium*. It is now recognized that non-typhoid salmonellae associated with intestinal invasion – *S. dublin*, *S. choleraesuis*, *S. gallinarum-pullorum* and in particular *S. virchow* – possess plasmids of differing sizes which contain genes important for invasive infection. All these plasmids possess *spv* (*Salmonella* plasmid virulence) genes contained on an 8-kb regulon. The regulon consists of the positive regulator *spvR* and four structural genes: *spvA*, *spvB*, *spvC* and *spvD*. Efficient transcription of *SpvR* depends on an alternative σ factor RpoS which is encoded on the chromosome. The activity of the RpoS increases, as the organisms enter the post-exponential phase of growth (Abe *et al.*, 1994). The expression of the *spv* genes is regulated by the growth phase of the bacteria: during early exponential growth in rich media these genes are not expressed, but the synthesis of *SpvA* begins in the transition period between late logarithmic and early post-exponential phase growth. The other proteins are expressed later. It appears that nutrient starvation, iron limitation and pH rather than cell density, is the stimulus for *spv* expression.

The *spv* genes enhance the growth of *Salmonella* strains within the macrophages and non-professional phagocytic cells (Heffernan *et al.*, 1987; Eriksson *et al.*, 2003). The nature of the initial signal for its induction is unknown.

Salmonella typhi

Natural History of Infection

Although *S. typhimurium* can cause systemic disease in the human host, infection is usually localized in the intestinal epithelium (Ohl and Miller, 2001). *Salmonella typhi* is not typically associated with acute diarrhoea, suggesting that the initial interaction between this serovar and the human gut is less inflammatory. After ingestion, *S. typhi* must pass through the stomach, which provides a considerable barrier to infection. Organisms cannot be cultured from the stomach 30 min after ingestion, and antacids and H₂ antagonists reduce the number of organisms required to initiate infection. Bacteria will multiply in the intestine, but stools are only intermittently positive to culture during the first week, and even after experimental infection with 10⁵–10⁷ cfu, the presence of organisms in the stools during the first 5 days did not necessarily indicate that illness would develop (Hornick *et al.*, 1970). They are transported from the small intestine to the mesenteric lymph nodes via the M cells of the Peyer's patch and then disseminated widely via the lymphatics and bloodstream to grow intracellularly within the cells of the reticuloendothelial system. This time corresponds roughly to the incubation period. After approximately 1 week there is secondary bacteraemia, and typhoid bacilli reinvade the gut via the liver and gall bladder, settling in Peyer's patches and causing inflammation, ulceration and necrosis. This may lead to the complications of perforation or haemorrhage.

The Virulence of *S. typhi*

The complete genome sequence of a multiple-drug resistant *S. typhi* CT18 was published in 2001 (Parkhill *et al.*, 2001). Scattered along the backbone of the conserved core DNA are regions unique to *S. typhi*, for example, SPI-7, a large pathogenicity island containing genes that encode for Vi polysaccharide production (Wain *et al.*, 2002). Almost all virulent *S. typhi* possess a Vi antigen – a polysaccharide composed of *N*-acetylglucosamine uronic acid. Organisms lacking the antigen require a much higher dose to infect; antibodies to Vi are detected in patients recovering from typhoid, and when Vi antigen is used as a vaccine, protective immunity is conferred.

Also present on the *S. typhi* genome are more than 200 pseudogenes, stretches of DNA that encode gene-like sequence but have been inactivated, usually by single-base mutations. One hundred and forty-five *S. typhi* pseudogenes are present as active genes in *S. typhimurium*, a *Salmonella* serovar that has a wider host range and causes different symptoms in humans. The genome of *S. typhi* may have undergone degeneration to facilitate a specialized association with humans and that by reducing the options for routes of invasion into human tissues this pathogen favours a route that promotes the likelihood of systemic spread (Wain *et al.*, 2002).

The macrophage has an important role to play in the pathogenesis of typhoid fever. This was recognized as long ago as 1891 by Mallory, who stated, 'the typhoid bacillus produces a mild diffusible *toxine*, partly within the intestinal tract, and partly within the blood and organs of the body. The *toxine* produced proliferation of the endothelial cells which acquire for a time malignant properties. The new formed cells are epithelioid in character, have irregular, lightly stained, eccentrically situated nuclei, abundant sharply defined acidophilic protoplasm and are characterized by marked phagocytic properties' (Mallory, 1898). In volunteer experiments, patients were made tolerant of endotoxin by repeated injection of small doses to the extent that they could tolerate 2.5 μ g with no ill effect. In spite of this the volunteers became ill when challenged with *S. typhi*, exhibiting the characteristic clinical features of the disease (Greisman, Hornick and Woodward, 1964). Like other members of the Enterobacteriaceae, *S. typhi* and other salmonellas possess a LPS with a lipid A core. Stimulation of cells of the monocyte lineage results in the release of tumour necrosis factor- α and other cytokines. This gives rise to the fever, chills and rigors common in the clinical presentation and explains the phenomena so carefully recorded by previous workers.

LPSs also assist salmonellae by defending the organism against the effects of the complement pathway. The long 'O' side chain on the molecule means that activated complement (membrane attack complex) is unable to damage the outer membrane. The *rck* gene, encoded on the *S. typhimurium* virulence plasmid, codes for a protein, which acts to prevent the formation and insertion of fully polymerized tubular C9 complexes into the outer membrane.

EPIDEMIOLOGY

Non-Typhoid Salmonellosis

Examples of the way in which changes in animal husbandry practice and food preparation habits affect the incidence are illustrated by the trends in laboratory reporting of some of the major gastrointestinal pathogens in England and Wales in Figure 29.1. The incidence of salmonellosis reached its highest level in 1997, when over 32 000 cases were reported. The 12.5% increase in laboratory-confirmed cases between 1996 and 1997 represented a sharp up-turn after a period of relative stability since the early 1990s. Much of the increase in 1997 was accounted by a resurgence of cases of *S. enteritidis* PT4 which is closely associated with eggs and poultry (PHLS, 1999) changes in farming practices, and a move to more industrial-scale farm size and

Figure 29.1 Trends in laboratory reporting of some of the major gastrointestinal pathogens in England and Wales (data from the Health Protection Agency).

feeding make infection more likely to occur and difficult to eradicate when it does.

Since 1997 the incidence of this phage type has continued to decline and, in 2001, *S. enteritidis* PT4 accounted for less than 50% of all cases for the first time since 1983 (Wall and Ward, 1999). The reason for this dramatic fall in the incidence of salmonellosis is mainly attributed to vaccination of poultry flocks (Ward *et al.*, 2000). The vaccine is based on *S. enteritidis* PT4, and very high proportion of flocks has been vaccinated. Improvements in the microbiological quality of food at all stages in the food chain from the point of production to the point of consumption, the so-called farm-to-fork approach, and the adoption of hazard analysis critical control point (HACCP) systems (O'Brien *et al.*, 1998) have also contributed to the decline in salmonellosis.

Although the incidence of *S. enteritidis* PT4 has declined, since autumn 2002, there has been an increase in infections caused by other *S. enteritidis* phage types associated with raw shell eggs imported from outside the UK. *Salmonella* spp. were not recovered from UK eggs bearing a quality mark (Lion mark) (PHLS, 2002a).

Infective Dose

The stomach acts as a barrier to *Salmonella* infection; consequently patients with achlorhydria, or who are taking antacids or H₂ antagonists, the young and the very old, are more susceptible to infection. Similarly ingestion of organisms in food, especially fatty food, is more likely to result in infection, as the organisms are protected from deleterious effects of gastric acid. This can be seen in outbreaks of *Salmonella* infection associated with chocolate (Linnane, Roberts and Mannion, 2002, PHLS, 2002b). Endoscopy with a contaminated instrument can also circumvent this natural defence (Spach, Silverstein and Stamm, 1993). A large number of experimental studies have been performed to determine the infective dose, and the lowest dose causing infection varied from 10⁵ to 10¹⁰ (Blaser and Newman, 1982). An exception to these relatively high doses was a single study where patients were infected with *S. sofia* and *S. bovis-morbificans* by the nasal route, and the minimum infective dose was only 25 organisms (Mackenzie and Livingstone, 1968).

Patients of all ages are affected by salmonellosis, but the main burden of disease falls on the elderly and those who are immunocompromised.

Outbreaks in Hospitals and Institutions

Outbreaks of salmonellosis may occur in many situations, but individuals in institutional care, for example, hospitals and old people's

homes, are particularly vulnerable and the mortality risks are significantly higher. Outbreaks characteristically take two forms, food borne or person-to-person spread. In a study carried out in England and Wales, between 1992 and 2000, food-borne transmission was reported in just 25 (1.8%) of 1396 hospital outbreaks investigated compared to 1212 (86%) that were caused by person-to-person spread (Meakins *et al.*, 2003). If a case of salmonellosis is admitted to the ward, *Salmonella* spreads rapidly if good control measures are not in place, and cases continue to rise sporadically over a number of days. Nursing and medical staff play a role in perpetuating such an outbreak through inadequate infection control practices or because they become infected and become asymptomatic carriers. Meakins *et al.* (2003) reported that *Salmonella* was the cause of 3.7% of hospital outbreaks.

Although person-to-person spread is the most common mode of transmission associated with hospital outbreaks, point-source outbreaks caused by the ingestion of a contaminated food item by a large number of patients can be a significant problem. In 1988, the Chief Medical Officer advised that raw shell eggs should be replaced with pasteurized eggs in recipes in institutions with high-risk groups. Despite this advice, a large nosocomial outbreak of *S. enteritidis* PT 6a occurred at a London hospital in 2002. The source was thought to be raw shell eggs from the hospital kitchen (PHLS, 2002c).

Typhoid

The incidence of typhoid is falling worldwide due to improvements in public health, such as provision of clean water and good sewage systems, but it still remains a major threat to human health. The World Health Organization estimates there are 17 million typhoid cases annually and that these infections are associated with about 600 000 deaths (Pang *et al.*, 1998). Typhoid is predominantly a disease of the developing world: the incidence in the Far East is approximately 1000/100 000 (Sinha *et al.*, 1999, Lin *et al.*, 2000). In some developing countries the majority of cases are reported to be in the 5–14 year age group, whereas other reports show a more even distribution but confirm that typhoid is an uncommon but serious infection in patients over 30 (Butler *et al.*, 1991, Lin *et al.*, 2000). The annual numbers of cases of typhoid in England and Wales between 1980 and 2001 are shown in Figure 29.2 (PHLS, 2002d). In industrialized countries the majority of *S. typhi* infections are acquired abroad (Figure 29.2). Infection is acquired by ingestion of contaminated food and water or contact with a patient or carrier of the disease. It is restricted in host range to human beings, and there is no known

Figure 29.2 Cases of typhoid in England and Wales between 1980 and 2001, including those infections acquired abroad (data from the Health Protection Agency).

animal reservoir. In addition, *S. typhi* have caused laboratory-acquired infections.

CLINICAL FEATURES

Infection with organisms of the genus *Salmonella* results in three main syndromes: infection localized to the intestine, often known as salmonellosis, invasive or bacteraemic disease and enteric fever.

Salmonellosis

Symptoms of salmonellosis can develop in as little as 6 h and usually appear within 24 h after ingestion of the organisms. Patients complain of nausea, vomiting and diarrhoea. Fever and abdominal pain are also common, but the degree of each of these symptoms varies considerably between patients. In salmonellosis, patients complain of symptoms related to enteritidis and dysentery; blood in the stool is not uncommon. Abdominal pain is usually mild or moderate but can be sufficiently severe to mimic an acute abdomen in some cases. After symptoms subside patients continue to excrete organisms in their stools for up to 3 months. Approximately 1–3% may excrete organisms for more than a year.

In community outbreaks the majority of patients will suffer no serious effects but a small proportion, usually the elderly, will suffer invasive disease with a significant mortality. This is more likely to occur with Blegdam, Bredeney, Cholerasuis, Dublin, Enteritidis, Panama and Virchow serotypes (Old and Threlfall, 1998). Bacteraemia may result in the seeding of the viscera, meninges, bones, joints and serous cavities (Hohmann, 2001). Infection of the bones can result in an acute osteomyelitis. This is common in patients with sickle cell disease and may be very difficult to treat (Workman *et al.*, 1996).

Certain *Salmonella* serotypes, particularly Enteritidis, Typhimurium and Dublin (Levine *et al.*, 1991), have become an important problem among those infected with HIV, who are estimated to be between 20 and 100 times more at risk of infection than the general population (Gruenewald, Blum and Chan, 1994, Angulo and Swerdlow, 1995). *Salmonella* septicaemia usually occurs late in the course of HIV disease in industrialized countries. In Africa, *Salmonella* septicaemia is one of the leading causes of treatable and preventable death in HIV-infected individuals (Gilks *et al.*, 1990). Bacteraemia in HIV-positive patients in Malawi was associated with an inpatient mortality of 47% and a 1-year mortality of 77% (Gordon *et al.*, 2002). Recurrent *Salmonella* septicaemia is rare in immunocompetent patients but is a common problem in HIV-infected individuals, especially in those who do not complete an adequate course of antimicrobials (Hart *et al.*, 2000, Gordon *et al.*, 2002). It has been considered an AIDS-defining illness since 1987.

Typhoid

The incubation period for typhoid is longer than that for salmonellosis, usually 1 week. Historical accounts of typhoid written before the development of antimicrobial chemotherapy emphasized four main stages, lasting roughly 1 week each. The first week was characterized by rising fever, the second by rose spots, abdominal pain and splenomegaly and the third by the abdominal complications of haemorrhage or perforation followed by recovery in the fourth week (Stuart and Pullen, 1946).

The disease classically begins with an intermittent fever pattern which becomes more sustained over the first few days of infection. Most patients report fever or rigors (Parry *et al.*, 2002) and headache; a smaller proportion report nausea, vomiting, abdominal cramps and cough.

Patients can present paradoxically with either diarrhoea [more common in young children and HIV patients (Parry *et al.*, 2002)]

or constipation. Given the diversity of these clinical symptoms and the lack of a strong clinical pattern, patients should be suspected of having typhoid with an appropriate history or ingestion of suspected food.

On examination a fever is usually present, and careful recording may demonstrate the stepwise progression characteristics of this syndrome. The abdomen may be tender, and approximately half of patients will have a palpable liver and/or spleen. There is relative bradycardia. Careful inspection of the skin may reveal the presence of rose spots which characteristically begin around the umbilicus, but this sign is difficult to elucidate in patients with dark skin. Signs in the chest or meningismus may suggest an alternative diagnosis, emphasizing the fact that clinical diagnosis of typhoid may be difficult. Paratyphoid fever shares many of these clinical features.

In countries where schistosomiasis is endemic, retained eggs may be a source for recurrent typhoid infection as it is thought that *S. typhi* binds to the egg surface and later multiplies to cause a relapse.

Many infections may mimic typhoid, and it is important to exclude malaria in those with an appropriate travel history. A detailed travel history should be taken to generate a full differential diagnosis which might include the conditions listed in Table 29.1.

Complications

Complications occur in 10–15% of patients and are particularly probable in patients who have been ill for more than 2 weeks (Parry *et al.*, 2002). The case fatality rate with antimicrobial chemotherapy is less than 5% but is higher in children under the age of 1 year and older adults (Butler *et al.*, 1991). In young children, seizures may occur as a result of fever, hypoglycaemia or electrolyte imbalance. The most important complications are intestinal perforation or haemorrhage. The pathophysiological background to these complications has already been described. Intestinal perforation results in release of colonic bacteria into the peritoneum with consequent peritonitis. Haemorrhage results from severe ulceration of Peyer's patches. In the period before antimicrobial therapy, the mortality of intestinal perforation was approximately 90%. The appearance of chloramphenicol reduced this to around 60%. Delay in administering antimicrobial treatment is the most important factor associated with high mortality. Currently, the average case fatality rate is less than 1% but varies from less than 2% in Vietnam to 30–50% in Papua New Guinea (Parry *et al.*, 2002). Relapse occurs in 5–10% of patients, and reinfection can also occur. The latter can be distinguished from relapse by molecular typing (Wain *et al.*, 1999). Asymptomatic carriage of *S. typhi* occurs in 10% of convalescing patients, and 1–4% become long-term carriers (Parry *et al.*, 2002). Typhoid fever in pregnancy may lead to miscarriage, although antimicrobial therapy has made this outcome less common (Seoud *et al.*, 1988).

Typhoid may be complicated by acute pneumonia causing diagnostic confusion. Meningitis, cholecystitis and hepatitis are rare

complications but should be considered when the appropriate clinical features are present. Like other salmonella infections, osteomyelitis or other localized infection may develop.

LABORATORY DIAGNOSIS

Specimens

A multiplicity of specimens is submitted for the isolation of *Salmonella*, including specimens of food and sewage, in addition to specimens from patients. Salmonellosis is most conveniently diagnosed by culture of diarrhoeal stool. Three stools should be submitted for culture to maximize the clinical yield. When patients are febrile or enteric fever is suspected, blood culture should be performed.

In enteric fever, culture of the stool may be negative in up to half of patients during the first week of infection but is more likely to be positive from the second week of illness. A positive isolate of *S. typhi* from stool alone is not diagnostic in the absence of characteristic clinical features, as up to 10% of patients become chronic carriers after acute infection. A definitive diagnosis is made by culture of enteric fever from a sterile site. Blood culture is positive in up to 75% of patients, but a higher yield is obtained by culturing bone marrow, with the added advantage that a positive culture can usually be obtained even when the patient has commenced antimicrobial therapy. *Salmonella typhi* can be isolated from urine, especially after the second week of illness. Chronic excretion of this organism in the urine can cause diagnostic confusion in a patient being investigated for urinary tract infection. The organism can also be isolated from jejunal juice obtained from a duodenal string test (Hoffman *et al.*, 1984). Positive cultures can be obtained from skin snips of rose spots, although in practice it is rarely necessary to perform this technique. Clot culture has a venerable place in the mythology of microbiology, enabling a bacterial culture and serological test to be performed on a single sample. It should now not be performed, as it has clearly been shown that routine clot culture is not cost effective if a sensitive blood culture method is used (Duthie and French, 1990).

The diagnosis of *Salmonella* spp. can be conveniently divided into four phases: initial isolation, screening identification, definitive identification and typing.

Initial Isolation

The problem with isolating *Salmonella* spp. from stools is in ensuring adequate sensitivity and selection (Anonymous, 1998). *Salmonella* will grow on strongly inhibitory media but *Shigella* spp., which are often sought at the same time, are more readily inhibited. Thus a compromise must be made. In order to maximize diagnostic yield a fluid enrichment medium, such as selenite F (Leifson, 1936), is usually inoculated in parallel with the plates, allowing these to be subcultured if the plates show no suspicious colonies. Selenite F is inhibitory to enterococci and *E. coli* due to the presence of sodium selenite. Salmonellae are able to grow continuously in this medium, and although the other species will slowly begin to multiply, useful selective enrichment does occur. Care must be taken with the quality control of this medium, as the degree of inhibition can vary widely and may reduce the diagnostic yield. The inhibition is most pronounced at low oxygen tension; so the medium should be poured into universal bottles to a depth greater than 5 cm (Gillespie, 1994). Rappaport, Konforti and Navon (1956) developed a magnesium chloride-malachite green enrichment broth, which they showed was more effective than Selenite F for the isolation of a wide range of *Salmonella* spp. This medium is not suitable for the isolation of *S. typhi* (Anderson and Kennedy, 1965) and is not often used in the clinical diagnostic laboratory, although it is frequently used, with modifications, for the isolation of *Salmonella* spp. from food (Fricker, 1987).

Deoxycholate citrate agar (DCA) is highly selective but may inhibit some shigellae. The growth of coliforms and Gram-positive organisms is strongly inhibited due to sodium citrate and sodium deoxycholate in the medium. Lactose and an indicator system are included, and H₂S-producing organisms will reduce the ferric ammonium citrate in the medium to produce a black centre to the colonies. Typically, Salmonellae produce pale colonies with a black centre, but this appearance can be mimicked by *Proteus* spp. and some *Citrobacter* organisms. Xylose lysine deoxycholate agar is a popular medium, and as it is less inhibitory than DCA, it is often used in parallel to optimize the yield of shigellae. The medium contains three sugars – xylose, lactose and sucrose – together with lysine. The colour changes that occur in the colonies depend on the biochemical reactions of the organisms. Organisms that do not ferment the sugars or decarboxylate the lysine will appear as colourless colonies, and those that ferment two or more sugars will produce bright yellow colonies. Organisms, including *Salmonella*, which ferment xylose only and decarboxylate lysine (with the exception of *S. paratyphi* A) and produce H₂S will appear as red colonies with a black centre. *Salmonella* spp. producing little or no H₂S, e.g. *S. typhi* and *S. pullorum*, will appear as red colonies with or without black centres. Red colonies can also be produced by *Proteus* spp. and *Pseudomonas* spp. A number of chromogenic agars are available, designed for the improved identification of salmonellae from faecal samples (Perez *et al.*, 2003), but the cost usually prohibits their use routinely.

Wilson and Blair medium is a more reliable modification of the original bismuth sulphite agar. It is highly inhibitory to other species and is particularly useful for the isolation of *S. typhi* from heavily contaminated specimens. Selection depends on the presence of brilliant green, sodium sulphite and bismuth ammonium citrate. *Salmonella typhi* has a characteristic silvery sheen with an adjacent brown-black zone in the agar.

Screening Identification

A large number of suspect colonies must be examined to maximize the diagnostic yield. To limit the number of full biochemical tests that must be performed, a screening test is performed to exclude organisms such as *Citrobacter* and *Proteus*. Several techniques are used, including short sugar series, the Kligler iron medium and Kohn's tubes. Commercial screening tests such as the APIZ are also available. Kligler's is the most popular of the composite media; it contains sucrose and an excess of lactose, ferric ammonium citrate and a suitable indicator. Organisms that ferment glucose but not lactose or sucrose, such as *Salmonella* spp., are inoculated; there is an initial acid production that turns the medium yellow, but under the aerobic conditions of the slope, this reverts to alkaline. When lactose is also fermented there is sufficient acid so that the medium does not revert. The medium is blackened by H₂S-producing organisms, and gas produced by sugar fermentation disrupts the medium. This can be used along with indole and urease tests (*Salmonella* spp. do not produce indole or hydrolyse urea), and together the results are used to select those organisms which should be definitely identified. The growth on the slope may be used for serological testing. Alternatively, commercial tests use the substrate for several biochemical reactions which when inoculated with a heavy suspension of organisms change colour rapidly, due to the action of preformed enzymes.

Definitive Identification

The definitive identification of *Salmonella* spp. depends on obtaining biochemical and serological confirmation of the diagnosis. The techniques employed for biochemical identifications are similar to those already described (see Hawkey, 1997). Serological identification depends on determining which flagella or H antigens (from the German word *Hauch*, meaning mist) and LPS or somatic O antigens (from the

German *Ohne hauch*, meaning without mist) are present. These are usually identified using a bank of polyclonal and specific rabbit antisera raised against boiled organisms by simple bacterial agglutination. Further identification is then made by reference to the Kauffman and White scheme (Old and Threlfall, 1998). Negative O agglutination may be found, and this may be due to the presence of an unusual or new serotype. Negative agglutination may also occur due to the presence of a capsular antigen (e.g. Vi) and can be overcome by heating the culture for 1 h at 100 °C. The flagellar antigens are diphasic in many serotypes, e.g. *S. typhimurium* produces antigenic specificity 'i' in phase 1 and '1,2' in phase 2. Phase 1 antigens are specific, whereas phase 2 antigens may share antigens with other serotypes. When salmonellae are found to have organisms in the nonspecific phase, variation can be induced by cultivation in semisolid agar containing antiserum against phase 2, which selects for phase 1 (Gillespie, 1994). Phage typing systems, based on host specificity of bacteriophages, have been developed for organisms most commonly implicated in food-borne outbreaks. Phage types are not indicative of clonality because phage-type conversions may result from the acquisition of both plasmids and bacteriophages. However, phage typing proved invaluable during the pandemic of *S. enteritidis* in the late 1980s and early 1990s (Old and Threlfall, 1998).

Molecular Methods for Detecting and Typing Salmonellae

Molecular techniques for the detection of *Salmonella* spp., such as PCR, have considerable advantages in terms of specificity, speed and standardization over the conventional methodologies described above. However, it is difficult to perform PCR directly on faecal samples due to the presence of inhibitory substances and large quantities of bacterial DNA other than the target DNA (Wilson, 1997). DNA extraction from faeces can be improved by pretreating the sample with polyvinyl pyrrolidone (McLauchlin *et al.*, 2000). Commercial kits for the detection of *Salmonella* spp. by real-time PCR, such as the RealArt™ *Salmonella* TM PCR Kit (Artus GmbH, Hamburg, Germany), are available but are not used routinely. Amar *et al.* (2004) found that culture and PCR methods used for the detection of *Salmonella* from clinical faecal samples were of similar sensitivity. However, using culture, results are available within 2–3 days, whereas those obtained by real-time PCR assays can be available within 3 h, which can be advantageous for rapid intervention and appropriate treatment.

For many diagnostic purposes and control of infection, serotyping and phage typing are sufficient. For adequate surveillance and determining the source of food-borne infections and outbreaks in hospitals and institutions, more sophisticated typing methods must be employed. Plasmid typing is based on the numbers and molecular weight of plasmids found in many *Salmonella* spp. and can be used for strain differentiation within serotypes during outbreak investigations (Threlfall *et al.*, 1994). For salmonella serotypes that do not carry plasmids, chromosomally based restriction fragment length polymorphism methods, such as ribotyping and insertion sequence (IS200) typing, can be used. IS200 typing has been shown to be more useful for certain serotypes (e.g. *S. infantis* and *S. heidelberg*) than other (e.g. *S. enteritidis*) (Stanley, Jones and Threlfall, 1991). Pulsed field gel electrophoresis and amplified fragment length polymorphism each have the advantage of providing fingerprints of the whole genome and, at present, are the most commonly used typing methods in the investigation of outbreaks (Ward *et al.*, 2002, Lan *et al.*, 2003).

Laboratory Diagnosis of Typhoid

Widal Test

The Widal test uses O and H antigens from the *S. typhi* and *S. paratyphi* in a simple bacterial agglutination test to aid the diagnosis of

enteric fever. Patients infected with *S. typhi* produce serum antibodies to the O and H antigens of this pathogen, and the detection of these specific antibodies forms the basis of this test, the standardized protocol for which was established in 1950 (Felix, 1950). Although simple to perform, the Widal test is difficult to interpret, requiring a detailed knowledge of the patient's medical, travel and vaccination history. Acute and convalescent serum should be obtained and a positive diagnosis made on the basis of a fourfold rise or fall in *S. typhi* O and H antibodies. Certain patients may have high H antibody titres due to previous infection or vaccination. The O antibody concentrations fall about 6 months after previous exposure to typhoid. Cross-reacting antibodies produced by exposure to other serotypes may be a problem, but this is usually identified by including a nonspecific salmonella antigen preparation in the test battery. In addition, patients with typhoid may mount no detectable antibody response or demonstrable rise in antibody titre (Parry *et al.*, 2002). If paired sera are not available a single serum may be valuable if it yields an antibody concentration significantly in excess of the community norm for the test. Thus a patient from an industrialized country with a titre of 180 was likely to have acute infection, whereas this figure would be equivocal for a patient likely to have previous exposure.

ELISA tests and immunoblotting with LPS prepared from strains of *S. typhi* have been evaluated for the detection of anti-*S. typhi* LPS IgM serum antibodies in infected patients and have compared favourably with the Widal test (Chart, 1995). However, the determination of a cut-off value that clearly delineates antibody-positive sera from antibody-negative sera remains a problem. PCR tests targeting the flagellin genes to detect *S. typhi* directly in the blood have been developed but are not widely used (Song *et al.*, 1993). Other molecular markers of *S. typhi*, including a distinctive IS200 insertion element present in multiple copies in the *S. typhi* genome, are under investigation as potential diagnostic targets (Calva *et al.*, 1997).

Antigen Detection

The O, H and Vi antigens may be detected in the blood and urine of patients with typhoid. Co-agglutination, counter-immunoelectroimmunophoresis and ELISA techniques for their detection have been described (Barrett *et al.*, 1982, Shetty, Srinivasa and Bhat, 1985). Sensitivity of over 90% has been reported but, although valuable, these techniques cannot replace culture with the increasingly unpredictable susceptibility pattern of enteric fever organisms.

TREATMENT

Salmonella spp. are susceptible to a range of antimicrobial agents, including chloramphenicol, 4-fluoroquinolones, ampicillin, trimethoprim, aminoglycosides and third generation cephalosporins. Salmonellosis rarely requires systemic antimicrobials unless infection is complicated by bacteraemia or localized infection, such as osteomyelitis. The importance of resistance and the serotypes in which it occurs differs from country to country. In the UK, from 1975 onwards there has been an increase in multiresistant (resistance to four or more antibiotics) *S. typhimurium*, including reduced susceptibility to ciprofloxacin (MIC 0.250 mg/l), which is the drug of choice for the treatment of invasive salmonellosis. In developing countries, multiresistance is more common (Old and Threlfall, 1998).

Traditionally chloramphenicol is the first-line agent for the treatment of typhoid and remains an appropriate treatment for typhoid in areas where the bacterium is still susceptible and resources for drug expenditure are few. The 4-fluoroquinolones, including ciprofloxacin and ofloxacin, are now the first choice agent. Antibiotic trials have shown that these drugs are safe in all age groups and rapidly effective (3–7 days) (Gotuzzo and Carrillo, 1994, White and Parry, 1996). The cost of fluoroquinolones and the potential emergence of resistance are

two problems associated with this treatment. Full fluoroquinolone resistance is rare, although quinolone-resistant strains are often resistant to other antibiotics making the choice of drugs limited. In patients with quinolone-resistant *S. typhi* infections, treatment with 20 mg of ofloxacin per kg of body weight for 10–14 days has been successful in 90–95% of patients (Wain *et al.*, 1997). Cefotaxime, ceftriaxone and cefoperazone have excellent *in vitro* activity against *S. typhi* and other salmonellae and have acceptable efficacy in the treatment of typhoid fever. Only intravenous formulations are available. Cefotaxime is given 1 g three times daily (in children: 200 mg/kg daily in divided doses) for 14 days. Ceftriaxone has an advantage of only requiring a single dose daily. The cephalosporins are not active against many MDR strains, and this limits its use in empirical treatment when resistant typhoid is likely.

Azithromycin

Animal models have shown that azithromycin is highly effective against *S. typhi* and non-typhoid *Salmonella*. It has now been shown to be effective in a series of open and randomized control trials. Oral administration is an aid to administration, and the results of clinical studies demonstrate that it is as effective as chloramphenicol, ceftriaxone and ciprofloxacin. It was also effective in cases of MDR typhoid. This provides a useful alternative for the management of children with uncomplicated typhoid in developing countries (Butler *et al.*, 1999, Girgis *et al.*, 1999, Frenck *et al.*, 2000).

Multiple drug-resistant *S. typhi* was first described in Mexico in the 1960s, probably arising from uncontrolled antibiotic use (Anderson and Smith, 1972, Olarte and Galindo, 1973). It is now commonplace in *S. typhi* and non-typhoid *Salmonella* in the Indian subcontinent (Rowe, Ward and Threlfall, 1997), Latin America, Africa and countries in the Far East (Bhutta *et al.*, 1991, Coovadia *et al.*, 1992, Rasaily *et al.*, 1994). Resistance to chloroamphenicol, ampicillin and trimethoprim is generally plasmid encoded, although additional chromosomal resistance to ciprofloxacin has been reported (Rowe, Ward and Threlfall, 1995). Because of the efficacy and low relapse and carrier rates associated with their use, the 4-quinolone drugs are now the drugs of choice in the treatment of adult typhoid, certainly in areas where multiresistant typhoid fever has been reported (Ferrecio *et al.*, 1988, DuPont, 1993). However, because of its cheapness, chloramphenicol will continue to be used in other areas where the local strains are sensitive, although azithromycin may in the future be a useful alternative especially in children.

In children with possible multiresistant typhoid, a third generation cephalosporin, e.g. cefotaxime will be the preferred drug if 4-quinolone drugs are to be avoided. However, their cost and the need for intravenous administration are significant disadvantages, particularly in the developing countries, and ciprofloxacin is being used increasingly in children with typhoid. Azithromycin is another potential alternative that combines oral availability with intracellular penetration and activity against the pathogen.

Treatment of Chronic Carriers

Chronic carriage is common in patients recovering from typhoid who have not been treated with antibiotics. Chloramphenicol therapy reduces chronic carriage rates to less than 10%, and chronic carriage rates after 4-fluoroquinolone therapy are thought to be less than 2% (Parry *et al.*, 2002). In some circumstances, eradication of chronic carriage might be necessary. Before embarking on this course the real benefits to the patient in the context of the risk posed to public health should be carefully considered. Thus treatment of a single asymptomatic person living alone might not be necessary, but a food handler with no other means of employment would require it. Chronic carriage may be eradicated by further courses of specific antimicrobial therapy, and clinicians vary widely in the regimes they recommend.

PREVENTION AND CONTROL

The provision of safe drinking water, effective sewage disposal and hygienic food preparation have contributed to the control of typhoid in developing countries. Mass immunization has been used successfully in some areas (Bodhidatta *et al.*, 1987). In developed countries, most cases are the result of travel to an endemic area, and travellers should take suitable precautions, such as boiling drinking water and cooking food thoroughly (Parry *et al.*, 2002).

Vaccination

In 1896, Almoth Wright described the first use of a typhoid vaccine given to two officers in the Indian Medical Service. Initial attempts at large-scale vaccination of soldiers in India and in the Boer War led to controversy about its efficacy, which continued over the next 50 years. It was not until the 1960s that controlled field trials were performed (Woodward, 1980, Engels *et al.*, 1998). These studies were with heat- or phenol-killed organisms and the most successful demonstrated protection of 65–88% for up to 7 years.

The first effective oral typhoid vaccine was made by attenuating a virulent strain of *S. typhi* Ty2, yielding the strain Ty2A after radiation (Germanier and Furer, 1975). It has been shown to be effective in a number of field trials and produces approximately 70% protection, lasting for up to 7 years (Levine *et al.*, 1987). The genome has multiple mutations, and the organism was originally thought to be attenuated because of specific mutations in the galE enzyme essential for production of the O polysaccharide. Volunteer studies with another *S. typhi* strain with a single galE mutation was not attenuated and caused disease, suggesting that the mechanism of attenuation is elsewhere. The vaccine is not very immunogenic and is given in four doses – one capsule on alternate days – and requires a booster every 5 years. It is a live, attenuated vaccine and therefore should not be administered to immunocompromised patients or patients taking antibiotics (Parry *et al.*, 2002).

An alternative vaccine approach is to use purified Vi antigen, which is both a virulence factor and a protective antigen. This idea had been proposed many years ago, but unpromising results from early field trials discouraged its use (Woodward, 1980). The Vi antigen is thought to prevent antibodies binding to the O antigen, enabling *S. typhi* to survive in the blood, and is also associated with the inhibition of complement-mediated lysis and phagocytosis. Immunization with the Vi antigen stimulates protective antibody responses against typhoid fever (Garmory, Brown and Titball, 2002). The vaccine can be given to adults and children over the age of 2 as a single dose of 25 µg administered intramuscularly. Two to three year boosters are required (Parry *et al.*, 2002). Like Ty2A approximately 70% protection is afforded for up to 7 years (Acharya *et al.*, 1987). It has the advantage that it is inexpensive to produce by a semisynthetic procedure using pectin from citrus fruit. A new Vi vaccine conjugated to a nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A (rEPA) with the potential to be immunogenic in infants under the age of 2 was evaluated recently in Vietnam. The protective efficacy was 91.5% (Lin *et al.*, 2001).

Another approach is to use strains of *Salmonella* with defined mutations in metabolic pathways. These strains arose out of a need to produce attenuated organisms for teaching purposes. It was only later that their potential as vaccine candidates was recognized (Hoiseth and Stocker, 1981). Work has continued in developing auxotrophic mutants, harbouring defined mutations in genes coding for enzymes in the prechorismate biosynthetic pathway (*aro* mutants). These strains are unable to scavenge essential aromatic metabolites such as *para*-aminobenzoic acid. As these substances are not available in mammalian tissues the organism is attenuated. As attenuation comes through metabolic handicap, these mutants should also be attenuated in immunocompromised populations. The most characterized strains are

CVD906 and CVD908 which are mutants of Ty2 and ISP 1820, respectively, in which *aroC* and *aroD* mutations have been induced. Of these, CVD908 is the most promising vaccine candidate. In phase II clinical trials with CVD908, LPS-specific IgA-secreting cells were detected in 92 and 100% low-dose and high-dose vaccines, and serum LPS-specific IgG was detected in 46 and 49%, respectively. There were few side-effects associated with the vaccine (Tacket *et al.*, 2000). Further studies are also being carried out on CVD 909, another potential vaccine candidate, which consists of CVD908 constitutively expressing the Vi antigen (Wang *et al.*, 2000).

Many other attenuation strategies are under investigation. Promising results have been shown in trials involving strain χ 4073. This strain has mutations in adenylate cyclase *cya* and camp receptor *crp* that affect the expression of genes involved in carbohydrate and amino acid metabolism. Following inoculation with a single dose of up to 5×10^8 cfu of χ 4073, most healthy volunteers developed a specific serum antibody response and specific antibody-secreting cells to *S. typhi* and the vaccine was well tolerated (Tacket *et al.*, 1997). In addition, a *phoP/phoQ* mutant constructed from strains Ty800, a derivative of *S. typhi* Ty2, has been shown to be safe and immunogenic (Hohmann *et al.*, 1996). Further studies are also being conducted on CVD915, a *guaBA* deletion mutant of *S. typhi* Ty2 (Wang *et al.*, 2001).

Attenuated *S. enterica* strains have also been manipulated to carry foreign genes, such as the tetanus toxin fragment (TetC), opening the prospect for oral vaccination against a wide range of diseases (Garmory, Brown and Titball, 2002).

Prevention of Salmonellosis in the Food Industry

Central to the prevention of transmission of salmonellosis via food is the cooperation of farmers, veterinarians, abattoir workers and agriculture ministries. Several codes of practice for the control of salmonellas in chickens have been in operation in the UK since 1993, and there have been many improvements in the poultry industry in infection control and hygiene at breeding sites. In 1994, vaccination against *S. enteritidis* started in breeder flocks and in 1998 in layer flocks (Ward *et al.*, 2000). A European Commission Green Paper, published in 1997, stressed that the responsibility for food safety rests with the food industry and proposed that HACCP systems be adopted by the food industry (European Commission Green Paper, 1997). HACCP is an analytical tool for the systematic assessment of the many steps on the production, processing, packaging and kitchen preparation of food and the identification of steps critical to the safety of the product, also referred to as the stable-to-table or farm-to-fork strategy (WHO, 1997, O'Brien *et al.*, 1998). Adequate education and training should be provided for workers at all levels in the food industry. Similarly good practice in food preparation facilities is necessary to minimize the risks of transmission. The Food Standards Agency recommends that food businesses should use pasteurized egg rather than raw egg, in products that will not be cooked or only lightly cooked before eating (Food Standards Agency, 2002). Coupled with these measures, all outbreaks should be investigated using epidemiological techniques both as a local and national surveillance programme. The final defence against salmonellosis must be the consumer both in preparation of food at home and in the exercise of choice in purchase of commercially prepared food. In kitchens and food preparation areas where ordinary eggs are being used, good food hygiene practices are important to avoid the risk of cross-contamination (Food Standards Agency, 2002).

Prevention of Salmonellosis in the Hospital Environment

Salmonellosis can be a particular problem in hospitals and similar institutions because of the presence of elderly or immunocompromised patients. Common-source outbreaks require urgent investigation of the patients to determine the presence of a pathogen and to

provide specimens for typing and also the food which should be investigated to indicate the source and breakdown in the hygienic arrangements. During a large *S. enteritidis* outbreak at a London hospital, control measures included removal of a range of high-risk foods from the patients' menus, including all raw shell egg-based products, meals prepared from raw chicken and sandwiches prepared on site (PHLS, 2002c). For a 2-week period, all food production was halted on site and cold food was bought in from external suppliers as individual pre-packed items. Good food and personal hygiene practices among all staff was reinforced, training was increased and monitoring at kitchen, ward and departmental level was carried out. A trust-wide hand washing campaign was also introduced (PHLS, 2002c).

As salmonellosis is transmitted by the faecal-oral route, it can be readily contained by isolation of the source in a single room with enteric precautions.

Klebsiella, Citrobacter, Enterobacter and Serratia spp.

C. Anthony Hart

Medical Microbiology Department, Royal Liverpool Hospital, Liverpool, UK

INTRODUCTION

The four genera *Klebsiella*, *Citrobacter*, *Enterobacter* and *Serratia* are all members of the family Enterobacteriaceae but exhibit different degrees of relatedness to each other and to other members of the family. For example, *Serratia* spp. are 25% related to the other three genera and *Enterobacter* spp. (except *E. aerogenes*) are 45% related to *Klebsiella*. Interestingly *Citrobacter freundii* and *C. diversus* are only 50% related to each other (Brenner, 1984). The phenotypic characteristics of the genera are summarized in Table 30.1. They are all oxidase-negative rods that are facultative anaerobes.

All the four genera are associated with nosocomial infections and infection in the immunocompromised host. However, *Klebsiella* spp. are much more frequently associated with infection, being responsible for 3% of community-acquired and 9% of hospital-acquired cases of septicaemia in one hospital (Eykn, Gransden and Phillips, 1990). They are estimated to be responsible for 16.7 infectious episodes per 10 000 hospital discharges (Jarvis *et al.*, 1985). The other three genera were together responsible for 0.9% of community-acquired and 4% of nosocomial episodes of septicaemia.

KLEBSIELLA SPECIES

The genus *Klebsiella* is named after the German bacteriologist Edwin Klebs (1834–1913). In the UK literature several other species have been differentiated on biochemical properties

(Table 30.2), including *K. pneumoniae* (Friedlander's bacillus), *K. aerogenes*, *K. ozaenae* and *K. rhinoscleromatis* (Orskov, 1984). On the basis of DNA homology studies, these should all be included in the species *K. pneumoniae*. However, to maintain continuity with previous literature, the old names are used to designate subspecies. For example, *K. aerogenes* is *K. pneumoniae* subsp. *aerogenes* and Friedlander's bacillus is *K. pneumoniae* subsp. *pneumoniae*. Other species in the genus include *K. granulomatis* (see Chapter 00) and *K. oxytoca* (Jain, Radsak and Mannheim, 1974). *Klebsiella ornitholytica*, *K. planticola* and *K. terrigena* have been reclassified as species in the new genus *Raoultella* (Drancourt *et al.*, 2001).

DESCRIPTION OF THE ORGANISM

Klebsiella spp. are straight bacilli, 0.3–1 µm × 0.6–6 µm, not motile and most isolates possess a thick polysaccharide capsule and fimbriae. Their DNA mol. % G+C is 53–58.

They are facultative anaerobes that have no particular growth factor requirement. They hydrolyse sugars fermentatively, mostly with release of carbon dioxide rather than hydrogen. *Klebsiella* spp. usually hydrolyse urea and most can utilize citrate and glucose as sole carbon sources. *Klebsiella oxytoca* differs from *K. pneumoniae* in being indole positive and able to liquefy gelatin, degrade pectate and utilize gentisate and *m*-hydroxybenzoate. All are lactose fermenters and those that are the most efficient carry *lac* genes on both chromosome and plasmid.

Table 30.1 Biochemical characteristics of the genera of *Klebsiella*, *Citrobacter*, *Enterobacter* and *Serratia*

PATHOGENICITY

Apart from rhinoscleroma, ozaena and granuloma inguinale, infections with *K. pneumoniae* are nosocomial and opportunistic. Rhinoscleroma is a chronic granulomatous infection of the upper airways, although contiguous skin and the trachea may also be affected. Lesions are characterized by a submucosal infiltrate of plasma cells and histiocytes called Mickulicz cells. These are foamy macrophages with vacuoles containing *K. pneumoniae* subsp. *rhinoscleromatis*. The infective dose, portal of entry and incubation period remain unknown. It is not clear how a bacterium with a hydrophilic capsule resistant to phagocytosis enters macrophages and survives (Hart and Rao, 2000).

The pathogenesis and pathogenic determinants of nosocomial and opportunistic *K. pneumoniae* infections are shown in Figure 30.2. Most of our information on transmission of *K. pneumoniae* comes from studies of outbreaks of nosocomial infection (Podschn and Ullmann, 1998). Reservoirs of *K. pneumoniae* tend to be the intestinal tract of other hospitalized patients (Le Frock, Ellis and Weinstein, 1979; Hart and Gibson, 1982; Kerver *et al.*, 1987), although other sites such as the oropharynx, skin (the nearer the perineum the heavier the colonization) and vagina may be carriage sites (Hart and Gibson, 1982). Although *K. pneumoniae* can be transmitted via surgical instruments, urinary catheters, food (Donowitz *et al.*, 1981) and even expressed breast milk (Cooke *et al.*, 1980), hands are by far the most important route (Knittle, Eitzman and Baer, 1975; Casewell and Phillips, 1977). *Klebsiella* spp. appear to be able to survive on skin better than, for example, *Escherichia coli* or *Citrobacter* spp. (Hart, Gibson and Buckles, 1981; Casewell and Desai, 1983), perhaps because of the hydrophilic capsule. This has been disputed by others (Fryklund, Tullus and Burman, 1995).

In most cases infection is preceded by intestinal colonization which, it is presumed, is mediated by fimbriae. Although there is considerable heterogeneity among the mannose-inhibitable type I fimbriae, the receptor-binding moiety (29 kDa subunit) is highly conserved (Abraham *et al.*, 1988). These fimbriae appear to be important in attachment to respiratory and urinary tract mucosal cells (Williams and Tomas, 1990). Some *K. pneumoniae* possess plasmid-encoded proteins that mediate autoagglutination and attachment to plastic surfaces (Denoya, Trevisan and Zorzopoulos, 1986).

Klebsiella pneumoniae becomes established in other mucosal sites by migration and can enter the blood by translocation. Once

in the bloodstream or in tissues it must evade the host's non-specific immune system. There is no doubt that the hydrophilic capsule inhibits phagocytic uptake of bacteria (Denoya, Trevisan and Zorzopoulos, 1986). Heavily encapsulated *K. pneumoniae* are more virulent than less encapsulated strains in experimentally infected mice (Williams *et al.*, 1983). Specific antibody can opsonize the bacteria and facilitate phagocytosis, but the ability of virulent *K. pneumoniae* to shed capsular material may render this process less efficient. The capsule may also render bacteria resistant to opsonization and killing by the alternative complement cascade (Domenico, Johanson and Straus, 1982). The presence of long O-polysaccharide chains on lipopolysaccharides (LPSs) contributes greatly to resistance to serum killing (Merino *et al.*, 1992), perhaps by sterically hindering the binding of the complement membrane attack complex to the outer membrane. However in murine models it is clear that the capsular polysaccharides are more important than LPS O-side chains in modulating complement deposition (Cortes *et al.*, 2002a).

Once in tissues the iron scavengers, in particular enterochelin, allow the bacteria to grow even when iron is scarce (Tarkkanen *et al.*, 1992). The presence of antibiotic resistance plasmids is also of assistance in allowing *Klebsiella* to grow in the tissues of patients receiving antibiotics. The tissue damage by *Klebsiella* is probably because of both release of toxic molecules by the bacteria and the host's response, in particular frustrated activated phagocytes releasing toxic oxygen radicals. The major bacterial determinant is endotoxin released either as LPSs alone or in complexes with capsular polysaccharide (Straus, 1987; Williams and Tomas, 1990). Global analysis of *K. pneumoniae* virulence-associated genes has been undertaken using transposon mutagenesis assays (Cortes *et al.*, 2002b; Struve, Forestier and Krogfelt, 2003). Mutations in genes involved in core LPS biosynthesis (*waaL*, *waaE* and *wbbO*), synthesis of cell membrane and surface structures (*plsX*, *surA* and *ompA*) and in protein and histone biosynthesis (*tufA* and *hupA*) all inhibited colonization of intestine and urinary tract, whereas mutations in genes encoding GDP-fucose synthesis (involved in capsule synthesis) and fimbria synthesis inhibited urinary tract colonization alone (Struve, Forestier and Krogfelt, 2003). Disruption of *htrA* (a heat-shock-induced serine protease) rendered *K. pneumoniae* much more sensitive to temperature, oxidative stress and complement-mediated killing (Cortes *et al.*, 2002b).

Capsule

A key characteristic of *Klebsiella* spp. is the production of mucoid colonies when grown on solid media. This is enhanced when the media contain an excess of carbohydrate. The mucoid character is due to the thick polysaccharide capsule (Figure 30.1) which absorbs a large amount of water. The capsular material may also diffuse freely into the surrounding medium as extracapsular polysaccharide. There are at least 82 different capsular (K) serotypes and subtypes with similar antigenicity but different polysaccharide backbones have been described (Allen *et al.*, 1987b). Despite this antigenic diversity, the range of monosaccharide units is limited to L-fucose, L-rhamnose, D-mannose, D-glucose, D-galactose, D-glucuronic acid or D-galacturonic acid, some with *O*-acetyl and pyruvate ketal groups (Sutherland, 1985). *Klebsiella pneumoniae* subsp. *pneumoniae* is predominantly serotype 3, as is *K. pneumoniae* subsp. *rhinoscleromatis*. *Klebsiella pneumoniae* subsp. *ozaenae* encompasses serogroups 3, 4, 5 and 6, but each of the serogroups has been associated with *K. pneumoniae* subsp. *aerogenes*.

The genetic control of *Klebsiella* capsular synthesis is complex. A 29-kb chromosomal fragment from *K. pneumoniae* K2 Chedid was able to induce K2 capsular biosynthesis in capsuleless mutants of *K. pneumoniae*, but an extra plasmid-encoded *rmpA* gene was required for its expression in *E. coli* (Arakawa *et al.*, 1991). *rmpA2* that is encoded on a 200-kb plasmid in bacteraemic isolates of *K. pneumoniae* is a trans-activator of capsular polysaccharide biosynthesis (Lai, Peng and Chang, 2003). Two genes *rcaA* (regulation of capsule synthesis) and *rcaB* have been cloned from the chromosome of *K. pneumoniae* subsp. *aerogenes* K21 that cause expression of a mucoid character in *E. coli*. This, however, is due to activation of synthesis of colanic acid which is antigenically similar to the K21 capsular polysaccharide (Allen, Hart and Saunders, 1987a). Capsular polysaccharide biosynthesis is greater under nitrogen than carbon limitation and increased at lower (approximately 30 °C) temperatures (Mengistu, Edwards and Saunders, 1994). The initial biosynthesis takes place in the cytoplasm and utilizes UTP and ATP. The assembled polysaccharide is transported across the inner membrane using an undecaprenyl phosphate (P-C55) carrier (Troy, 1979). How it traverses the periplasmic space

and outer membrane and forms the capsule is unclear. Group II capsules of *E. coli* are homopolymers of a single monosaccharide (Jann and Jann, 1990). These are transported across the periplasmic space utilizing the so-called traffic ATPases or ABC (ATP-binding cassette) transporters (Ames and Joshi, 1990; Pavelka, Wright and Silver, 1991). A further set of polypeptides are required for translocation of these group II *E. coli* capsular polysaccharides across the outer membrane and to tether them in place (Boulnois and Roberts, 1990). Unfortunately the capsules of *Klebsiella* spp. are more closely related to those of group I *E. coli*; for example, the *Klebsiella* K5 and K54 antigens are structurally identical to *E. coli* K55 and K28 respectively (Altman and Dutton, 1985). The capsular polysaccharides appear to form fibres protruding radially from the bacterial surface (Figure 30.1). The presence of the capsule imparts a net negative charge to the bacterium and render it highly hydrophilic.

Adhesins

Klebsiella spp. possess both fimbrial and non-fimbrial adhesins (Pruzzo *et al.*, 1989; Tarkkanen *et al.*, 1992). The fimbriae can be of type 1 or type 3 (mannose-resistant haemagglutination of tanned erythrocytes only), and occasionally P fimbriae.

A mannose-inhibitable non-fimbrial adhesin has been found on unencapsulated *Klebsiella* spp. (Pruzzo *et al.*, 1989), as has a plasmid-encoded non-fimbrial adhesin (29 kDa) which facilitates adhesion of *Klebsiella* to epithelial cells (Darfeuille-Michaud *et al.*, 1992). The situation is reversed for certain *K. pneumoniae* capsular serotypes that have mannose disaccharide units in their polysaccharide (Athamna *et al.*, 1991). Here the disaccharide acts as the receptor (rather than adhesin) for a mannose/*N*-acetylglucosamine-specific lectin on the surface of macrophages.

Lipopolysaccharide

The repertoire of O-antigens on *K. pneumoniae* LPS is limited to eight (O types 1, 3–5, 7–9 and 12), with O:1 being the most common.

Figure 30.1 Thin-section electron micrograph of *Klebsiella pneumoniae* stained with ruthenium red to demonstrate the capsule. Bar = 1 μ m.

Other Toxins

Klebsiella pneumoniae strains carrying genes for, or expressing heat-labile and heat-stable enterotoxins have been described (Betley, Miller and Mekalanos, 1986). Their clinical importance is unclear (Figure 30.2). A channel-forming bacteriocin (microcin E492) from *K. pneumoniae* is able to induce apoptosis in human cells (Hetz *et al.*, 2002).

Iron Scavenging

Klebsiella pneumoniae is able to scavenge iron from its surrounding medium using either enterochelin (phenolate siderophore), which is detected more frequently in pathogenic isolates, or aerobactin (hydroxamate siderophore).

NATURAL HABITAT

Although *Klebsiella* spp. are listed as part of the enteric flora in healthy individuals; if they are present it is only in small numbers ($<10^2$ cfu/g faeces). Premature babies and especially those in neonatal intensive care units (Tullus *et al.*, 1988; Hart, 1993), hospitalized patients even when moderately (Le Frock, Ellis and Weinstein, 1979) or severely ill (Kerver *et al.*, 1987), those with chronic disease and elderly individuals are relatively easily colonized by *Klebsiella* spp. This colonization may also extend to the oropharynx (Mackowiak, Martin and Smith, 1979). Administration of antimicrobials that affect the colonization resistance (Van der Waaij, 1982) of the intestinal tract also predisposes to colonization by *Klebsiella* and other Enterobacteriaceae. In one study it was found that the half-life for carriage of aminoglycoside-resistant *K. pneumoniae*, but not of *K. oxytoca* in elderly patients, was 100 days and some subjects excreted bacteria for over 200 days (Hart and Gibson, 1982). *Klebsiella* spp. can be part of

the normal flora of a variety of other animals and are widely distributed in the inanimate environment. A recent study found *Klebsiella* spp. in 53% of 208 samples of surface water (streams, lakes and the Baltic Sea) and *K. pneumoniae* was the species most frequently isolated (Podschn *et al.*, 2001).

EPIDEMIOLOGY

Klebsiella spp. are important nosocomial pathogens worldwide. In a UK prevalence survey, *Klebsiella* spp. were responsible for 8.3% of urinary tract infection, 4% of wound infections and 3.5% of pneumonias (Meers *et al.*, 1980). In the USA the importance of *K. pneumoniae* as a cause of nosocomial bacteraemia has declined from 9.1% of cases in 1975 to 4.5% in 1985–1989 (Pittet, 1993). In neonatal intensive care units *Klebsiella* spp. appear in the top three or four pathogens both in developed (Gladstone *et al.*, 1990) and developing countries (Rajab and De Louvois, 1990). Explosive life-threatening outbreaks of septicaemia due to multidrug-resistant *Klebsiella* spp. occur with monotonous regularity (Donowitz *et al.*, 1981; Morgan, Hart and Cooke, 1984; Fryklund, Tullus and Burman, 1995). In this setting septicaemia usually follows intestinal colonization with *Klebsiella* spp. which, it is suggested, can result from use of ampicillin rather than cephalosporins in the unit (Tullus and Burman, 1989). Outbreaks of infection are a feature in compromised patients, often with multidrug-resistant organisms (Casewell *et al.*, 1977; Curie *et al.*, 1978). *Klebsiella* spp. have been reported to be responsible for 14% of cases of bacteraemia associated with intravascular devices (Eykyn, Gransden and Phillips, 1990).

Rhinoscleroma is found in Eastern Europe, and occasionally in Italy, Switzerland, Spain and southern France. It is also endemic in Africa, Latin America and parts of the Middle and Far East. It is commoner in women than men and usually presents in early adulthood. It is associated with poor and crowded living conditions with poor sanitation.

Figure 30.2 Pathogenesis of nosocomial and opportunistic *Klebsiella pneumoniae* infection. MIAT*, mannose-inhibitable adhesin/phage T7 receptor.

Pneumonia due to *K. pneumoniae* subsp. *pneumoniae* is an uncommon occurrence and generally occurs as a community-acquired infection in elderly debilitated males.

CLINICAL FEATURES

Nosocomial *Klebsiella* infections can occur at almost any site, and the clinical features do not differ from those caused by any of the Enterobacteriaceae. Although *K. pneumoniae* subsp. *pneumoniae* is historically associated with pneumonia, a worldwide study of bacteraemic pneumonia found Friedlander's bacillus is less than 1% of cases (Ko *et al.*, 2002). In addition a distinctive syndrome of *K. pneumoniae* bacteraemia in association with community-acquired liver abscesses meningitis or endophthalmitis was found, the first being found almost exclusively in Taiwan (Ko *et al.*, 2002). Risk factors for community-acquired *K. pneumoniae* bacteraemia include alcoholic liver disease and diabetes mellitus (Tsay *et al.*, 2002).

Rhinoscleroma begins as a painless chronic inflammatory swelling which causes nasal or respiratory tract obstruction. The nasal lesions enlarge locally to produce the so-called Hebra nose, which is grossly distorted and splayed. Local spread and local metastatic foci, often with lymph node involvement, are frequently described. Ozaena is seldom seen nowadays and there are doubts over its status as a disease entity.

DIAGNOSIS

The nosocomial *Klebsiella* spp. are simple to detect by standard cultural techniques, and their isolation from normally sterile sites or in significant numbers from sites with a normal flora provides evidence of infection.

The diagnosis of rhinoscleroma depends upon the typical histopathological appearance (Mickulicz cells) which can be made more specific by using anti-capsular antibody (Meyer *et al.*, 1983). The differential diagnosis of rhinoscleroma includes espundia, rhinosporidiosis, leprosy, yaws and malignancy.

Antimicrobial Susceptibility

Klebsiella spp. seem to have a particular propensity to acquire, build up and maintain antibiotic resistance plasmids (Hart, Gibson and Buckles, 1981), especially if nosocomially acquired (Tsay *et al.*, 2002). Most *Klebsiella* are intrinsically resistant to ampicillin, but acquisition of plasmid-encoded resistance has resulted in outbreaks of nosocomial infection. In the 1970s and 1980s outbreaks of infection due to gentamicin- and tobramycin (but not amikacin)-resistant *K. pneumoniae* were reported in increasing numbers (Casewell *et al.*, 1977; Curie *et al.*, 1978; Morgan, Hart and Cooke, 1984). With the introduction of second- and third-generation cephalosporins, isolates of *K. pneumoniae* resistant to cefuroxime, ceftazidime and cefotaxime soon emerged. Initially this was chromosomally encoded (Hart and Percival, 1982), but subsequently plasmid-encoded extended-spectrum β -lactamases caused large outbreaks of infection especially in adult intensive care units (Jacoby and Medeiros, 1991; Hibbert-Rogers *et al.*, 1994). In general, these extended-spectrum β -spectrum lactamases have arisen by evolution of *TEM* and *SHV* genes (Hibbert-Rogers *et al.*, 1994). Resistance to fluoroquinolones can be high; for example, in one French hospital 97% of β -lactamase-resistant *K. pneumoniae* were resistant to ciprofloxacin (Bergogne-Bérézin, Decré and Joly-Guillon, 1993). It appears that *Klebsiella* spp. do not remain predictably susceptible to a new antibiotic beyond a relatively short 'honeymoon period'.

Epidemiological Typing Methods

The major typing method for *Klebsiella* spp. is capsular serotyping. Although this was originally done by the Quellung reaction, other

techniques such as immunofluorescence (Murcia and Rubin, 1979) or counter-current immunoelectrophoresis (Palfreyman, 1978) are more readily applicable. An analysis of *K. pneumoniae* isolated from blood showed that K2 (8.9% of isolates), K21 (7.8%) and K55 (4.8%) were the most common serotypes and that 25 serotypes accounted for 70% of the isolates (Cryz *et al.*, 1986). In a UK survey, K21 (42% of isolates) and K2 (16.5%) were the most common isolates from nosocomial infections (Casewell and Talsania, 1979). Other methods available for typing *Klebsiella* spp. are biotyping (Simoons-Smit *et al.*, 1987), antimicrobial susceptibility patterns, Klebecin typing (Edmondson and Cooke, 1979) and a variety of molecular methods including pulsed-field gel electrophoresis (PFGE) of digested chromosomal DNA (Gouby *et al.*, 1994). A recent comparison of PFGE versus O:K serotyping has concluded that both were highly discriminative but PFGE was more effective (Hansen *et al.*, 2002).

TREATMENT AND PREVENTION

Because *K. pneumoniae* can be resistant to many different antimicrobial agents, empirical therapy must be based on knowledge of local susceptibility patterns. Prevention of nosocomial infection requires adherence to infection-control policies, and handwashing is an important part of this. Passive immunization with anticapsular polysaccharides has had some effect in treating and preventing *Klebsiella* infection in burns patients (see references in Cryz *et al.*, 1986).

Klebsiella pneumoniae subsp. *rhinoscleromatis* is sensitive *in vitro* to many antibiotics, including streptomycin, cotrimoxazole, gentamicin and tobramycin. However, ciprofloxacin (Borgstein, Sada and Cortes, 1993) or ofloxacin appear to be the drugs of choice but they must be given for long periods (months). Surgical removal of lesions will also be necessary.

CITROBACTER SPECIES

The genus *Citrobacter* was first named in 1932, but until recently the name had not gained full acceptance (Sakazaki, 1984). Species in the present genus have been previously named *Levinia amalonatica*, *E. freundii*, *Salmonella hormaechii*, *S. ballerup* and the Ballerup/Bethesda group. Currently 11 species are recognized: *Citrobacter koseri* (formerly *C. diversus*), *C. freundii*, *C. amalonaticus*, *C. farmeri*, *C. youngae*, *C. braakii*, *C. gilleni*, *C. muralinae*, *C. werkmanii*, *C. sedlakii* and *C. rodentium* (O'Hara, Roman and Miller, 1995).

DESCRIPTION OF THE ORGANISM

Citrobacter spp. are rods (1 μm \times 2–6 μm), usually non-encapsulated, but some *C. freundii* strains produce Vi capsular antigen (Houng *et al.*, 1992). They are motile by means of peritrichous flagella and some possess class I fimbriae (Abraham *et al.*, 1988). All are lactose fermenters but some isolates of *C. freundii* are late lactose fermenters. This together with their ability to produce H₂S in the butt of triple sugar or Kligler's iron-agar has led to their being confused with *Salmonella* spp. but *C. freundii* is indole positive. At least 42 O-antigens, one of which cross-reacts with *E. coli* 0157 (Bettelheim *et al.*, 1993), and 90 H-antigens are expressed by the genus. The mol. % G+C of their DNA is 51–52.

PATHOGENESIS

The virulence determinants of *Citrobacter* spp. are little understood. It is presumed that they colonize the intestine and other sites using fimbriae. Production of capsule (Vi) and *E. coli* 0157 lipopolysaccharide is more related to confusing microbiologists than causing disease. *Citrobacter rodentium* and some strains of *C. freundii* carry the *eae* (enteropathogenic *E. coli* attaching and effacing) gene and are associated

with murine colonic hyperplasia (Frankel *et al.*, 1994). Recently an outbreak of gastroenteritis and haemolytic uraemic syndrome was associated with *C. freundii* producing verotoxin 2 (Tschäpe *et al.*, 1995). Expression of a 32-kDa outer membrane protein was found among isolates of *C. koseri* causing neonatal meningitis (Li *et al.*, 1990). *Citrobacter koseri* is easily engulfed by human macrophages, but survives phagolysosome fusion and replicates within them (Townsend *et al.*, 2003).

EPIDEMIOLOGY AND INFECTIONS

Normal Habitat

Citrobacter spp. are found in the intestinal tract of humans and other animals and are widely distributed in the environment. *Citrobacter koseri* appears to become established with some ease in the neonatal intestine and even in the mother's or nurse's intestinal flora (Williams *et al.*, 1984; Goering *et al.*, 1992). In contrast, spontaneous loss of intestinal carriage of other *Citrobacter* spp. that were multidrug resistant occurred more readily than that of *Klebsiella* spp. or *E. coli* (Hart and Gibson, 1982).

Citrobacter spp. are an infrequent cause of bacteraemia; in a UK survey 0.7% of episodes were caused by *C. freundii* and *C. koseri* equally (Eykyn, Gransden and Phillips, 1990), and they do not appear in the 'top 10' bacteraemic isolates from 1975 to 1989 in the USA (Pittet, 1993). *Citrobacter koseri* does, however, appear to be an important neonatal pathogen (Williams *et al.*, 1984; Goering *et al.*, 1992). In common with other Enterobacteriaceae, *Citrobacter* spp. can cause meningitis, bacteraemia pneumonia, urinary tract infection and wound infections. Although *C. koseri* is predominantly a neonatal pathogen, occasional cases of meningitis are reported in adults. Following *C. koseri* neonatal meningitis, abscess formation is common and the long-term outlook is poor with seizures, paralysis and mental retardation in 50% of cases (Straussberg, Harel and Amir, 2001).

Most infections are sporadic and the reservoir for *Citrobacter* spp. is the intestinal tract (Chen *et al.*, 2002). Spread is most likely to be by hands, although *Citrobacter* spp. survive less well on skin than *Klebsiella* or *Enterobacter* spp. (Hart, Gibson and Buckles, 1981). For epidemiological purposes *Citrobacter* spp. have been differentiated by biotype, O-serotyping, plasmid profiles (Williams *et al.*, 1984; Goering *et al.*, 1992), outer membrane protein profiles (Tschäpe *et al.*, 1995) and analysis of chromosomal DNA (Morris *et al.*, 1986).

DIAGNOSIS

Citrobacter spp. can be easily grown from most infected sites. One of the major pitfalls in the laboratory is distinguishing them from *Salmonella* spp. and *E. coli*.

Antimicrobial Susceptibility

Antibiotic susceptibilities are not entirely predictable, but in one survey all isolates of *C. freundii* and *C. koseri* were sensitive to ciprofloxacin and imipenem, and over 50% were sensitive to gentamicin and trimethoprim (Reeves, Bywater and Holt, 1993). A particular feature of *Citrobacter* spp. is the carriage of inducible cephalosporinases (AmpC β -lactamases) and the frequency of the emergence of the de-repressed mutants overproducing such enzymes (Stapleton, Shannon and Phillips, 1995). These enzymes are chromosomally encoded, not inhibited by clavulanate, able to hydrolyse third-generation cephalosporins and are induced by their substrates. They have been detected in strains isolated well before the 'antibiotic era' (Barlow and Hall, 2002). Approximately 10% of hospitalized children were found to be excreting *Citrobacter* spp. expressing these enzymes (Berkowitz and Metchock, 1995).

TREATMENT AND PREVENTION

Antimicrobial chemotherapy will depend upon the local susceptibility pattern. However, treatment with fluorinated quinolones, imipenem or amikacin is likely to be successful depending on the site of infection. Prevention is by appropriate infection-control measures (Williams *et al.*, 1984).

ENTEROBACTER SPECIES

Enterobacter cloacae was first described as *Bacterium cloacae* and as *Cloaca cloacae* but renamed *E. cloacae* when the genus was established (Richard, 1984).

Enterobacter spp. are biochemically active and *E. aerogenes* is similar to *K. pneumoniae*. *Enterobacter* spp. differ from *Klebsiella* spp. in being motile and from *Serratia* spp. by being negative for lipase, Tween 80 esterase and DNAase. Currently there are 15 species in the genus: *E. cloacae*, *E. aerogenes* (syn *K. mobilis*), *E. agglomerans* (now *Pantoea agglomerans*), *E. gergoviae*, *E. sakazakii*, *E. cowanii*, *E. hormaechei*, *E. taylorae*, *E. asburiae*, *E. intermedius*, *E. amnigenus*, *E. dissolvens*, *E. kobei*, *E. pyrinus* and *E. nimipressuralis*. The role of the last seven species in human infection is unclear. *Enterobacter amnigenus* and *E. intermedius* are environmental bacteria that do not grow at 41 °C.

DESCRIPTION OF THE ORGANISM

Enterobacter spp. are 0.6–1.0 $\mu\text{m} \times 1.2$ –3.0 μm long, motile by means of peritrichous flagella and possess class 1 fimbriae (Abraham *et al.*, 1988). They ferment glucose with production of acid and gas and are methyl red negative and Voges-Proskauer positive. Although the optimal growth temperature is 30 °C, most clinical isolates grow well at 37 °C. *Enterobacter cloacae* has 53 O-antigens and 56 H-antigens. Approximately 80% of *E. aerogenes* isolates are encapsulated. The capsule is usually thinner than that of *Klebsiella* but shares some antigens (e.g. K68, K26 and K59). *Enterobacter (Pantoea) agglomerans* and *E. sakazakii* produce a yellow diffusible pigment at 20 °C on agar, the mol. % DNA + C content is 52–60. Analysis of a collection of 206 strains of *E. cloacae* from a variety of sources indicated that although phenotypically similar they were genetically quite diverse (Hoffmann and Roggenkamp, 2003).

PATHOGENICITY

Enterobacter spp. are important nosocomial and opportunistic pathogens. There is little information on their virulence determinants. It is presumed that they adhere to mucosal surfaces using fimbriae.

EPIDEMIOLOGY

Normal Habitat

Enterobacter spp. are found in soil and water but *E. cloacae* and *E. aerogenes* can be a minority component of the intestinal flora of human and other animals and in sewage (up to 10⁷ cfu/g).

Enterobacter spp. and in particular *E. cloacae* (the most common) and *E. aerogenes* are associated with sporadic and occasionally epidemic nosocomial infection (Gaston, 1988). *Enterobacter sakazakii* and *E. hormaechei* have been particularly associated with neonatal sepsis (Arseni *et al.*, 1987; da Silva *et al.*, 2002), and *E. taylorae* is a rare cause of nosocomial infection. *Enterobacter* spp. are responsible for 1.5% (Eykyn, Gransden and Phillips, 1990) to 6% (Pittet, 1993) of bacteraemic episodes in adults. Common source outbreaks have been linked to enteral feeds and dextrose infusions (Maki *et al.*, 1976),

probably due to an ability to grow in concentrated glucose solutions. Hospital cross-infection can produce outbreaks, for example, by contamination of urinals (Mummery, Rowe and Gross, 1974) or by transfer on hands in neonatal units (Haertl and Bandlow, 1993; Ahmet, Houang and Hurley, 1995). *Enterobacter* spp. as well as *Klebsiella* spp. survive on hands (Hart, Gibson and Buckles, 1981).

For epidemiological purposes, *Enterobacter* spp. have been subdivided by biotype, antibiogram, cloacin typing, phage typing (Gaston, 1988), plasmid profile, pyrolysis mass spectrometry (Ahmet, Houang and Hurley, 1995) and a variety of molecular biological techniques including PFGE (Haertl and Bandlow, 1993) and repetitive element polymerase chain reaction (Georghiou *et al.*, 1995).

ANTIMICROBIAL SUSCEPTIBILITY

All isolates of *E. cloacae* and *E. aerogenes* are resistant to cephradine, cefuroxime and amoxicillin, but most UK isolates remain sensitive to cefotaxime, ceftazidime, ceftiprome, imipenem, gentamicin and ciprofloxacin (Reeves, Bywater and Holt, 1993). The presence of plasmid-encoded resistance is not uncommon. Like *Citrobacter* spp., *Enterobacter* spp. have the capacity to produce both inducible and de-repressed chromosomally encoded cephalosporinases. Recently strains of *E. aerogenes* resistant to imipenem have emerged (de Champs *et al.*, 1993). These were found to hyperexpress a chromosomally encoded cephalosporinase, a variety of plasmid-encoded β -lactamases (TEM types) and to have lost an outer membrane (porin) protein. Other species such as *E. amnigenus*, *E. gergorviae* and *E. sakazakii* appear less resistant (Stock and Wiedemann, 2002).

TREATMENT AND PREVENTION

Treatment depends upon the local antimicrobial susceptibility patterns and prevention is by adherence to appropriate control of infection procedures. In a carefully controlled study bacteraemia due to *Enterobacter* spp. did not adversely affect the outcome in ICU patients provided there was appropriate antimicrobial chemotherapy (Blot, Vandewoude and Colardyn, 2003).

SERRATIA SPECIES

The type species, *Serratia marcescens*, was first described by Bizio in 1823 as a cause of red discoloration of cornmeal porridge: 'bleeding polenta'. The red pigment produced by *S. marcescens* is water insoluble, not light fast and is called prodigiosin (Yu, 1979). It has been responsible for the appearance of 'blood' on foodstuffs throughout history. Its presence in sputum has also led to a misdiagnosis of bronchiectasis or even bronchial carcinoma. *Serratia marcescens* has also been used extensively as a biological tracer. The earliest experiment was in the House of Commons in 1906 and involved gargling with a solution of *S. marcescens* and then declaiming to an audience of agar plates (doubtless more attentive and receptive than the usual audience!).

Serratia spp. are indole negative, produce lecithinase and lipase and are more likely to be gelatinase and DNAase positive than the other Enterobacteriaceae (Grimont and Grimont, 1984). The genus contains 10 species, namely *S. marcescens*, *S. liquefaciens*, *S. rubidaea* (previously *S. marinorubra*), *S. ficaria*, *S. fonticola*, *S. odorifera*, *S. entomophilia*, *S. plymuthica*, *S. grimesii* and *S. proteamaculans* subsp. *quinovora*. Of these, *S. marcescens*, *S. liquefaciens* and *S. rubidaea* are most often associated with human infection. *Serratia fonticola* is found in water. *Serratia ficaria* shuttles between fig tree and fig wasp but can cause human infection, and *S. plymuthica* and *S. proteamaculans* subsp. *quinovora* are rare causes of human disease.

DESCRIPTION OF THE ORGANISM

Serratia spp. are straight rods 0.5–0.8 $\mu\text{m} \times 0.9$ –2.0 μm . Most are motile by means of peritrichous flagella. In a survey of respiratory tract isolates, over 17% of *Serratia* spp. possessed type 3 fimbriae (Hornick *et al.*, 1991). Mucoid colonies of *S. plymuthica* occur regularly but most other *Serratia* spp. are non-capsulate. *Serratia odorifera* does possess a microcapsule that cross-reacts with *Klebsiella* K4 or K68 antisera. There are 21 somatic antigens (01–021), 25 flagellar (H1–H25) antigens and 16–50% of strains have the serotype O14:H12. Prodigiosin is produced by two biogroups of *S. marcescens* and most *S. rubidaea* and *S. plymuthica* between 20 and 35 °C. Colonies of these bacteria are completely red or have a red centre or margin. Most species produce a fishy-urinary odour. *Serratia odorifera* and *S. ficaria* smell musty. All *Serratia* spp. are Voges-Proskauer positive (except for 40% of *S. plymuthica*) and hydrolyse tributyrin; mol. % DNA G+C content is 52–60. Recently a spore-forming strain of *S. marcescens* subsp. *sakuensis* has been isolated from domestic wastewater (Ajithkumar *et al.*, 2003).

PATHOGENICITY

Other than class 3 fimbriae no other virulence determinants have been ascribed to *Serratia* spp. However, their ability to survive in disinfectant solution, to grow at relatively low temperatures and to adhere to plastics can provide a reservoir for infection. They are not part of the adult normal flora but can colonize premature neonates (Christensen *et al.*, 1982; Newport *et al.*, 1985).

Prodigiosin production seems unrelated to pathogenicity since up to 80% of clinical isolates are non-producers, despite the fact that it is being developed as an anti-cancer agent (Manderville, 2001). *Serratia marcescens* produces a pore-forming haemolysin, which allows the bacterium to acquire haemoglobin and haem using an extracellular scavenger protein (Letoffe, Ghigo and Wandersman, 1994). In addition to the haemolysis and iron scavenger protein, transposon mutagenesis studies identified LPS biosynthetic enzymes as important virulence determinants (Kurz *et al.*, 2003). *In vitro*, a metalloprotease secreted by *S. marcescens* has been shown to contribute to the bacterium's cytotoxicity (Marty *et al.*, 2002).

EPIDEMIOLOGY AND INFECTIONS

Normal Habitat

Serratia spp. are widely distributed in the environment (water, soil and plants) and can be found in the rodent gut (Grimont and Grimont, 1984) and occasionally in the human intestinal tract. *Serratia* spp. appear to colonize the premature neonate's intestinal tract when in intensive care but are rarely found in staff or mothers (Christensen *et al.*, 1982; Newport *et al.*, 1985).

Serratia spp. are nosocomial and opportunist pathogens, *S. marcescens* being the most important. The inanimate environment, especially when moist, is the major reservoir of *S. marcescens* as is the premature neonate's intestinal tract (Christensen *et al.*, 1982; Newport *et al.*, 1985). Transmission has been by fomites such as disinfectant and cleansing solutions, contact lenses (Ahanotu and Ahearn, 2002), hand lotions, urinary catheters, catheter hubs, parenteral fluids, mechanical respirators and fibre-optic bronchoscopes (Yu, 1979). Spread appears to be via hands, although *Serratia* spp. tend to be infrequently detected on hands (Christensen *et al.*, 1982; Newport *et al.*, 1985). Community-acquired *S. plymuthica*, *S. ficaria* and *S. proteamaculans* subsp. *quinovora* infections have resulted by contamination from soil and plant material.

Infections can be sporadic or epidemic. *Serratia* spp. is a relatively rare cause of bacteraemia, causing 0.4% of cases in one large UK

hospital (Eykyn, Gransden and Phillips, 1990). In the USA in 1975, *Serratia* spp. were responsible for 3.8% of cases of nosocomial bacteraemia but since then have not appeared in the top 10 isolates (Pittet, 1993). Bacteraemia in premature neonates can be particularly devastating (Berger *et al.*, 2002).

Epidemiological typing methods for *Serratia* spp. include serotyping (Newport *et al.*, 1985), bacteriocin susceptibility, phage typing and biotyping (Grimont and Grimont, 1984), antibiograms (Christensen *et al.*, 1982) and a variety of molecular techniques including polymerase chain reaction of repetitive intergenic consensus sequences (Lin *et al.*, 1994).

CLINICAL FEATURES

Serratia spp. can cause urinary tract infection, pneumonia, meningitis (rarely), endophthalmitis, bacteraemia and wound infections. One particularly striking 'non-illness' is the red diaper syndrome due to excretion of *S. marcescens* in the infant stool (Yu, 1979).

DIAGNOSIS

Serratia spp. are easily cultured on most media from infected sites. Some strains of *S. plymuthica* do not grow well at 37 °C.

Antimicrobial Susceptibility

As for *Enterobacter* spp., *Serratia* spp. are generally resistant to cefuroxime, cephradine and amoxicillin but sensitive to ceftazidime, imipenem, ceftiofime and ciprofloxacin (Reeves, Bywater and Holt, 1993). Susceptibility to cefotaxime and gentamicin is less predictable. *Serratia* spp. are also relatively resistant to disinfectants, *S. marcescens* being the most resistant and *S. plymuthica* the least. *Serratia* spp. can also express chromosomally encoded cephalosporinases (*AmpC*). The rarer *Serratia* spp. are naturally resistant to cefazolin, cefuroxime and rifampicin but usually sensitive to cotrimoxazole, piperacillin, carbapenems and fluoroquinolones (Stock *et al.*, 2003).

Serratia spp. are able to acquire and maintain resistance plasmids; incompatibility groups B, C, F1, F11, H2, M, N, P and W have been detected (Grimont and Grimont, 1984). Plasmids appear to be able to move from genus to genus, and one American hospital outbreak of infection due to gentamicin-resistant *S. marcescens* was followed by another due to similarly resistant *K. pneumoniae* carrying the same plasmid (Thomas *et al.*, 1977). Recently plasmid-encoded resistance to imipenem has been described in clinical isolates of *S. marcescens* (Ito *et al.*, 1995).

TREATMENT AND PREVENTION

Specific treatment depends upon the susceptibility of the isolate but most are still susceptible to ciprofloxacin, imipenem and ceftazidime. Prevention is by appropriate infection-control measures. Especially care must be taken with storage of disinfectants, plastic blood containers and contact lenses.

Donovanosis and *Klebsiella* spp.

John Richens

Centre for Sexual Health and HIV Research, Royal Free and University College Medical School, London, UK

INTRODUCTION

Donovanosis is the name given to an ulcerative tropical sexually transmitted infection that was first described in India by McLeod (1881). Charles Donovan was the first to describe the presence of intracellular inclusions (now known as Donovan bodies) as the characteristic pathological feature (Donovan, 1905). The disease has been known by a confusing variety of different names. Among experts, donovanosis is the preferred term, whilst Index Medicus retains granuloma inguinale as its major medical subject heading. Donovan bodies have to be distinguished from the protozoal Leishman-Donovan bodies that characterize leishmaniasis which were also described by Charles Donovan at much the same time. Donovanosis is one of the least common sexually transmitted infections, and it has declined markedly in many formerly endemic areas (Gupta and Kumar, 2002). It has been targeted for eradication in Australia (Bowden and Savage, 1998a), and arguments have been put forward for global eradication (O'Farrell, 1995).

DESCRIPTION OF THE ORGANISM

The Gram-negative intracellular coccobacilli associated with donovanosis were first cultured successfully in chick embryo yolk sac by Anderson in the United States (Anderson, 1943). Subsequently, very few successful isolations were reported, but a resurgence in interest in the organism developed when successful culture efforts were reported by one group in Durban, employing human peripheral blood mononuclear cells (Kharsany *et al.*, 1997), and a second group employing HEp 2 cells in Darwin (Carter *et al.*, 1997). Both groups have subsequently scrutinized the genetic material of their cultured organisms, confirming the long-held hypotheses that the organism is closely related to *Klebsiella* species. The Darwin group have put forward a case for renaming the organism *Klebsiella granulomatis* (Carter *et al.*, 1999), citing 98.8% homology of the rRNA gene to *Klebsiella pneumoniae* and 99.8% homology to *Klebsiella rhinoscleromatis* (the latter organism causes a histologically analogous intracellular infection, rhinoscleroma, in the upper respiratory tract). They also reported 99.7% and 99.8% homology between the *PhoE* genes in *Calymmatobacterium* and *K. pneumoniae* and *K. rhinoscleromatis*, respectively. The Durban group have argued that the differences from *Klebsiella* are great enough to justify retaining the separate species name, *Calymmatobacterium* (Kharsany *et al.*, 1999). The ultrastructural features of the organisms in tissue and in culture have been recently described by Kharsany *et al.* (1998) and are typical of Gram-negative bacteria.

PATHOGENESIS

The histopathological features of established infection comprise the presence of intracellular bacteria within histiocytes, surrounded by a dense plasma cell infiltrate, ulceration of skin or mucosa and local epithelial hyperplasia (Sehgal, Shyamprasad and Beohar, 1984). Infection spreads readily to local lymph nodes where a notable characteristic is the breakdown of overlying skin to form further ulcers. Haematogenous dissemination is a rare event, most likely to occur in pregnant women with untreated lesions of the cervix (Paterson, 1998). Involvement of bone and viscera may occur in these cases. The intracellular location of bacteria may be linked to the lack of the sucrose transporter gene *ScrA* found in extracellular *Klebsiella* species (Hart and Rao, 1999). An intriguing detailed histopathological and ultrastructural study of the behaviour of donovanosis within the epidermis has been recently undertaken by Ramdial *et al.* (2000).

EPIDEMIOLOGY

The disease is most frequently encountered in India, Brazil, Papua New Guinea and parts of South Africa. It is on the verge of eradication from the Australian aboriginal population and has already disappeared from the southern United States where it used to be common. The association of the disease with risky sexual behaviour and the anogenital location of lesions point strongly to sexual transmission as the dominant mode of spread, although unconvincing efforts have been made to argue the importance of non-sexual transmission (Goldberg, 1964). Mother-to-child transmission may occur during delivery (Bowden *et al.*, 2000).

CLINICAL FEATURES

The classic presentation is a painless beefy-red ulcer in the anogenital region, developing 3–40 days after exposure (Clarke, 1947). Hypertrophic lesions standing out from the level of surrounding skin are often seen. As lesions advance, a pungent odour often develops. Single or multiple lesions may occur. When the infection reaches local lymph nodes, the picture ranges from painless adenopathy, to subcutaneous abscess (often referred to as a pseudobubo), to ulcerative lesions arising in the overlying skin. Primary lesions of the mouth with extension to cervical nodes may occur (Veeranna and Raghu, 2002). In females, primary lesions may occur on the cervix (Arnell and Potekin, 1940) and infection may extend upwards into the uterus and tubes. Complications include the development of lymphoedema,

scarring and the late development of squamous carcinoma. Destructive lesions result in genital deformity including penile autoamputation. Rare cases of perinatal transmission have been described, often involving the ears when infectious material is forced into the external auditory meatus from the cervix during delivery (Bowden *et al.*, 2000). The extraordinary diversity of possible clinical presentations is well illustrated in a recent letter from Australia describing donovanosis presenting as psoas abscess, perinephric abscess, intraoral lesions, cervical adenopathy, infertility and spinal cord compression (Mein, Anstey and Bowden, 1999). Haematogenous spread of infection to bone, joints, liver and spleen has been observed in several patients, especially following delivery in women with untreated cervical lesions of donovanosis (Cherny *et al.*, 1957; Paterson, 1998). In these circumstances, the infection may cause death (Pund and McInnes, 1944). In two studies of donovanosis in HIV-coinfected patients, one from South Africa showed no influence of HIV on clinical outcomes (Hoosen *et al.*, 1996), while the other, from India, showed delayed response to treatment with erythromycin in HIV-infected patients (Jamkhedar *et al.*, 1998).

DIAGNOSIS

The differential diagnosis of donovanosis ulceration includes syphilis, chancroid and genital amoebiasis. Inguinal lesions have to be distinguished from lymphogranuloma venereum, tuberculosis, lymphoma and filariasis. Lesions of the cervix and glans penis are not infrequently mistaken for carcinoma, and it is not unknown for Donovan bodies to be missed on haematoxylin and eosin-stained biopsies, only to be recognized in resection specimens after radical surgery (Rajam and Rangiah, 1953; Hoosen *et al.*, 1990).

The mainstay of diagnosis is the identification of Donovan bodies in material collected from lesions (Richens, 1991). Such materials are collected by gently abrading the lesion to make a smear or by taking punch or snip biopsies. Donovan bodies show up well with Giemsa, Wright's or Leishman stains. They are not clearly seen with haematoxylin and eosin in biopsy material which is better processed with Giemsa, silver stains or a slow overnight Giemsa (Sehgal and Jain, 1987). Donovan bodies appear as pleomorphic coccobacilli 1–2 µm × 0.5–0.7 µm, clustered in groups within thin-walled vacuoles of macrophages. They may need to be distinguished carefully from the types of inclusions found in conditions such as leishmaniasis, histoplasmosis, rhinoscleroma and malakoplakia. Culture is not established for routine diagnosis but could be considered by laboratories able to maintain HEp 2 cells (Carter *et al.*, 1997). Careful decontamination of biopsy material with amikacin, vancomycin and metronidazole is recommended (Kharsany *et al.*, 1997). Polymerase chain reaction (PCR) tools for diagnosis have been developed but are not commercially available (Carter and Kemp, 2000). A serological test for donovanosis with 100% sensitivity and 98% specificity has been described, but it is not currently in use (Freinkel *et al.*, 1992). All patients with donovanosis should be offered screening for other sexually transmitted infections and for HIV.

TREATMENT

Recent experience in Australia with azithromycin suggests that this antibiotic is superior to alternatives, although direct comparisons with alternatives have not been conducted (Bowden *et al.*, 1996; Mein *et al.*, 1996; Bowden and Savage, 1998b). Azithromycin may be administered on a daily or weekly basis with equivalent good results (Bowden *et al.*, 1996). Published guidelines (Richens, 1999; Sexually Transmitted Diseases Treatment Guidelines, 2002) for the management of donovanosis also recommend doxycycline, fluorinated quinolones, ceftriaxone and erythromycin as alternatives. Antibiotic treatment should be continued until lesions have fully healed. A change

of antibiotic therapy or addition of a second agent should be considered in patients not responding. Operative procedures may be required for patients with deforming genital lesions (Bozbora *et al.*, 1998). Metronidazole is useful as adjunctive therapy for patients with especially malodorous lesions.

CONTROL

Partner management should be undertaken whenever donovanosis is diagnosed. The recent Australian campaign to eradicate donovanosis provides a useful model for other endemic areas. Key features of this campaign were setting up a co-ordinating structure, dialogue with aboriginal community leaders, education for the community and for health workers, provision of drugs and diagnostic support, improved surveillance, operational research and liaison with neighbouring Papua New Guinea which contains an important reservoir of infection.

Proteus, Providencia and Morganella spp.

Peter M. Hawkey

Division of Immunity and Infection, The Medical School, Edgbaston, Birmingham B15 2TT, UK

TAXONOMY AND GENERAL DESCRIPTION OF THE GENERA

These genera have been grouped as the tribe Proteeae as they can oxidatively deaminate phenylalanine and tryptophan. Other characteristics which suggest an oxidase-negative non-lactose-fermenting bacterium may belong to this tribe are swarming (*Proteus*), motility, methyl red (MR)⁺/Voges-Proskauer⁻, H₂S positive, urease production (except *Providencia*), protease/lipase production (*Proteus*) and resistance to polymyxins.

DNA homology studies have shown that *Proteus morganii*, as it was previously known, has but 20% homology with the other members of the Proteeae (Brenner *et al.*, 1978), and in consequence the separate genus *Morganella* was created and existing and new species redistributed amongst *Proteus* and *Providencia*. Because of the similarities in pathogenicity and natural habitat, clinical microbiologists do still tend to group these bacteria together. *Proteus mirabilis* and *Proteus vulgaris* were originally described in 1885, and although the taxonomic status of *P. mirabilis* has been stable, *P. vulgaris* has undergone some changes. DNA hybridization studies by Hickman *et al.* (1982) suggested that *P. vulgaris* can be divided into three groups: (i) biogroup (BG) 1 strains being named as *Proteus penneri*, which is also defined as genomospecies 1; (ii) BG 2 strains are genetically distinct (genomospecies 2) and the name *P. vulgaris* has been reassigned to this species; (iii) BG 3 strains contain the genomospecies 3, 4, 5 and 6, of which genomospecies 3 has been named *P. hauseri*, the rest being unnamed (O'Hara *et al.*, 2000b). *Proteus myxofaciens* is not a human pathogen and is only reported to have been isolated from gypsy moth larvae (Farmer *et al.*, 1985). The bacterium, previously known as *Proteus morganii*, described by Morgan in 1906 from the faeces of children with diarrhoea, was reassigned to its own genus *Morganella* (Brenner *et al.*, 1978). Subsequently two subspecies, *morganii* and *sibonii*, have been characterized (O'Hara, Brenner and Miller, 2000a; O'Hara *et al.*, 2000b).

There are currently five recognized species in the genus *Providencia*, which was named after Providence, Rhode Island, where C.A. Stuart worked on these bacteria. The new species *Providencia rustigianii* and *Providencia heimbachae* were originally grouped within *Providencia alcalifaciens*, but neither are found in human clinical specimens (Muller *et al.*, 1986). The remaining species are easily distinguished (Table 32.1). The occurrence of plasmid-encoded urease activity in some strains of *Providencia stuartii*, which were previously confused with *Proteus* (now *Providencia*) *rettgeri* should be noted (Farmer *et al.*, 1985). Full descriptions of the species have recently been reviewed (O'Hara, Brenner and Miller, 2000a).

The biochemical characteristics useful in differentiating the genera of the tribe Proteeae are summarized in Table 32.1 (in bold type).

A rapid identification scheme for the common species, using six media, has also been described (Senior, 1997). One of the most striking features of the genus *Proteus* in culture is their ability to swarm on solid media. Short motile cells at the edge of the growing colony differentiate into very elongated hyperflagellated swarm cells. These align along their axes and by coordinated flagella action swarm as a two-dimensional raft within a film of hydrated polysaccharide. Migration ceases periodically with increased cell septation and reduced flagellation, giving rise to the bulls-eye appearance (Figure 32.1). Transposon mutagenesis has shown that many differentiation and flagellar genes are involved in swarming. A sugar transferase gene (*cmfA*) and a membrane-spanning protein influencing cell shape (*ccmA*) have also been shown to influence swarming (Hay *et al.*, 1999). Putrescine has recently been shown to act as an extracellular signal for effective swarming, putrescine-repressing activity of the SpeB enzyme which is involved in the synthesis of putrescine (Sturgill and Rather, 2004).

All members of the genus possess flagellae (usually peritrichous) and are motile with the exception of some strains of *M. morganii*. The flagellae of *P. mirabilis* are variable in morphology.

The major antigenic determinates of the Proteeae are somatic (O) and flagellar (H) antigens. Typing schemes for detecting O antigens have been described in detail for most of the species (Penner, 1981).

PATHOGENICITY OF PROTEEAE

A detailed review of potential virulence factors in *Proteus* ssp. has been published (Rozalski, Sidorczyk and Kotelko, 1997). It has long been recognized that the possession of urease (a nickel metallo-enzyme) by a number of the members of the Proteeae represents a likely pathogenicity factor (Mobley and Hausinger, 1989). A wide range of biochemically and genetically distinct ureases are found amongst all of the urease-positive members of the Proteeae, many of which have now been cloned and sequenced. The gene in *P. mirabilis* is chromosomal and consists of the structural genes *ureABC*; *ureD* is upstream and *ureEFG* downstream, *ureDEFG* encode proteins that are involved in nickel ion insertion and enzyme assembly. The *ureR* gene lies upstream of *ureD* and is a positive transcriptional regulator required for both basal and induced urease activity, which is an essential virulence factor in urinary tract infections (Dattelbaum *et al.*, 2003). This gene cluster interestingly shows considerable homology and organizational similarities to urease gene clusters on plasmids in *Escherichia coli*, *Prov. stuartii* and *Salmonella cubana*, suggesting common routes of evolution (D'Orazio and Collins, 1993). The formation of urinary stones results from the pH rise that occurs in urine due to the release of ammonium ions from urea as a result of activity of bacterial ureases. The stones are a mixture of struvite

(MgNH₄ PO₄·6H₂O) and carbonate apatite (Ca₁₀(PO₄)₆ CO₃) which precipitate at pH < 6.5 (Mobley and Hausinger, 1989). It has been observed that *P. mirabilis* is associated with blocked urinary catheters rather than other urease-producing bacteria (Mobley and Warren, 1987). The capsular polysaccharide from *P. mirabilis* enhances

Figure 32.1 Swarming culture of *Proteus mirabilis* (blood agar, 22 °C incubated for 40 h) demonstrating the 'bull's-eye' appearance.

struvite formation, possibly by weakly concentrating Mg²⁺ because of its structure and anionic nature (Dumanski *et al.*, 1994). The most frequently encountered member of the Proteaceae in infected colonized urinary catheters is *Prov. stuartii* (Mobley *et al.*, 1988). It appears this is not due to increased entry of *Prov. stuartii* into the catheter system but due to the ability of *Prov. stuartii* to adhere to catheter material via mannose-resistant *Klebsiella*-like haemagglutinins (MR/K), whereas strains only found in patients for a short duration express mannose-sensitive haemagglutinins (Mobley *et al.*, 1988). The formation of crystalline encrustations in urethral catheters does not only require that the bacteria produce urease as do *P. mirabilis*, *P. vulgaris* and *Prov. rettgeri* but that the urine pH rises above 8.0, these species producing encrustations in a model whereas urease-positive *M. morganii*, *K. pneumoniae* and *P. aeruginosa* did not (Stickler *et al.*, 1998). *Proteus mirabilis* also expresses MR/K-type fimbriae which probably contribute to catheter adherence, but also produce *P. mirabilis* fimbriae (PMF), uroepithelial cell adhesin (UCA), ambient temperature fimbriae and mannose-resistant/*Proteus*-like fimbriae (MR/P) (Rozalski, Sidorczyk and Kotelko, 1997). The association of MR/P fimbriae and the development of pyelonephritis was made by Silverblatt and Ofek in 1978 (cited in Rozalski, Sidorczyk and Kotelko, 1997), and the relevant gene has been cloned. The use of mrpA[–] mutants in a mouse model of ascending urinary tract infection confirms the important role of MR/P fimbriae in the pathogenesis of acute pyelonephritis (Rozalski, Sidorczyk and Kotelko, 1997). PMF have been shown to play a role in the development of both bladder colonization and kidney colonization (Zunino *et al.*, 2003). Recently the gene encoding UCA has been cloned, and amino acid sequence homology was found between a range of different pilins in other bacteria, such as *Haemophilus*, *E. coli* pilins F17, G and IC (Cook *et al.*, 1995). UCA seems to be distinct from MR/P and may be responsible for uroepithelial cell adhesion. The use of a Tn5-based

transposon mutagenesis system in *P. mirabilis* to produce swarm cell-negative mutants in the mouse model has shown the importance of hyperflagellated swarm cells in establishing ascending infections of the urinary tract (Allison *et al.*, 1994). During swarm cell differentiation a number of virulence factors are produced, including an extracellular metalloprotease with activity against IgA (Senior, Loomes and Kerr, 1991). Molecular analysis of the *zapA* gene, which encodes a metalloprotease (serralyisin type) is expressed only in swarmer cells; *zapA*⁻ mutants failed to degrade IgA and had decreased survival in the mouse UTI model (Walker *et al.*, 1999).

Siderophores are essential for bacteria to acquire iron, particularly when multiplying in an animal host. The Proteae are unique amongst Enterobacteriaceae in possessing amino acid deaminases which result in the production of α -keto and α -hydroxycarboxylic acids, such as phenylpyruvic and indolylpyruvic acids; these in turn, bind actively to iron and have been demonstrated to have siderophore activity (Drechsel *et al.*, 1993).

A study of traveller's diarrhoea in UK patients demonstrated a strong association with the isolation of *Prov. alcalifaciens* from faeces (Haynes and Hawkey, 1989). A case-control study in Bangladesh also demonstrated a highly significant association with diarrhoea in children (Albert, Faruque and Mahalanabis, 1998). There has also been a report of *Prov. alcalifaciens* with evidence for its aetiological role in causing a large outbreak of food poisoning in Japan (Murata *et al.*, 2001). It has further been shown that strains of *Prov. alcalifaciens* isolated from the faeces of patient suffering from diarrhoea in Bangladesh are capable of invading Hep-2 cell monolayers, with actin condensation (Albert *et al.*, 1995). Subsequently some strains have been shown to be resistant to complement and translocate from the gut (Vieira, Koh and Guth, 2003).

EPIDEMIOLOGY

Habitat

Most of the Proteae are widely distributed in nature, being frequently found in the faeces of animals and humans as well as in associated materials such as decomposing meat and sewage. All of the clinically significant species were found in a study of faecally contaminated calf bedding, bovine meat being suggested as a possible route of colonization of the human gut (Hawkey, McCormick and Simpson, 1986). Faeces have been reported as a source for nosocomial infections caused by *P. mirabilis* (Burke *et al.*, 1971), *M. morgani* (Williams *et al.*, 1983) and *Prov. stuartii* (Hawkey *et al.*, 1982). Maternal vaginal carriage of *P. mirabilis* (probably secondary to faecal carriage) has been described as a significant source of neonatal infections (Bingen *et al.*, 1993). The carriage of *P. mirabilis* in the prepuce of 22% of uncircumcised and 1.7% of circumcised male infants is thought to explain the occurrence of *P. mirabilis* infections in male babies (Glennon *et al.*, 1988).

Proteus mirabilis and less frequently *P. vulgaris*, possibly due to its low carriage rate in faeces (Senior and Leslie, 1986), are associated with urinary tract infections and the infected urine, particularly when patients have an indwelling catheter, can be a source for cross-infection; infected urine can therefore be regarded as a habitat for Proteae (Hickman and Farmer, 1976; Warren, 1986). Similarly *Prov. stuartii* (Hawkey *et al.*, 1982) and *M. morgani* (McDermott and Mylotte, 1984) nosocomial infection can be acquired from infected urine, although in the case of the last organism infected wounds may be a significant source (Williams *et al.*, 1983).

Providencia alcalifaciens can be isolated from both human and animal faeces and has been assumed in the past not to be a human pathogen. However, early workers such as C.A. Stuart and Patricia Carpenter (Central Public Health Laboratory, London) thought it could cause diarrhoeal illness (Penner, 1981). Recently good evidence for an enteropathogenic role has emerged (see above).

HUMAN INFECTIONS

The most common infection caused by Proteae is infection of the urinary tract. *Proteus mirabilis* is by far the most common species of Proteae isolated from the urinary tract most frequently being nosocomial (de Champs *et al.*, 2000) and is the third most frequently isolated species of Enterobacteriaceae in the clinical laboratory (Hickman and Farmer, 1976). Whilst the association of Proteae with urinary tract infection, particularly the anatomically abnormal or catheterized urinary tract (*P. mirabilis* and *Prov. stuartii* in particular), is very well documented (Warren *et al.*, 1982; Hawkey, 1984; Ehrenkranz *et al.*, 1989), detailed prospective epidemiological studies using strain typing are rare. It seems likely that faecal carriage can be a source for subsequent infection of the abnormal tract (Hawkey *et al.*, 1982). The colonized groin area of geriatric patients has also been proposed as a source for a Proteae (Ehrenkranz *et al.*, 1989), although this needs to be proven by typing studies. Cross-infection of both multiple and an endemic strain amongst catheterized patients in the hospital setting via hands and fomites (e.g. jugs and specific gravity cylinders) has been documented particularly for *Prov. stuartii* (Hawkey *et al.*, 1982; Rahav *et al.*, 1994). In neonatal units, the vaginal carriage of *P. mirabilis* (Bingen *et al.*, 1993) and rectal/vaginal carriage in a nurse (Burke *et al.*, 1971) and probable subsequent spread via hands have led to serious outbreaks of septicaemia, meningitis and omphalitis. Cross-infection by *M. morgani* is rare, but episodes in which infected wounds co-infected with *P. mirabilis* have acted as a source with subsequent transfer to other patients have been described and documented with strain typing (Williams *et al.*, 1983). In a review of 19 cases of *M. morgani* bacteraemia the most common source was found to be an infected wound, and extensive use of cephalosporins (to which *M. morgani* is often resistant) was thought to be an important factor leading to the development of infection (McDermott and Mylotte, 1984). The source and route of transmission of *Prov. alcalifaciens* in human diarrhoeal illness have not been investigated, but are likely to be via food (Murata *et al.*, 2001) or asymptomatic faecal carriage leading to transient hand carriage.

EPIDEMIOLOGICAL TYPING METHODS

A wide range of epidemiological typing methods have been applied to Proteae, the oldest being O serotyping (Penner, 1981) which has been replaced by molecular methods. In the case of the swarming *Proteus* spp. use has been made for many years of the Dienes test. Originally described by Dienes in 1946, a line of demarcation appears between two swarming strains if they are different, whereas identical strains swarm into one another (Figure 32.2). The phenomenon appears to be largely due to both sensitivity to and production of bacteriocins (Senior, 1977). It is an easily applied method and has been shown to have a similar index of discrimination to ribotyping and PFGE (Pfaller *et al.*, 2000).

Bacteriocin typing schemes have been described for Proteae (Senior, 1977), as has Bacteriophage typing (Hickman and Farmer, 1976). In a study of all species of Proteae a wide range of ribotype patterns were seen, suggesting that this method would be a sensitive typing method (Pignato *et al.*, 1999). A recent comparison of ribotyping and arbitrarily primed polymerase chain reaction typing (AP-PCR) in investigating *P. mirabilis* cross-infection in a maternity hospital concluded that AP-PCR was equivalent to ribotyping and easier to perform (Bingen *et al.*, 1993). Ribotyping has been successfully applied to an outbreak of *Prov. stuartii* catheter infection, suggesting multiple sources of infecting bacteria (Rahav *et al.*, 1994). Tandem tetramer-based microsatellite typing has been suggested to have a high discrimination index when applied to *P. mirabilis* (Cieslikowski *et al.*, 2003). PFGE has been applied to *P. mirabilis* typing (Sabbuba, Mahenthiralingam and Stickler, 2003).

Figure 32.2 Diene's test, lines of compatibility are seen between isolates 1 and 2; 3 and 6 indicating that they are indistinguishable but different from each other. Isolates 4 and 5 are incompatible and different from the other two groups of isolates (1 and 2; 3 and 6). Blood agar, incubated for 48 h at 22 °C.

CLINICAL MANIFESTATIONS

The urinary tract is the most commonly infected site, although infection of the anatomically normal and uncatheterized tract is rare. Pyelonephritis and urinary stone formation are common features of infection with *P. mirabilis* for the reasons described above. *Providencia stuartii*, *Proteus mirabilis* and *M. morganii* are the most frequently found species in the catheterized urinary tract; often more than one species of Proteeae is present and usually mixed with other bacterial species. *Providencia stuartii* is the species which persists best; in a prospective study of bacteriuria in 20 catheterized patients, the mean duration of new episodes was 10.4 weeks for *Prov. stuartii*, 5.5 weeks for *P. mirabilis* and 2.9 weeks for enterococci (Warren *et al.*, 1982).

The frequent presence of *Prov. stuartii* in catheter bags has been shown to explain the condition in which the bag turns deep purple in colour, termed the purple urine bag syndrome. Some strains of *Prov. stuartii* possess an indoxyl sulphatase which degrades high levels of urinary indoxyl sulphate (usually in patients with bacterial overgrowth of the small bowel) to indoxyl, which condenses to form the insoluble dyes indirubin (red) and indigo (blue). These dyes are soluble in the plasticizers of the bag wall and stain it purple (Dealler Hawkey and Millar, 1988).

Proteus mirabilis has been reported as causing a number of other infections, such as bacteraemia arising from the infected/colonized urinary tract (Muder *et al.*, 1992; de Champs *et al.*, 2000), nosocomial wound infections (Chow *et al.*, 1979; Williams *et al.*, 1983; de Champs *et al.*, 2000) and meningitis in neonates arising from infected umbilical stumps (Burke *et al.*, 1971). It is also found with other bacteria in brain abscess derived from middle ear infections. Chronic colonization of the ear may cause local infections and local spread results in its isolation from brain abscesses. Other members of the Proteeae, notably *M. morganii*, are associated with soft-tissue infections, such as wound infections (Tucci and Isenberg, 1981; Williams *et al.*, 1983; McDermott and Mylotte, 1984). In studies of bacteriuria *P. mirabilis* is the most frequently reported of the Proteeae

(McDermott and Mylotte, 1984). *Proteus vulgaris* and *P. penneri* cause a spectrum of infections similar to *P. mirabilis* but are somewhat rarer. In long-term care and geriatric facilities, where patients with urinary catheters are common, *Prov. stuartii* is the most frequent cause of bacteraemia (Hawkey, 1984; Muder *et al.*, 1992). *Providencia stuartii* has been noted to cause nosocomial pneumonia and wound and burn infections, but these are rare (Hawkey, 1984). The role of Proteeae in diarrhoeal disease has long been debated (Penner, 1981). Definitive evidence for the enteropathogenicity of *Prov. alcalifaciens* has now emerged (see above).

LABORATORY DIAGNOSIS

Isolation

All members of the Proteeae likely to be encountered in clinical material are capable of growth on commonly used laboratory media (nutrient, blood and MacConkey's agar) incubated at 37 °C in room air. A number of selective media have been developed for the isolation of Proteeae (Penner, 1981). PIM agar, which has been used in a number of studies, utilizes clindamycin and colistin as the selective agents and tryptophan/tyrosine as differential agents (Hawkey, McCormick and Simpson, 1986).

Identification of Proteeae is generally reliably achieved using one of the recognized commercial identification systems, either automated or manual and chromogenic agars are useful for urinary isolates (Filius *et al.*, 2003). It is worth noting that *Prov. stuartii* may pose problems and be misidentified by most systems if supplementary tests are not included (Cornaglia *et al.*, 1988). A modified MacConkey's agar which detects phosphatase activity has been shown to alleviate this problem (Thaller *et al.*, 1992). The biochemical characteristics of the Proteeae species are summarized in Table 32.1. In the case of blood culture isolates, the pathogenic status of those isolates is clear; however, from colonized wounds and catheter urines the clinical condition of the patient is paramount in deciding the level of identification and reporting. One study has shown that the Proteeae may be selectively under-reported by some microbiology laboratories from catheter urine specimens, with the potential for missed treatment of bacteraemic patients (Damron *et al.*, 1986).

RESISTANCE TO ANTIMICROBIALS AND CHEMOTHERAPY OF PROTEEAE

β -Lactam antibiotics are widely used to treat infections caused by bacteria belonging to the family Enterobacteriaceae. In the case of the Proteeae, *P. mirabilis*, unlike the other species [except *Prov. alcalifaciens*, which is generally very susceptible to antibiotics (Penner, 1981)], does not appear to produce a chromosomal cephalosporinase or AmpC type penicillinase (Livermore, 1995). In consequence, many cases of infection caused by *P. mirabilis* can often be treated with ampicillin or older cephalosporins such as cephadrine or cephalexin. *Providencia stuartii* carries a number of intrinsic plasmid-mediated antibiotic resistance determinants and may be difficult to treat (Hawkey, 1984; Warren, 1986). The extended-spectrum cephalosporins are suitable for treating infections caused by the *Providencia* spp., *M. morganii* and *P. vulgaris*, although plasmid-mediated extended-spectrum β -lactamases are being increasingly reported from the Proteeae particularly *P. stuartii* (Tumbarello *et al.*, 2004) and *P. mirabilis* (de Champs *et al.*, 2000). The TEM family of β -lactamases is found in most of the species of Proteeae at varying frequencies, often dictated by local usage of ampicillins (Hawkey, 1984). Imipenem resistance is very rare in the Proteeae with the exception of occasional isolates of *P. mirabilis*, when altered penicillin-binding proteins appear to be

responsible (Neuwirth *et al.*, 1995), although the carbapenemase IMP-1 has been reported from Japan in a *P. vulgaris* isolate (Arakawa *et al.*, 2000).

Most isolates of Proteaceae are susceptible to aminoglycosides, provided none of the plasmid-mediated aminoglycoside-inactivating enzymes are present [e.g. APH(3')]. *Providencia stuartii* and probably some strains of *Prov. rettgeri* carry a chromosomally encoded gentamicin 2'-N-acetyl-transferase (AAC2') which is not always expressed. The enzyme probably plays a role in the maintenance of peptidoglycan structure (Franklin and Clarke, 2001). Commonly used antibiotics for the treatment of urinary tract infections caused by Proteaceae are trimethoprim and fluoroquinolones, such as ciprofloxacin, which are effectively subject to sensitivity testing of individual isolates as resistance to these agents is increasing. Caution should be observed in using chloramphenicol to treat brain abscesses caused by *P. mirabilis* as most strains carry an inducible chloramphenicol acetylase gene (Charles *et al.*, 1985) which will result in treatment failure. *Providencia stuartii* has been regarded by some workers to be resistant to the disinfectant chlorhexidine. It has been suggested that chlorhexidine inhibits membrane-bound ATPase, and this may provide an understanding for resistance, although a study of *Prov. stuartii* mutants resistant to high levels of chlorhexidine failed to confirm this (Chopra, Johnson and Bennett, 1987). Proteaceae are usually intrinsically resistant to the polymyxins and nitrofurantoin, possibly due to particular properties of their bacterial membranes.

An interesting alternative to antibiotic treatment for UTIs caused by *P. mirabilis* has been suggested following the successful protection of mice from infection by vaccination with purified mannose – resistant, *Proteus*-like fimbriae (Li *et al.*, 2004).

Yersinia spp.

M. B. Prentice

Department of Microbiology, University College Cork, Cork, Ireland

INTRODUCTION

The genus *Yersinia* contains three species that are well-established human pathogens. *Yersinia pestis* is responsible for bubonic plague, an often-fulminant systemic zoonosis. *Yersinia pseudotuberculosis* and *Y. enterocolitica* cause yersiniosis, a self-limiting gastrointestinal illness that may have serious complications in special circumstances. As for many other bacterial pathogens, genome-sequencing projects are now revealing the genetic basis for these phenotypic differences.

DESCRIPTION OF THE ORGANISMS

Taxonomy

Yersinia pestis was isolated for the first time by Alexandre Yersin in 1894 in Hong Kong (Yersin, 1894), following the spread of infection from mainland China. *Yersinia pseudotuberculosis* was first reported in 1883 from caseating lesions in rodents and was for many years classified with *Yersinia pestis* in the genus *Pasteurella* (Bercovier and Mollaret, 1984). *Yersinia enterocolitica* was first reported as a *Y. pseudotuberculosis*-like organism isolated from enteric specimens and skin lesions of patients in the United States in 1939 (Schleifstein and Coleman, 1939) and later named *Bacterium enterocoliticum*. In the 1960s European microbiologists identified another heterogeneous group of bacteria resembling but distinct from *Yersinia* (then *Pasteurella*) *pseudotuberculosis* and termed them *Pasteurella X*. In 1964 Frederiksen pointed out similarities between *Pasteurella X* and *Bacterium enterocoliticum* and proposed the new species name *Yersinia enterocolitica* to cover this biochemically disparate group (Frederiksen, 1964). *Yersinia intermedia*, *Y. frederiksenii*, *Y. kristensenii*, *Y. aldovae*, *Y. mollaretti* and *Y. bercovieri* have subsequently been split off from *Y. enterocolitica sensu stricto* within the group of *Y. enterocolitica*-like organisms on biochemical and genetic grounds. They are of doubtful pathogenicity and little clinical significance.

Apart from *Y. ruckeri*, a fish pathogen, DNA relatedness among *Yersinia* spp. is at least 40%. The molar G+C ratio of *Yersinia* is 46–50%, consistent with that for Enterobacteriaceae (Bercovier and Mollaret, 1984). Multi-locus sequence typing (MLST) of housekeeping genes suggests that *Y. pestis* is actually a clone derived from *Y. pseudotuberculosis* (Achtman *et al.*, 1999). At least two strains of *Y. pestis* have now been sequenced (Parkhill *et al.*, 2001; Deng *et al.*, 2002), allowing *Y. pestis* genomic array construction. Microarray-based gene complement comparison between *Y. pestis* and *Y. pseudotuberculosis* strains confirms the very close relationship shown on MLST typing (Hinchliffe *et al.*, 2003). Current *Y. pestis* strains form a very

homogeneous group that is estimated to have emerged 1500–20000 years ago (Achtman *et al.*, 1999).

In this short period of evolutionary time, *Y. pestis* has evolved the ability to colonise an insect vector (the flea) and establish a transmission cycle between mammalian hosts by novel subcutaneous and pneumonic routes of infection.

Organism Morphology and Growth

Gram-negative coccobacilli are short rods with rounded ends 1–3 µm long and 0.5–0.8 µm in diameter (Bercovier and Mollaret, 1984: 67). They are non-sporing, and only *Y. pestis* strains (grown *in vivo* or at 37 °C) form a capsule (Brubaker, 1991; Perry and Fetherston, 1997). *Yersinia pestis* in particular shows bipolar staining and pleomorphism. *Yersinia pestis* is non-motile but all other species are motile at 25 °C and non-motile at 37 °C. All species are facultative anaerobes and produce catalase but not oxidase.

All yersiniae grow on nutrient agar forming smaller colonies than other Enterobacteriaceae. All have a growth optimum of less than 37 °C (25–29 °C) and grow over a range of 4–42 °C. *Yersinia pestis* requires 48-h incubation to produce 1 mm colonies at 25–37 °C, whereas the enteropathogenic yersiniae produce visible colonies after 24 h. *Yersinia pestis* colonies are opaque, smooth and round with irregular edges, whereas other *Yersinia* spp. rapidly produce smooth-edged colonies with an elevated centre. Yersiniae are non-haemolytic on blood agar. Although *Y. enterocolitica* grows well on MacConkey agar and other enteric media, *Y. pestis* and *Y. pseudotuberculosis* grow poorly on MacConkey agar on primary isolation (however, laboratory-adapted *Y. pseudotuberculosis* strains may flourish) (Mair and Fox, 1986). Iron is required for the growth of all yersiniae and is important in pathogenicity.

Normal Habitat

Yersinia pestis is primarily a rodent pathogen usually transmitted by the bite of an infected flea and therefore has two main habitats: (i) in the stomach or proventriculus of various flea species at ambient temperature or (ii) in the blood stream or tissues of a rodent host at body temperature (Perry and Fetherston, 1997). There may be an inanimate reservoir in the soil of rodent burrows for some months after their inhabitants have died (Mollaret, 1963), but *Y. pestis* has exacting nutritional requirements (Brubaker, 1991) that make it less well equipped to survive in the environment than the other *Yersinia* spp. *Yersinia pseudotuberculosis* and *Y. enterocolitica* are spread by the enteric route, and their habitat is either in the host's gut or its associated lymphatic tissue, or in the food and water by which the host is

infected. *Yersinia enterocolitica* strains lacking virulence determinants and other avirulent *Yersinia* spp. are frequently found in the environment (including human foods) and can be isolated in equal frequency from the stools of asymptomatic and symptomatic humans (Van Noyen *et al.*, 1981). Outbreaks of disease related to specific food or water supplies contaminated with fully virulent *Y. enterocolitica* are relatively rare but well recognised (Cover and Aber, 1989; Lee *et al.*, 1990; Jones, 2003).

PATHOGENICITY

Yersinia pestis must cause disseminated infection with bacteraemia of at least 10^8 bacteria per ml in the mammalian host for transmission by a flea vector (Brubaker, 2003) or the respiratory route. In contrast, *Y. pseudotuberculosis* and *Y. enterocolitica* are more likely to be transmitted if the host remains alive to spread the infection by chronic faecal excretion. The main virulence factors are listed in Table 33.1. All the pathogenic yersiniae share a tropism for lymphoid tissue and an ability to avoid the non-specific immune response of the host (Brubaker, 1991, 2003). Although *Y. pestis* and *Y. pseudotuberculosis* grow well in macrophage cell lines (Pujol and Bliska, 2003), in animal models of disease they are predominantly found in extracellular sites in the later stages of systemic infection.

Factors Unique to *Y. pestis*

Yersinia pestis possesses two plasmids not found in other *Yersinia* spp. that produce virulence factors and other factors required for flea colonisation: the 100-kb pFra plasmid (sometimes called pMT1) (Prentice *et al.*, 2001) and the 9.5-kb pPst (or pPCP1) plasmid (Table 33.1).

pFra encodes a phospholipase D enzyme Ymt (originally called *Yersinia* murine toxin because of its action on some strains of mice), essential for survival of *Y. pestis* in the flea midgut (Hinnebusch

et al., 2002). It also encodes a polypeptide [Fraction 1 (F1-antigen)] which is exported on to the cell surface, forming a fibrillar capsule (Zavialov *et al.*, 2003) that protects against phagocytosis by macrophages (Du, Rosqvist and Forsberg, 2002).

The small pPst plasmid carries the *pla* gene, encoding the Pla surface protease which activates mammalian plasminogen and degrades complement (Sodeinde *et al.*, 1992), as well as adhering to the extracellular matrix component laminin (Lahteenmaki *et al.*, 1998). The localised, uncontrolled proteolysis resulting from these activities promotes disseminated *Y. pestis* infection from the subcutaneous site of the fleabite. Disseminated infection and bacteraemia with a Gram-negative organism carries the risk of causing sudden host death by endotoxic shock, mainly due to cell wall lipid A. Shortening host life is unhelpful for maintaining the plague transmission cycle (Keeling and Gilligan, 2000) and *Y. pestis* remodels its lipid A to be less acylated and less toxigenic at 37 °C (Kawahara *et al.*, 2002), potentially prolonging host survival with a high-grade bacteraemia.

Virulent *Y. pestis* strains possess the property of pigmentation: colonies acquire brown colouration on haemin-containing media by storing haemin in the outer membrane. White non-pigmented *Y. pestis* mutants arise spontaneously on plating a fully virulent strain on haemin media and are of greatly reduced virulence in mice, but virulence is restored in mice that are overloaded with iron or haemin (Jackson and Burrows, 1956). In *Y. pestis*, the pigmented phenotype is genetically linked with other iron metabolism-related virulence factors (Perry and Fetherston, 1997; Buchrieser *et al.*, 1999). The haemin storage locus essential for the pigmentation phenotype is required for the blocking of the flea gut (Hinnebusch, Perry and Schwan, 1996; Darby *et al.*, 2002; Joshua *et al.*, 2003), apparently by the production of a biofilm (Darby *et al.*, 2002; Joshua *et al.*, 2003).

Factors Shared by *Y. pestis* and *Y. pseudotuberculosis*

The pH 6 antigen is a fibrillar protein expressed on the surface of *Y. pestis* grown at pH 6.7 or less at above 37 °C. Its expression is

Table 33.1 Pathogenicity factors of *Yersinia*

<i>Yersinia</i> spp.	Host/vector virulence factor	Gene	Gene location	Action
<i>Y. pestis</i> only	Fraction 1 antigen (Du, Rosqvist and Forsberg, 2002)	<i>cafI</i>	100 kb pFra	Inhibits macrophage phagocytosis
	Phospholipase D/murine toxin (Hinnebusch <i>et al.</i> , 2002)	<i>ymt</i>	100 kb pFra	Promotes <i>Y. pestis</i> survival in flea midgut
	Plasminogen activator (Sodeinde <i>et al.</i> , 1992)	<i>pla</i>	9.5 kb pPst plasmid	Dissemination from subcutaneous injection
<i>Y. pestis</i> and <i>Y. pseudotuberculosis</i>	pH 6 antigen (Lindler and Tall, 1993)	<i>psaA</i>	Chromosomal	Fibrillar surface protein, binds host lipoproteins
	Low calcium response (Cornelis <i>et al.</i> , 1998)	<i>yadA</i> , <i>yopH</i> , <i>lcrV</i> etc	70 kb Lcr/pYV plasmid	Type III secretion system and adhesion
All pathogenic yersiniae	Lipopolysaccharide (Darwin and Miller, 1999; Skurnik, Peippo and Ervela, 2000; Karlyshev <i>et al.</i> , 2001)	<i>rfb</i>	Chromosomal	Endotoxin activity
	Pigmentation (Hinnebusch, Perry and Schwan, 1996; Darby <i>et al.</i> , 2002; Joshua <i>et al.</i> , 2003)	<i>hms</i> locus	Chromosomal	Serum resistance (enteropathogenic <i>Yersinia</i> only: <i>Y. pestis</i> is rough) Biofilm formation, essential for <i>Y. pestis</i> flea blocking, present in enteropathogens
Mouse-lethal strains of all three species	Yersiniabactin synthesis (Carniel, Guilvout and Prentice, 1996)	<i>irp2</i>	Chromosomal	Siderophore present in all strains of <i>Yersinia</i> spp. that are highly virulent for mice (numerous other siderophores in all <i>Yersinia</i>)
Enteropathogenic yersiniae only	Inv protein	<i>inv</i>	Chromosomal	Invasion of mammalian epithelial cells
	Ail protein (Miller <i>et al.</i> , 1989; Pierson and Falkow, 1990) (<i>inv</i> inactivated in <i>Y. pestis</i>)	<i>ail</i>		
<i>Y. enterocolitica</i> only	Myf antigen (Iriarte <i>et al.</i> , 1993)	<i>myfA</i>	Chromosomal	Homologous to pH 6 antigen i.e. fimbrial structure
	ST toxin (Ramamurthy <i>et al.</i> , 1997)	<i>yst</i>	Chromosomal	Resembles <i>E. coli</i> ST toxin

associated with a more rapidly progressive illness after *Y. pestis* infection in mice (Lindler and Tall, 1993). It may act as a 'stealth cloak', coating the organism with host antigens by binding lipoprotein (Makoveichuk *et al.*, 2003).

Factors Common to all Pathogenic Yersiniae

The pYV (plasmid associated with *Yersinia* virulence) or Lcr (low calcium response) plasmid is a 70-kb plasmid essential for virulence in all the three pathogenic species. It was originally recognised to regulate a complex reaction in which *in vitro* vegetative growth is restricted when yersiniae are grown at 37 °C in low calcium conditions (<2.5 mM Ca²⁺). At the same time a series of proteins encoded by the virulence plasmid are produced and, in some cases, secreted in quantity. The growth restriction is reversed either by reduction of temperature to 26 °C or by the addition of Ca²⁺. The proteins produced include Yops (originally an acronym for *Yersinia* outer membrane proteins: they are now known not to be all membrane anchored) and the adhesin YadA.

The plasmid-encoded Yop virulon was one of the first recognised bacterial type III secretion systems, injecting paralyzing bacterial proteins into host immune response cells, thus allowing pathogenic *Yersinia* spp. to avoid phagocytosis and remain outside host cells. This phenotype is in contrast to that produced by chromosomally encoded type III secretion systems in *Salmonella*, where the SPI-1 (*Salmonella* pathogenicity island I)-encoded system facilitates bacterial invasion of epithelial cells and the SPI-2-encoded system facilitates the replication of intracellular bacteria within membrane-bound *Salmonella*-containing vacuoles (Waterman and Holden, 2003). There are now known to be chromosomal type III secretion systems in *Yersinia*, but their function is not yet defined (Haller *et al.*, 2000; Parkhill *et al.*, 2001). The virulon consists of the Yop proteins and a type III secretion apparatus, called Ysc.

The Ysc apparatus is composed of 25 proteins (Figures 33.1 and 33.2). There are two groups of Yops (Figure 33.2): intracellular effectors (YopE, YopH, YpkA/YopO, YopP/YopJ, YopM and YopT) and those (YopB, YopD and LcrV) forming the molecular syringe or translocation apparatus to deliver the effectors into the eukaryotic cells, penetrating the plasma membrane (Cornelis *et al.*, 1998) (Figure 33.1). YopE, YopT, YopO and YopH disrupt the host actin cytoskeleton. YopH

was the first bacterial protein recognised to be a tyrosine phosphatase (Guan and Dixon, 1990) and has multiple disruptive effects on macrophage, neutrophil and lymphocyte function (Cornelis *et al.*, 1998; Hamid *et al.*, 1999; Yao *et al.*, 1999). YopP (called YopJ in *Y. pseudotuberculosis* and *Y. pestis*) causes macrophage-specific apoptosis (Monack *et al.*, 1997).

In *Y. pestis*, unlike the enteropathogenic *Yersinia* spp., all freely excreted Yops apart from Lcr V (the cytoplasmic V antigen) are hydrolysed after excretion by the outer membrane plasminogen activator Pla encoded by the Pst plasmid. Also in contrast to the findings in animal models of enteropathogenic *Yersinia* infection, large amounts of LcrV accumulate in animals infected with *Y. pestis* (Brubaker, 2003). LcrV has long been recognised as a protective antigen when included in experimental plague vaccines, and it has recently been found to act as an immunosuppressant, decreasing the production of the proinflammatory cytokines interferon- γ and tumour necrosis factor- α by upregulating host interleukin-10 (Brubaker, 2003). Effector Yops are still delivered via the *Y. pestis* injectisome to paralyse and lyse host phagocytic cells, even with active Pla hydrolysing free Yops, and the overall effect of this combined assault on the non-specific immune system is to allow uncontrolled multiplication of *Y. pestis* in extravascular buboes (Brubaker, 2003).

In vitro regulation by Ca²⁺ was originally thought to mean that Yops would be induced by the calcium-restricted intracellular environment of the host after invasion had occurred, but it is now known that host cell contact in the presence of Ca²⁺ can trigger Yop expression (Pettersson *et al.*, 1996).

YadA forms a fibrillar matrix on the surface of the enteropathogenic yersiniae, making them adherent to a variety of molecules on eukaryotic cells and promoting intestinal colonisation in *Y. enterocolitica* (but not apparently in *Y. pseudotuberculosis*) (Cornelis *et al.*, 1998). It is produced at 37 °C irrespective of the Ca²⁺ concentration. It is the prototype of a family of adhesins seen in a variety of Enterobacteriaceae (Hoiczky *et al.*, 2000). In *Y. pestis*, the *yadA* gene is inactivated by a point mutation but several other homologues of *yadA* are present on the chromosome (Parkhill *et al.*, 2001).

Yersinia pestis lipopolysaccharide (LPS) is rough (lacks extended O-group chains) (Brubaker, 1991; Skurnik, Peippo and Erelva, 2000). The enteropathogenic yersiniae produce longer O-group side chains corresponding to the different serotypes.

Factors in Mouse-Lethal Yersiniae Belonging to all Three Species

The siderophore Yersiniabactin is synthesised by genes located on a chromosomal high-pathogenicity island present in *Yersinia* and apparently transmissible between different Enterobacteriaceae (Carniel, Guilvout and Prentice, 1996; Schubert *et al.*, 1998). The term high pathogenicity refers to the fact that island was shown to be present in all strains of *Yersinia* spp. that are highly virulent for

mice or humans but absent from strains with lower virulence (de Almeida *et al.*, 1993). Besides Yersiniabactin, there are multiple iron and iron-containing compound uptake systems in *Y. pestis* and other *Yersinia* spp. (Perry and Fetherston, 1997). Enteropathogenic low-virulence *Y. enterocolitica* strains unable to produce yersiniabactin can utilise siderophores produced by other bacteria (e.g. desferrioxamine B) and these substances potentiate their virulence (Perry, 1993).

Factors in Enteropathogenic *Yersinia*

The chromosomal genes *inv* (invasion: encodes *Yersinia* invasin) and *ail* (attachment invasion locus) when introduced into non-invasive *Escherichia coli* confer the ability of *Y. enterocolitica* strains to penetrate cultured human epithelial cells. Only pathogenic serotypes of *Y. enterocolitica* produce these two proteins (Miller *et al.*, 1989; Pierson and Falkow, 1990). Invasin specifically binds host cell β_1 -chain integrin receptors on the surface of intestinal M cells (Marra and Isberg, 1997). Synthesis of Inv is maximal at 28 °C and that of Ail at 37 °C, suggesting they act at different phases of the infective process. *Yersinia pseudotuberculosis* also produces Inv but Ail is not apparently important for adhesion to mammalian cells in *Y. pseudotuberculosis* (Yang *et al.*, 1996). The *inv* gene is disrupted in *Y. pestis*, but the *ail* gene is apparently intact (Parkhill *et al.*, 2001).

Although, as stated above, *Y. pestis* produced rough LPS, lacking an O-antigen, both *Y. enterocolitica* and *Y. pseudotuberculosis* require O-antigens for pathogenicity (Darwin and Miller, 1999; Karlyshev *et al.*, 2001).

Pathogenic *Y. enterocolitica* strains produce a family of heat-stable enterotoxins which have the same method of action as the heat-stable toxin STa of *E. coli* (Ramamurthy *et al.*, 1997) and a fibrillar adhesin Myf (mucoid *Yersinia* factor) (Iriarte *et al.*, 1993), which resembles ph6 antigen seen in *Y. pseudotuberculosis* and *Y. pestis*. The contribution of these gene products to pathogenicity is controversial.

A possible schema for *Yersinia* evolution, linking these pathogenicity factors with overall genome-sequence data is shown in Figure 33.3.

EPIDEMIOLOGY

Y. pestis

From historical descriptions of disease and current areas of endemicity, *Y. pestis* has been linked with three pandemics (Plate 11). The first began in the reign of the Roman Emperor Justinian in AD 541 (Perry and Fetherston, 1997). The second pandemic corresponds to the Black Death, which killed up to one-third of the European population between 1347 and 1352 (Ziegler, 1982). The third (current) *Y. pestis* pandemic followed the spread of infection from mainland China to Hong Kong in 1894 (Yersin, 1894). Most mortality in this pandemic was seen in India (White, 1918) and China (Teh, 1922) in the late nineteenth and early twentieth century, when millions died. It has been suggested that each pandemic is associated with a different biovar of *Y. pestis*, distinguished by a different *in vitro* phenotype of glycerol fermentation and nitrate reduction (Devignat, 1951).

The aetiology of the Black Death is still controversial, with some authors disputing that *Y. pestis* could have caused this syndrome (Scott and Duncan, 2001; Cohn, 2002). Recently, it has been claimed that ancient DNA evidence from Marseilles, France, proves the association of *Y. pestis* with the Black Death beyond any doubt (Drancourt *et al.*, 1998; Raoult *et al.*, 2000). This evidence has not been reproducible in ancient DNA studies of human remains from other well-documented Black Death burial sites (Gilbert *et al.*, 2004).

Yersinia pestis has been isolated from all continents and plague is enzootic in Africa, North and South America and Asia (Middle East, Far East and countries of the ex-USSR), following the third pandemic (Butler, 1983; Christie and Corbel, 1990; Perry and Fetherston, 1997). Many different combinations of rodent and flea vector species have been described. Classically, efficient flea vectors feeding on an infected host permit the establishment of *Y. pestis* in the proventriculus. Subsequent 'blocking' of the gastrointestinal tract with an overgrowth of *Y. pestis* and regurgitation of infected blood introduces the pathogen into the bloodstream of a new host. Sylvatic plague with a cycle of infection in rodents outside urban areas is the rule. Between 1987 and 2001, 36 876 cases of plague with 2847 deaths were reported to the World Health Organization. Most of the cases were from Africa and

Asia. The United States, which contains a very large enzootic focus, contributed only 125 human cases (12 fatalities) over this period, probably because the areas involved are rural and largely uninhabited. Urban plague requires contact with infected fleas from urban rodents. Worldwide the urban black rat *Rattus rattus* is the most important reservoir and *Xenopsylla cheopis* (the oriental rat flea) the most efficient vector for human disease (Butler, 1983; Christie and Corbel, 1990). Transmission can also rarely occur from human to human by the human flea *Pulex irritans* or by the respiratory route from human to human or domestic animal to human (Doll *et al.*, 1994; World Health Organization, 1999).

Yersinia pseudotuberculosis also causes a zoonosis of wild and domestic animals with human as an incidental host (Ljungberg *et al.*, 1995; Sanford, 1995). Disease incidence is highest in the winter months and results from contact with sick or asymptomatic animals or ingestion of food or water contaminated with their excreta. *Yersinia enterocolitica* exists worldwide in the environment as commensal biotype IA strains, but the disease-causing serotypes are more frequently identified with a specific host. [There is some evidence that a subset of biotype IA strains are host associated and have some pathogenicity factors that are active *in vitro* (Tennant, Grant and Robins-Browne, 2003).] Serotype O:9 and O:3 strains are the predominant types associated with diarrhoea in Northern Europe, and the disease is more common in autumn/winter (Tauxe *et al.*, 1987; Cover and Aber, 1989; Prentice, Cope and Swann, 1991). Human disease is linked to asymptomatic infection in pigs and consumption of pork products (Tauxe *et al.*, 1987). In Belgium (Verhaegen *et al.*, 1998) and Scandinavia (Cover and Aber, 1989) and New Zealand (Fenwick and McCarthy, 1995) *Y. enterocolitica* is a common cause of diarrhoeal illness. In Germany, 40% of blood donors have antibodies to *Yersinia* Yop proteins (similar in all pathogenic *Yersinia* spp.), despite relatively infrequent isolation of *Y. enterocolitica* and almost no *Y. pseudotuberculosis* cases (Neubauer and Sprague, 2003), suggesting a high level of asymptomatic infection with *Y. enterocolitica*. In the United Kingdom, serological and culture evidence of infection is less frequently seen than in Germany (Prentice, Cope and Swann, 1991). In the United States, sporadic infection is uncommonly reported but outbreaks are well recognised, some also associated with pork products (Lee *et al.*, 1990; Jones, 2003) and O:3 strains are now more commonly isolated than the highly pathogenic O:8 biotype 1B strains which used to predominate (Lee *et al.*, 1990).

CLINICAL FEATURES

Plague

Lymphadenitis in the regional lymph nodes serving the area of the fleabite produces a tense tender swelling or bubo after 2–6 days incubation in cases of bubonic plague. Fever and prostration is usual and progression to septicaemic plague with meningitis or secondary pneumonia can occur. Pneumonic plague may result in transmission of infection by aerosol. Primary septicaemia can occur in the absence of a bubo. Untreated bubonic plague has a mortality of 50–90% and untreated meningitis or septicaemia is usually fatal (Tieh *et al.*, 1948; Butler, 1983).

Yersiniosis

Yersinia pseudotuberculosis causes mesenteric adenitis and chronic diarrhoea in animals, which resolve spontaneously or progress to a fatal septicaemia with widespread deposition of caseating lesions in the lymphatic tissue (Fukushima *et al.*, 1994; Martins, Bauab and Falcao, 1998). Humans develop a mesenteric adenitis that may simulate appendicitis (pseudoappendicitis) (Attwood *et al.*, 1987). With improvements in water supply hygiene, human *Y. pseudotuberculosis* infection has become rarer (Fukushima *et al.*, 1994). Far-eastern scarlatiniform

fever is a childhood form of *Y. pseudotuberculosis* infection reported from far-eastern Russia, characterised by a desquamating rash, arthralgia and polyarthritides (Kuznetsov, 1974). A similar childhood syndrome has also been associated with *Y. pseudotuberculosis* in Japan, but not Western countries, possibly reflecting the restriction of superantigen-producing strains of *Y. pseudotuberculosis* to the Far East (Fukushima *et al.*, 2001).

Most *Y. enterocolitica* infections are in children of under 5 years of age (Prentice, Cope and Swann, 1991; Abdel-Haq *et al.*, 2000). Following an incubation period of 1–11 days (Cover and Aber, 1989), *Y. enterocolitica* causes an enteritis [containing frank blood in 25–50% of cases (Marks *et al.*, 1980; Abdel-Haq *et al.*, 2000) and occasionally pseudoappendicitis (as a result of terminal ileitis rather than mesenteric adenitis)]. Infection can occasionally be chronic and relapsing (Hoogkamp-Korstanje, de Koning and Heeseman, 1988). Pseudoappendicitis is more common in young adults. Spontaneous resolution is the norm, but certain groups such as iron-overloaded patients (e.g. thalassaemia, haemochromatosis and iron-supplement overdose), those with liver disease or diabetes and the elderly are at increased risk of a septicaemic illness with a fatal outcome (Cover and Aber, 1989; Prentice, Cope and Swann, 1991). *Yersinia enterocolitica* may be a more common cause of mycotic aneurysm than *Salmonella* spp. in some populations (Prentice *et al.*, 1993). Medical interventions associated with systemic disease include the use of desferrioxamine (iron-chelation therapy in thalassaemia) and blood transfusion. The latter occurs when a blood donor has asymptomatic bacteraemia at the time of donation and depends on the ability of *Y. enterocolitica* to grow at 4 °C in stored blood (Prentice, 1992; Hogman and Engstrand, 1996). Immunological complications are important especially in Northern Europe where HLA-B27 is frequent (Hermann *et al.*, 1993). Reactive arthritis follows several weeks after diarrhoea with other complications such as erythema nodosum and glomerulonephritis (van der Heijden *et al.*, 1997). *Yersinia enterocolitica* antibodies are found in autoimmune thyroid disease patients in these countries but it is not thought that *Y. enterocolitica* is a major factor in triggering thyroid disease (Toivanen and Toivanen, 1994).

LABORATORY DIAGNOSIS

Staining, Culture and Antigen Detection

Plague

In known endemic areas the clinical features described above are well recognised, and a presumptive diagnosis may be made on the appearance of bipolar staining Gram-negative rods from a bubo aspirate, CSF or sputum. Bipolar staining is more prominent with Wright-Giemsa staining than Gram staining. Rapid diagnosis is provided by detection of *Y. pestis* F1-antigen by immunofluorescence in clinical material. A promising rapid antigen-detection test in the form of an F1-antibody-containing dipstick has been shown to be a sensitive and specific assay in field conditions on a variety of clinical specimens (sputum, bubo aspirate and csf) in a developing country (Chanteau *et al.*, 2003). A polymerase chain reaction (PCR) assay based on the *Y. pestis*-specific *pla* gene (Hinnebusch and Schwan, 1993) located on a high copy number plasmid is probably the most successful of several molecular targets tested and has been adapted to a real-time 5'-nuclease assay (Higgins *et al.*, 1998).

Culture of non-contaminated samples (blood and lymph nodes) with routine biochemical identification is required for confirmation of rapid identification methods and sensitivity testing. It should be remembered that *Y. pestis* is potentially dangerous to laboratory workers (a Hazard Group 3 or P3 pathogen), and all samples sent from suspected cases should be labelled as high risk. Regrettably, we must now consider that identification of a patient with *Y. pestis* infection, particularly pulmonary disease, in a non-endemic country with no history of travel to a plague endemic zone suggests deliberate release

of the organism (Inglesby *et al.*, 2000). In the UK, the reference laboratory for all *Yersinia* spp. including *Y. pestis* is HPA-colindale Laboratory of Enteric Pathogens (61 Colindale Avenue, London NW9 5HT. Tel.: (+ 44) 020 8200 4400x3173; Fax: (+ 44) 020 8905 9929).

In the United Kingdom, the response to any covert or overt release of *Y. pestis*, as for other bioterrorism pathogens, would be coordinated by the Health Protection Agency and up-to-date information is available from their Web site. A comprehensive Plague Manual (World Health Organization, 1999) can be downloaded from the World Health Organization's Web site. Extensive information on plague diagnosis, treatment and control is also available from the Centers for Disease Control. Strict federal anti-bioterrorism legislation now applies to all laboratories and individuals culturing or holding *Y. pestis* strains in any circumstances in the United States (American Society for Microbiology).

Yersiniosis

Isolation from clinical material free from contamination (blood culture and lymph nodes) is by culture on conventional media (blood agar and nutrient agar) incubated at 25 and 37 °C. Growth occurs in conventional and proprietary blood culture broths, but prolonged incubation may be required for primary isolation. For isolation from faeces, routine enteric media such as MacConkey, desoxycholate or SS agar incubated at 25–30 °C for 48 h can be used. A selective medium specifically for yersiniae, cefsulodin-irgasan-novobiocin (CIN) agar, incubated at 30 °C, is commercially available (Oxoid, Basingstoke, UK). Cold enrichment by incubation in phosphate-buffered saline at 4 °C for 3 weeks is extremely effective at encouraging the overgrowth of yersiniae in mixed culture with other Enterobacteriaceae. This is impractical in a routine diagnostic service and may promote the isolation of commensal yersiniae (Van Noyen *et al.*, 1981). *Yersinia pseudotuberculosis* is rarely isolated from faeces culture even in proven cases of human infection, unless an outbreak has been recognised, and diagnosis is usually serological (Mair and Fox, 1986). Twenty-five different published PCR methods for detection of plasmid or chromosomal *Y. enterocolitica* target genes in clinical specimens or foodstuffs are listed in a recent review (Fredriksson-Ahomaa and Korkeala, 2003). In all comparisons, PCR was more sensitive than culture (Fredriksson-Ahomaa and Korkeala, 2003), and widespread use of PCR may increase the apparent incidence of *Y. enterocolitica*.

Serology

A passive haemagglutination test using *Y. pestis* F1-antigen (unique to *Y. pestis*) is available in countries where plague is endemic (World Health Organization, 1999). Whole-cell agglutination antibody is diagnostic for infection with serogroups I, III and V of *Y. pseudotuberculosis*, but groups II and IV share O-antigen sugars with group B and D salmonellae (Mair and Fox, 1986). High titres may be obtained soon after the onset of symptoms. *Yersinia enterocolitica*-agglutinating antibodies are more likely to be found in convalescence (Mair and Fox, 1986). *Yersinia enterocolitica* O:9 strains share polysaccharide antigens with *Brucella abortus* (Weynants *et al.*, 1996), and cross-reactions between O:5, 27 strains and *E. coli* also occur (Chart, Okubadejo and Rowe, 1992).

Identification

Table 33.2 gives the main reactions distinguishing the species. Other genus-specific characteristics have been mentioned under the general description above. The API-20E kit (bioMérieux, Marcy l'Étoile, France) incubated at 28 °C reliably identifies *Y. enterocolitica* and *Y. pseudotuberculosis* (Sharma *et al.*, 1990; Neubauer *et al.*, 1998). Further biochemical characterisation of *Y. enterocolitica*-like strains into five biovars and different species is possible (Wauters, Kandolo

Table 33.2 Characteristics of *Yersinia* spp.

Biochemical tests incubated at 28 °C for 3 days unless indicated. All catalase positive, oxidase negative. None forms H₂S in TSI medium. +, 90% or more of strains positive; –, 90% or more of strains negative; d, 11–89% strains positive [adapted from Bercovier and Mollaret (1984)].

and Janssens, 1987). Biotyping and serotyping of *Yersinia* spp. is a reference laboratory service, offered in the United Kingdom by the laboratory mentioned above for *Y. pestis* identification. In the clinical laboratory, dealing with fresh isolates, the possession of the pYV-related property of pigmentation and small colony growth on Congo Red-magnesium oxalate agar (CR-MOX) at 37 °C gives useful information about clinical significance (Farmer *et al.*, 1992). As a plasmid-related property, this may be lost on repeated subculture, but simultaneous testing for non-plasmid-derived factors associated with virulent serotypes (such as the absence of pyrazinamidase and the inability to ferment salicin or aesculin) overcomes this (Farmer *et al.*, 1992). The main serotypes associated with disease in Europe are O:9, O:3 or O:5, 27. These are of low virulence with little capacity to cause systemic disease outside the risk groups outlined above. Biotype 1B and serotype O:8 strains mainly found in North America have the capacity to cause severe disease in non-iron-overloaded hosts.

ANTIMICROBIAL SENSITIVITIES

Yersinia pestis clinical isolates are generally sensitive *in vitro* to most agents active against Gram-negative bacteria. Antibiotics active *in vitro* include streptomycin, ciprofloxacin, chloramphenicol, tetracycline, ampicillin, cotrimoxazole and cephalothin. A strain resistant to multiple antimicrobials was first reported from Madagascar in 1997 (Galimand *et al.*, 1997), and subsequently a different strain resistant to the first-line antibiotic streptomycin was also identified (Guiyoule *et al.*, 2001). Worryingly, both plasmids responsible for these resistance patterns were self-transferrable to other bacteria.

A similar generally sensitive spectrum is seen for *Y. pseudotuberculosis* (Soriano and Vega, 1982), but *Y. enterocolitica* strains express one or two chromosomal β -lactamases: a non-inducible broad-spectrum β -lactamase (enzyme A) and an inducible cephalosporinase (known as enzyme B, strictly speaking a class C enzyme) (Pham *et al.*, 2000). Despite the presence of an inducible cephalosporinase in *Y. enterocolitica*, the newer third-generation cephalosporins, as well as quinolone and penam antimicrobials, are active *in vitro* against all *Yersinia* species (Soriano and Vega, 1982; Pham *et al.*, 2000) including *Y. pestis* (Smith *et al.*, 1995; Frean *et al.*, 1996).

MANAGEMENT OF INFECTION

Streptomycin is traditionally regarded as the most effective treatment for plague at a dosage of 1 g twice daily (30 mg/kg/per day) for 10 days (Butler, 1983). Retrospective case review suggests the more

readily available aminoglycoside gentamicin is as effective as streptomycin in the treatment of human plague, when given at standard doses for severe sepsis (Boulanger *et al.*, 2004). Oral chloramphenicol is recommended for plague meningitis. In a mouse septicaemia model, third-generation cephalosporins and quinolones were as effective as streptomycin and tetracycline (Bonacorsi *et al.*, 1994). However in a mouse model of pneumonic plague, β -lactam antibiotics were less effective than aminoglycosides and quinolones (Byrne *et al.*, 1998). A consensus view of treatment for pneumonic plague resulting from biological weapon attack suggests streptomycin, gentamicin, tetracycline or fluoroquinolones may be effective (Inglesby *et al.*, 2000).

Yersiniosis is usually a self-limiting condition but for chronic or relapsing illness with *Y. enterocolitica*, focal disease outside the gastrointestinal tract or septicaemia, cotrimoxazole or ciprofloxacin has been recommended (Hoogkamp-Korstanje, 1987; Gayraud *et al.*, 1993; Crowe, Ashford and Ispahani, 1996). First-generation cephalosporins and amoxicillin/clavulanate are not effective as sole therapy in septicaemia (Gayraud *et al.*, 1993) and fluoroquinolones are probably the treatment of choice. *Yersinia pseudotuberculosis* is treated with similar agents to those effective against *Y. enterocolitica*, and as β -lactamases are absent, ampicillin can also be used (Van Noyen *et al.*, 1995; Martins, Bauab and Falcao, 1998).

PREVENTION AND CONTROL

The control of plague is based on reducing the likelihood of people being bitten by infected fleas or exposed to aerosols from humans or animals with plague pneumonia. A detailed summary of the international and patient-centred measures in force to prevent the spread of plague from and within enzootic areas is given in the WHO Plague Manual mentioned above. Bubonic plague is an internationally quarantinable disease. Current vaccines are restricted in application by local and systemic reactions and short duration of protective immunity. They are indicated only for those working with live *Y. pestis* in laboratories, or likely to be in contact with rats and fleas in endemic areas (Butler, 1983; Titball and Williamson, 2001). A new subunit vaccine is in clinical trials (Titball and Williamson, 2001). Person to person spread of yersiniosis has been described but is rarely demonstrated. Most documented outbreaks have been food or water borne (Tauxe *et al.*, 1987; Cover and Aber, 1989; Prentice, Cope and Swann, 1991). Control is based on the avoidance of consumption of contaminated food and water. The food industry has to be particularly alert to avoid contamination of products whose safety is assured by refrigeration with psychrotrophic yersiniae able to grow at 4 °C.

Vibrio spp.

Tom Cheasty

Laboratory of Enteric Pathogens, Centre for Infection, Colindale Avenue, London, UK

INTRODUCTION

A number of major texts have been written about cholera and cholera vibrios, and this chapter provides an outline for the clinical microbiologist (Pollitzer, 1959; Barua and Burrows, 1974; Colwell, 1984; Barua and Greenough, 1992; Wachsmuth, Blake and Olsvik, 1994). The genus *Vibrio* (Pacini, 1854) is among the oldest still recognized by bacteriology. Taxonomy was reviewed by Baumann, Furniss and Lee (1984) who listed 20 species, of which 12 had been isolated from clinical material. More recently, Farmer and Hickman-Brenner (1992) listed 34 species. However, of these only 12 had been isolated from clinical material. These studies illustrate the way in which our knowledge of the genus *Vibrio* has advanced. Until recently, *Vibrio* consisted of a heterogeneous and poorly described group of organisms. However, a stricter definition of the genus, coupled with the transfer of some members to other well-understood groups, has allowed the taxonomy to be clarified. Some, such as the organisms now known as *Campylobacter*, have been transferred to their own genera.

Vibrios are fermentative, Gram-negative bacteria that are oxidase positive. They are part of a widespread group of organisms, many of which are common in the environment. In clinical bacteriology we focus our attention mainly upon *Vibrio cholerae*, the cause of cholera, and *V. parahaemolyticus*, a major cause of food poisoning. However, it is important to remember that they are not the only vibrios that can cause human disease and indeed there are very many other vibrios that are not associated with human disease.

The genus as currently understood is comparatively well characterized and consists of oxidase positive fermentative organisms. All members are facultative anaerobes and grow well on artificial culture media. It is usual to speak of these organisms as belonging to two groups: those isolated from clinical specimens and the marine vibrios. However, this distinction is by no means clear.

All vibrios grow better with the addition of sodium chloride to culture media. An absolute requirement for sodium is not restricted to vibrios of marine origin. However, many of those isolated from clinical material are thought to originate from marine sources. Of the 12 vibrios isolated from clinical specimens, most have also been associated with marine environments. They have been isolated from food poisoning-associated consumption of seafoods and from wound infections resulting from contamination with a variety of marine materials (Table 34.1).

DESCRIPTION OF THE ORGANISM

The Family Vibrionaceae

The genus *Vibrio* is part of the family Vibrionaceae. The family also includes the genera *Photobacterium*, *Aeromonas* and *Plesiomonas*.

Table 34.1 Examples of disease syndromes associated with vibrios

Species	Enteritis	Wound infection	Ear infection	Septicaemia
<i>V. cholerae</i> O1, O139	+			
<i>V. cholerae</i> non-O1	+	+		+
<i>V. mimicus</i>	+		+	
<i>V. fluvialis</i>	+			
<i>V. parahaemolyticus</i>	+			+
<i>V. vulnificus</i>		+		+
<i>V. damsela</i>		+		+
<i>V. metschnikovii</i>		+		
<i>V. alginolyticus</i>		+	+	+

Members of the family are usually oxidase positive and have polar flagella for motility. Peritrichous flagella may occasionally be produced.

The organisms are rigid Gram-negative rods, motile by polar flagella in liquid media, but some species produce peritrichous flagella on solid media. They are chemoorganotrophs; metabolism is both oxidative and fermentative. They utilize glucose fermentatively and are catalase positive; most species are oxidase positive and reduce nitrate to nitrite. They are facultative anaerobes but do not have exacting nutritional requirements.

It is not certain that this family is a natural grouping in an evolutionary sense. It arose out of the wish to separate these organisms from the Enterobacteriaceae. DNA homology studies suggest *Vibrio* and *Photobacterium* may be closely related. However, *Aeromonas* is more distantly related and may in fact be closer to *Pasteurella multocida* and the Enterobacteriaceae than to vibrios, and Colwell, Macdonell and De Ley (1986) proposed the removal of *Aeromonas* from the family Vibrionaceae to a new family Aeromonadaceae. It is only in recent years that the definition of the genus *Vibrio* has become more delineated.

The Genus *Vibrio*

Historically, taxonomically and medically the genus *Vibrio* focuses on the organisms that cause cholera. These are largely members of the species *V. cholerae*; other species may occasionally cause clinically similar illness. Advances in molecular biology, immunology and bacterial taxonomy mean that *V. cholerae* is now among the best understood of bacterial species. The taxonomy of the organisms, the virulence mechanisms by means of which it causes disease and the means of treating apparent cholera have all been thoroughly investigated (see pathogenesis of cholera).

Genus Definition

The organisms are short asporogenous rods, with axis curved or straight, $0.5 \times 3 \mu\text{m}$. They are single or occasionally united in S shapes or spirals. They are motile by a single polar flagellum which is sheathed in certain if not all species. Some species produce lateral (peritrichous) flagella on solid media. Carbohydrates are fermented with the production of acid and no gas. A wide range of extracellular enzymes is produced, including amylase, chitinase, DNAase, gelatinase, lecithinase and lipase. They grow on simple mineral media. NaCl stimulates growth with an optimum of 1–3%. Some strains require NaCl for growth. Temperature optima range from 18 to 37 °C and pH range 6.0–9.0. They are sensitive to O/129 (2,4-diamino-6,7-diisopropylpteridine). G+C content of DNA is 40–50 mol%.

Non-Cholera Vibrios

The non-cholera Vibrios are found in aquatic environments worldwide and tend to be found more frequently in association with the warmer coastal waters and water temperatures of 18 °C or more (Kaspar and Tamplin, 1993). They are readily found in and on a wide variety of seafood including shellfish, particularly oysters. Only a small number of the many species apart from *V. cholerae* are associated with human disease (Figure 34.1), and of these the most significant are *V. parahaemolyticus*, *V. mimicus* and *V. vulnificus*. Because these bacteria are natural inhabitants of the aquatic environment, they create a continuous threat to the health of humans and the safety of food.

Vibrio parahaemolyticus

Vibrio parahaemolyticus is a well-known cause of diarrhoeal disease, symptoms include diarrhoea (which can be bloody), abdominal cramps, nausea and fever. Hughes *et al.* (1978) reported an outbreak of 'dysentery-like' disease following a fish meal in Bangladesh. Also in susceptible hosts *V. parahaemolyticus* can also cause severe

wound, soft-tissue and septicemic infections, and Daniels *et al.* (2000) reported a fatality rate of 29% in septicemia cases in the USA.

Vibrio vulnificus

Vibrio vulnificus comprises three biotypes, with biotype 1 (indole and ornithine decarboxylase positive) the most common found in clinical and environmental isolates and biotype 2 (indole and ornithine decarboxylase negative) a pathogen only for eels. *Vibrio vulnificus* is predominantly associated with causing severe wound infections, septicemia and occasionally diarrhoea. Most infections are associated with the consumption of raw shellfish and in particular oysters (Strom and Paranjpye, 2000). In the USA *V. vulnificus* is considered to be the most common cause of serious vibrio infection with a reported fatality rate of more than 50% in cases of primary septicemia (Klontz *et al.*, 1998).

Antibiotics used for the treatment of extraintestinal infections with both *V. vulnificus* and *V. parahaemolyticus* include tetracyclines and the newer fluoroquinolones. Rehydration is the key to diarrhoeal episodes caused by these vibrios.

For the laboratory isolation of these non-cholera vibrios, from cases of extraintestinal infection blood agar or other non-selective media are adequate whereas for the isolation from faeces, TCBS is the agar of choice.

Other Non-cholera Vibrios

The remaining non-cholera vibrios including *V. alginolyticus*, *V. damsela*, *V. fluvialis* and *V. metschnikovii* are mainly considered to be opportunistic pathogens. Infections caused by these species although small in number are commonly associated with contamination of wounds, incidents of trauma and ear infections following exposure to the aquatic environment (West, 1989; Hornstrup and Gahrn-Hansen, 1993). *Vibrio fluvialis* has also been reported as an occasional cause of gastroenteritis.

PATHOGENESIS OF CHOLERA

Explanations of the pathogenesis of infection usually focus on interaction of the organism with its host. In this context, cholera is a comparatively simple disease. *Vibrio cholerae* enters the intestine and attaches to the mucosal surface. When attached, it produces cholera toxin (CT), which attaches to the intestinal mucosal cells. An important function of mucosal cells is the control of ion transport; under normal conditions the net flow of ions is from the lumen to the tissue, which results in a net uptake of water. CT disrupts ion fluxes without causing apparent damage to the mucosa (Gangarosa *et al.*, 1960). CT decreases the net flow of sodium into the tissue. This produces a net flow of chloride and water out of the tissue into the lumen, causing the massive diarrhoea and electrolyte imbalance that is associated with this infection.

What a bacterium can do to its host is only part of its life as a pathogen. An organism must be transmitted between hosts and establish itself in new hosts. The ability of an organism to survive in the external environment and to adapt to the internal environment provided by the host is an important aspect of its pathogenic armamentarium. When considered in this way, the pathogenesis of cholera and the ecology of *V. cholerae* are much more complex.

Transmission

Until the 1970s it was believed that the ecology of *V. cholerae* was restricted to its role as a human pathogen. That is to say, if infection of the human host could be eliminated the major ecological niche of *V. cholerae* would have been eliminated and the organism would no longer be able to survive. It is now clear that the human host represents only a small compartment of the ecology of the vibrio. Thus, even if

Figure 34.1 The pathogenesis of cholera

the human infection were eliminated, this would not materially influence the survival of the species. It is now clear that *V. cholerae*, including strains belonging to serogroups O1 and O139, is a member of the autochthonous flora of brackish waters. It is able to persist and grow in a variety of aquatic environments in association with a variety of aquatic plants, zooplankton and blue-green algae independently of infected humans. In some circumstances, it may be a member of the biofilm flora found on submerged surfaces. This ability to colonize many different bodies of water and to associate with different members of microbiota undoubtedly contributes to the patterns of endemic cholera. This environmental survival was originally investigated in the search for an explanation for seasonal patterns of cholera in endemic areas. However, it has much wider implications than this (Colwell, 1984; West, 1989; Drasar, 1992; Pascual *et al.*, 2000). In addition to water, contaminated food also plays an important part in the transmission of *V. cholerae*.

Infective Dose

When the interaction of a pathogen with a host is considered, this is often described as though it were a unitary process, i.e. that a bacterium and a person come into contact and this results in disease. The situation is much more complicated than this. For *V. cholerae* we are fortunate in having the results of volunteer studies in which the numbers of bacteria required to initiate infection in healthy adults were examined. The numbers of bacteria involved in the initiation of infection under these conditions were much larger than might have been expected for a major epidemic disease (Table 34.2) (Cash *et al.*, 1974; Levine *et al.*, 1982, 1984; Suntharasarnai *et al.*, 1992). These results can be interpreted in several ways. It may be that they indicate the scale of the importance of host factors in initiating infection. Thus, for example, neutralization of gastric acid by bicarbonate decreases the numbers of bacteria required to initiate infection from 10^8 to 10^5 . Bacterial factors may also be important. The numbers of organisms required may reflect the size of bacterial population needed to ensure that the cells responsive to environmental signals are available. Thus, it may be that only a small fraction of laboratory-grown cells are immediately responsive to the environmental signals transmitted in the intestinal environment.

This would mean that not all cells were equally able to initiate the transcriptional regulation of those genes required for expression of virulence. It is also important to realize that these volunteer studies do not reflect the situation during an epidemic. Studies of epidemics caused by Classical and El Tor biotypes of *V. cholerae* suggest that in an epidemic most people are exposed to the organism. However, although many become temporary carriers, few develop clinical disease. The case-carrier ratio is 1 : 50 for the Classical biotype and 1:90 for the El Tor biotype. It is not certain that these differences are significant – they may simply represent the different methodologies used in the studies.

Table 34.2 Human challenge studies with virulent *V. cholerae* inoculum 10^5 bacteria Stomach acid neutralized

	Classical biotype		El Tor biotype	
	Inaba 569B	Ogawa 395	Inaba N16961	Ogawa E7946

Positive stool culture diarrhoea	28	12	25	6
Positive stool culture severe diarrhoea (cholera)	14	10	10	1
Total number of subjects	52	25	38	10

Virulence Factors

Since the description of CT and the demonstration that the small intestinal mucosa remains intact in cholera, there has been a major resurgence of interest in the virulence factors of cholera vibrios. Prior to these discoveries, it was believed that the destruction of mucus by mucinase was the main virulence factor and that this caused destruction of the intestinal mucosa. A number of virulence factors have been described. Not all are firmly established as factors important in the disease. Some have been demonstrated in experimental systems, others have been invoked to explain the side effects caused by genetically manipulated candidate cholera vaccine strains in some early studies. A general schema for the initiation of clinical infection is set out in Figure 34.1. All strains with the ability to cause cholera possess a set of virulence genes required for pathogenesis in humans. These genes are found in clusters and include genes for CT, the toxin-coregulated pilus (TCP), a colonization factor, and ToxR, a regulatory protein that coregulates the expression of both CT and TCP. These virulence genes or their homologues have also been found in environmental strains comprising a variety of serogroups and may thus provide an important environmental virulence gene pool (Chakraborty *et al.*, 2000).

Cholera Toxin

CT is the most important of the virulence factors produced by *V. cholerae*. CT is encoded by a lysogenic, filamentous bacteriophage CTX Φ which is found as a prophage in the bacterial chromosome. Typically the CTX Φ genome has two functionally distinct regions (i) the core which is 4.6-kb and encodes CT as well as other virion structural gene-encoded proteins; and (ii) the 2.5-kb RS2 region that encodes the regulation, replication and integration functions of the CTX Φ genome. Strains of *V. cholerae* that do not produce CT do not produce disease in human volunteers (Levine *et al.*, 1982). Such strains may cause a milder form of diarrhoea because of the presence of other toxins (Cash *et al.*, 1974; Levine *et al.*, 1988). This has proved a particular problem with candidate genetically engineered vaccine strains.

CT consists of a number of subunits: one A or enzymatic subunit and five identical B or binding subunits. The molecular weight of the A subunit is 27 kDa and that of each of the B subunits is 11.7 kDa. The genes that code for the toxin subunits are part of the same operon. These genes are part of a coordinated regulated system that also controls the expression of TCP and other virulence factors (DiRita *et al.*, 1991). The expression of these virulence factors is modulated by environmental influences. Environmental regulation of this system seems to be mediated by the toxR protein which spans the cytoplasmic membrane (DiRita, 1992). The system is further complicated by the fact that toxR is itself environmentally regulated and its expression at 37 °C may be downregulated in favour of the heat-shock response (Figure 34.2) (Parsot and Mekalanos, 1990).

Although the details of the regulatory system are not fully understood, it is certain that when *V. cholerae* colonize the intestine, the toxin is produced. It seems that the A and B subunits are produced separately and then assembled in the bacterial cytoplasm. TcpG is a chaperon, which is involved in the assembly of toxin-coregulated pili and may be involved in this process. Following assembly, the CT is transported to the periplasmic space and excreted by the bacterium. This is in contrast to the situation with heat-labile toxin of *Escherichia coli*, cells of which seem to have to lyse to release the toxin. When released into the intestine, CT binds to mucosal cells via the host Gm, ganglioside. The B subunits bind to the ganglioside and form a pseudopore in the cell membrane, thus enabling the A subunit to enter the cell. Prior to insertion into the cell, the A subunit is nicked probably in the small intestinal environment after release by the bacterium. This nicking converts the A subunit into two smaller proteins, A1 and A2. It is the A1 subunit that enters the cells via the pore formed by the B subunits. The A subunit ADP ribosylates a membrane protein called G.

Figure 34.2 Environmental control of virulence in *V. cholerae*.

This G protein regulates the activity of the host cell adenylyl cyclase and thus determines the level of cyclic AMP in the host cells. This brings about an uncontrollable rise in cyclic AMP levels. This has a variety of effects, but in this context the most important is to alter the activities of sodium and chloride membrane transport systems (DiRita, 1992). These changes result in a disruption of the bidirectional ion fluxes in the mucosal membrane. The overall effect of this is to increase the relative concentrations of sodium and chloride ions in the lumen. Diarrhoea then results as a direct effect of the osmotic imbalance. It is the osmotic imbalance which prevents, or at least much reduces, the active absorption of fluid that causes the diarrhoea.

CT may not be produced in large enough amounts to produce the diarrhoea in all individuals. The efflux of fluids must be sufficient to overcome the absorptive capacities of the colon. It is important to remember that the result of CT is a physiological lesion. Cells remain normal and are capable of carrying out normal functions, including absorption of salts and water. It is merely that the membrane fluxes from the cell to lumen are much exaggerated. It is for this reason that rehydration together with a source of energy can correct the physiological disturbance by amplifying and reinforcing the ability of the membrane to absorb and reabsorb fluid.

Toxin-Coregulated Pili

Attachment or adhesion to the intestinal mucosa is an essential part of the virulence mechanism of intestinal pathogens. *Vibrio cholerae* produces a variety of haemagglutinins and pili which had been postulated to be important in virulence (Freter and Jones, 1976; Jones and Freter, 1976). But these do not occur uniformly in all virulent strains. Toxin-coregulated pili were not demonstrated in spite of many investigations, because of the conditions under which test organisms were grown. Only when strains grown on solid media were investigated, were pili obvious. Since their discovery, it has been demonstrated that their production is regulated by the same cascade mechanism as is important for the production of toxin (Kaufman *et al.*, 1993; Pearson *et al.*, 1993). Thus, virulent *V. cholerae* produce TCP, a type IV pilus, which is considered to be the most important colonization factor because it has been demonstrated to be necessary for intestinal colonization in both animal models and human challenge studies, and a

toxin that is important for the regulation of ion fluxes at the same time, when the correct environmental conditions trigger the transcription of the virulence genes (Parsot and Mekalanos, 1990; DiRita, 1992). The genes for TCP are a component of the vibrio pathogenicity island, which is distinct from the CTXΦ genome. Biogenesis of TCP requires the products of a number of genes (the *tcp* gene cluster) located adjacent to the *tcpA* gene on the chromosome. The *tcpA* gene encodes for the major subunit of TCP (Ogierman *et al.*, 1993; Kovach, Shaffer and Peterson, 1996). How toxin-coregulated pili bring about attachment of *V. cholerae* to the mucosal cells is still not fully understood. Kirn *et al.* (2000) have proposed a multistep model in which TCP-mediated bacterial interactions promote microcolony formation, resulting in the local accumulation of bacteria on the epithelial surface. Most research has concentrated on the study of the regulation of the genes responsible for their production. Nevertheless, their importance in virulence has been established in volunteer studies. The strains that do not produce toxin-coregulated pili are avirulent in human volunteers (Herrington *et al.*, 1988).

Other Virulence Factors

Vibrio cholerae produces a number of other toxins in addition to CT. The existence of these toxins was first recognized when human volunteer studies were undertaken using mutagenized and biochemically engineered strains of *V. cholerae* that did not produce CT. Initial studies with live or vaccine strains showed that these strains that did not produce entire CT still produced symptoms. A number of toxins have been described, including the zona occludens toxin (ZOT) (Fasano *et al.*, 1991; Baudry *et al.*, 1992). This toxin disrupts the tight junctions between mucosal cells. In effect, this increases the surface area of the mucosa available for ion and water loss. Such losses normally occur through the brush border, but the action of this toxin exposes the sides of the cells and this may increase the efficiency of the virulence. Another enterotoxin, or accessory cholera enterotoxin (ACE), has also been described. Both ZOT and Ace proteins have been shown to have other cellular functions; Ace is associated with phage packaging and secretion whilst ZOT is needed for CTXΦ assembly (Waldor *et al.*, 1996).

Vibrio cholerae has also been reported to produce verocell toxin, which is analogous to the toxin produced by *Shigella dysenteriae* 1. *Vibrio cholerae* also produces haemolysin. The role of these additional toxins in the pathogenesis of cholera is not well understood. The variety of toxins produced by *V. cholerae* probably reflects its undoubted ability to produce a number of extracellular enzymes. These may well be important for the bacteria in non-intestinal environments such as aquatic systems, as part of the biofilm communities and in association with aquatic microflora and fauna. The production of extracellular enzymes and toxins may help the organism to digest a variety of substances and to increase the range of nutrients available to it.

In 2000 Heidelberg *et al.* published the entire genome sequence of *V. cholerae* O1 biotype El Tor (N16961). The genome was shown to consist of two circular chromosomes, one large (2961146 bp) and one small (1072314 bp). Most of the genes for growth and pathogenicity are located on the large chromosome, whilst on the small chromosome are located components of essential regulatory and metabolic pathways. The role(s) of these two chromosomes remains an enigma. It is possible that large chromosome genes (*chrI*) adapts the organism for growth in the human intestine, whereas the small chromosome (*chrII*) genes are essential for survival in environmental niches (Schoolnik and Yildiz, 2000).

Vibrio cholerae Non-O1, Non-O139 (Non-cholera Vibrios, Non-O1 *V. cholerae*)

Some of these strains also appear to produce CT together with ZOT (Karasawa *et al.*, 1993). Many others appear to produce cytotoxins that are not cholera like (McCardell, Madden and Shah, 1985). A few

produce a toxin similar to the heat-stable toxin of *E. coli* and some produce a shigella-like toxin (O'Brien *et al.*, 1984). Others produce no detectable enterotoxin at all and are probably non-pathogenic. Much research is still needed.

V. mimicus

These organisms were originally considered to be sucrose-negative *V. cholerae*. Some strains produce CT. Others produce an enterotoxin similar to the heat-stable toxin produced by non-O1 *V. cholerae* and haemolysins similar to that produced by *V. parahaemolyticus* (Ramamurthy *et al.*, 1994).

V. parahaemolyticus

The factors necessary for pathogenesis have not yet been established. However, shigella-like toxin is produced (O'Brien *et al.*, 1984). An enterotoxin has been purified, but it is not certain that this is responsible for the symptoms of *V. parahaemolyticus* food poisoning. The haemolysin is also thought to act as a virulence factor. Studies of this have revealed a regulatory system analogous to the *toxR* system in *V. cholerae* (Lin *et al.*, 1993).

EPIDEMIOLOGY OF CHOLERA

Cholera is a pandemic disease par excellence. Although it has undoubtedly been common in India since records began, and has spread to neighbouring countries on frequent occasions, the great days of cholera came after the resumption of world trade following the Napoleonic wars. Whether widespread cholera had occurred previously is not known. Writings of Europeans in India had from the earliest days of this intercourse made reference to this disease. Epidemics undoubtedly occurred among Europeans especially European troops stationed in India (Orton, 1831; MacPherson, 1872; MacNamara, 1876). Until 1817, spread was probably limited but in that year the first pandemic started and reached Europe. This was rapidly followed by the second pandemic, which reached England through the port of Sunderland in 1831. It is notable that Snow, who later became famous for the elucidation of the water-borne transmission of cholera (Snow, 1849, 1855), was working as a doctor's apprentice in Newcastle at about this time. Early nineteenth-century Europe was ravaged by a series of epidemics of cholera. We do not know for certain what caused these epidemics, although it is assumed to be *V. cholerae*. It was not until the fifth pandemic that Koch (1884) succeeded in isolating and identifying the organism. Even when the organism had been isolated, there were many who did not believe that it was the cause of the disease, though few went so far as Pettenkofer von (1892) in their wish to demonstrate that *V. cholerae* was non-pathogenic. He drank a culture and did not get cholera. As we now know, this probably reflects the relative resistance of some people to cholera vibrios. Comparable studies in healthy volunteers have not always been successful in inducing disease. Pandemics of cholera occur worldwide; we are now in the seventh pandemic, and with the emergence of *V. cholerae* O139 have been waiting to see if we are about to see the beginning of the eighth pandemic (Table 34.3).

However, for most practical purposes it is the local epidemics in endemic areas that are of the greatest practical importance. Historically it is likely that endemic cholera has been restricted to the Ganges delta. However, in the recent pandemic – the seventh pandemic – many other endemic areas have been detected. How an area becomes an endemic focus is unclear; the answers probably relate to aspects of the ecology of *V. cholerae* that we do not fully understand. In endemic areas successive, usually seasonally related, epidemics of cholera occur.

Historically, cholera has been considered to be a water-borne disease (Feachem, 1981, 1982; Feachem, Miller and Drasar, 1981).

Table 34.3 The chronology of cholera

At home	To 1817	Endemic on the Indian Subcontinent	
The historic pandemics	1817–1823	First pandemic	John Snow and the Broad Street Pump (1854)
	1829–1850	Second pandemic	
	1852–1860	Third pandemic	
	1863–1879	Fourth pandemic	
The classical pandemics	1881–1896	Fifth pandemic	Robert Koch and the comma bacillus (1884)
	1899–1923	Sixth pandemic	
The El Tor pandemic	1961 to date	Seventh pandemic	De and Chatterje cholera toxin (1953)
O139 Bengal	1992 to date		

There is considerable evidence that water-borne transmission of cholera is very important. However, in an epidemic situation, food-borne transmission is also very significant. *Vibrio cholerae* has often been isolated from seafood and shellfish, and the vibrios are able to grow well in cooked rice and on other foods. However, external contamination of foods may be equally important. In the recent outbreak in Chile, cholera was transmitted by vegetables irrigated with untreated sewage. Similar transmission related to melons was seen in Peru (Crowcroft, 1994). Thus, both food and water can act as vehicles for transmission (Glass *et al.*, 1991; Risks of Transmission of Cholera by Food, 1991). Poor sanitation is undoubtedly important for maintaining transmission during epidemics. This probably explains why secondary transmission is rare when cases are imported into countries with good sanitation. Investigations of other outbreaks in an epidemic situation may demonstrate what vehicle is important.

Major questions remain about the epidemiology of cholera. Two questions are of particular importance:

1. How does cholera survive in the inter-epidemic periods in endemic areas? That is, why are there cholera seasons?

There is linked to this a subsidiary question:

- 1a. How do new endemic areas develop?
2. How do pandemics arise?

Recent studies on the survival of *V. cholerae* have provided some clues to both of these questions. However, neither can be regarded as settled.

Vibrio cholerae is now accepted as being a normal member of the autochthonous flora of natural aqueous habitats. A variety of members of the aquatic flora and fauna have been suggested as likely to produce the right habitat. These include the plants, crustaceans, amoebae and various forms of phytoplankton (Thorn, Warhurst and Drasar, 1992; Islam, Drasar and Sack, 1993, 1994). These studies assume that the vibrios persist as active members of a biofilm microbiota. It is likely that the occurrence of starved and viable, but not culturable, forms (VBNC) is also important. These studies are particularly pertinent when considering the maintenance of endemic foci and the development of new endemic foci. If we postulate that in endemic areas vibrios persist as part of the normal flora of a number of bodies of water it can be readily seen how local epidemics will arise. Seasonal variation can be explained in terms of variations in the aquatic microbiota, e.g. algal blooms linked to an increase in the numbers of *V. cholerae* in water. Further, colonization of lakes and watercourses in non-endemic areas may result in the development of new endemic areas and the range of areas in which cholera is endemic. Endemic foci associated with colonized water sources probably occur in Bangladesh (Tamplin *et al.*, 1990), Louisiana (Blake *et al.*, 1980) in parts of Africa (Glass *et al.*, 1991) and perhaps in Australia (Desmarchelier and Reichelt, 1981). It is possible that during the current South American outbreak, new endemic foci have been established.

It has long been assumed that pandemics result from the spread of strains of *V. cholerae* from a single source. The Ganges delta has been considered to be the ancestral home of vibrios, and it has long been believed that pandemics spread from this area. Under this theory, a new, highly virulent strain of *V. cholerae* would develop in an endemic focus and then spread widely. However, application of ribotyping systems to cholera vibrios isolated during the seventh pandemic casts doubts on this dogma.

A variety of ribotypes have been demonstrated, each in part restricted to a particular area (Koblavi, Grimont and Grimont, 1990). Thus, different types of *V. cholerae* El Tor occur on the Indian subcontinent, Africa and in South America. It has been suggested that this diversity of types represents the acquisition of virulence factors by *V. cholerae* normally resident in aquatic environments in the different areas. Studies on isolates from the epidemic caused by *V. cholerae* O139 suggest a single type is responsible for all the cases so far studied.

The reasons for the mechanisms of pandemic spread remain obscure. In the most recent pandemics rapid travel of persons by air and the movement of ballast water by ships can be seen as a means of moving local microbiotas around the world and possibly enhancing the range for colonization of *V. cholerae*. However, in past pandemics this did not occur. Carriers in cholera, in the long-term sense that they occur in typhoid, are very rare and, thus, spread by humans, until the advent of rapid air transport does not seem to be an adequate explanation. Although the epidemiology of cholera has been studied since before the advent of microbiology and the pioneering studies of John Snow established many of the principles of epidemiology, our increased knowledge of the survival of the vibrio, its pathogenicity and the advent of molecular typing methods have not made our understanding that much clearer. For example, cholera had not been seen in South America for nearly 100 years, and it was assumed for some reason it would not occur there and perhaps the population was not susceptible. The recent extension of the seventh pandemic to South America has made us realize that there is no area of the world in which cholera cannot become established. The advent of the new strain of *V. cholerae* O139 has added a further question: how is and by what mechanism, do new pandemics occur during the history of cholera? Of the pandemics for which a cause is known, three were caused by different organisms.

CLINICAL FEATURES OF CHOLERA

The presentation of cholera is diverse, with many asymptomatic cases and others with severe symptoms. The incubation period varies from >1 day to 5 days, symptoms are frequently sudden and the infection can be rapidly progressive. Patients may lose as much as 100% of their body weight in diarrhoea over 3 to 4 days, bringing about death in a few hours if not adequately treated, but a less fulminant course is usual. All of the symptoms arise as a result of the dehydration and electrolyte disturbance consequent on the loss of water and salts into the gut lumen. Diarrhoea is severe, but abdominal pain is usually absent. Vomiting is often present in the early stages of cholera. Rarely ileus may occur on presentation and is associated with shock, and this may mimic acute intestinal obstruction. The state of consciousness is altered but the patient can be roused to lucidity. There is generalized weakness and cardiac arrhythmias may arise.

Other species are associated with enteritis and wound or ear infection after contamination arising in marine environments. In some cases septicaemia may result. Examples of species associated with these syndromes are given in Table 34.1.

LABORATORY DIAGNOSIS

Collection and Transport of Specimens

Many vibrios have been isolated from samples routinely submitted to clinical laboratories. When a suspected outbreak of cholera is being

investigated, such samples may not be sufficient. The drying and acidification of specimens during their transport to the laboratory may prove to be a problem. Wherever possible samples should be dealt with a minimum delay. Alkaline peptone water used for the selective enrichment of vibrios can also be used for transport. This can act as an enrichment transport system. An alternative enrichment transport system using Tellurite taurocholate peptone broth has been used successfully in Bangladesh. Of the routinely available transport media, Cary and Blair is the most satisfactory and may maintain the viability of vibrios for up to 4 weeks. In the absence of a suitable transport system blotting paper can be impregnated with liquid stool and packed in plastic bags. If these do not dry out, the vibrios will remain viable for about 4 weeks.

A rapid presumptive diagnosis can be achieved by mixing a drop of liquid faeces with a drop of specific antiserum. In patients with cholera the characteristic darting movement of the vibrios is inhibited.

Isolation

Vibrios can be isolated on normal laboratory media. Specialist media have been devised for the isolation of *V. cholerae*, and these may be applicable to the isolation of other organisms. There are doubts about the cost-effectiveness of employing specialized media for the isolation of vibrios, unless cholera is suspected. When a specialized medium, such as thiosulphate citrate bile salts sucrose agar (TCBS), has been employed in parallel with other media in routine clinical practice vibrios have been isolated, when present, on a variety of media. TCBS is extremely useful for isolating *V. cholerae*. But it should be remembered that some vibrio species do not grow well on TCBS. These include *V. metschnikovii*, *V. hollisae* and *V. cincinnatiensis*. Growth of *V. damsela* may also be reduced. The results obtained with TCBS produced by different manufacturers may be different, and each batch should be quality controlled to ensure the isolation characteristics are understood.

Isolation Methods

A simple schema for the isolation of *V. cholerae* is set out in Table 34.4. Although a number of vibrios have been isolated from clinical material, not all are of equal importance. In the routine laboratory, it is important that the system in place will ensure that *V. cholerae* is recognized if it occurs.

Different isolation techniques are necessary for halophilic and for non-halophilic vibrios. Enrichment methods designed principally for the isolation of *V. parahaemolyticus*, for example, are not ideal for the non-halophilic vibrios. If cholera vibrios are being looked for, the alkaline peptone water should not contain salt. This reduces overgrowth by other halophilic vibrios. It is also important to keep the pH alkaline: at a lower pH *Aeromonas* may so overgrow the vibrios that they cannot be isolated. This is particularly so with freshwater samples. Only one species of *Vibrio* is likely to be significant in any one clinical specimen. A method that permits isolation of both non-halophilic (*V. cholerae*) and halophilic (*V. parahaemolyticus*) vibrios is thus needed.

Table 34.4 Detection of *V. cholerae* in the laboratory

Day 0	Streak inoculate selective (TCBS) and non-selective media Inoculate alkaline peptone water
Incubate	
Day 1	Suspicious colonies → agglutination with <i>V. cholerae</i> O1 antiserum Subculture for purity Alkaline peptone water
Day 2	Streak inoculate to selective and non-selective media incubate Confirm agglutination results with pure culture; set up identification tests Test suspicious colonies isolated from alkaline peptone water

If the presence of a vibrio is suspected in patients with loose motions, about 5–10 ml of faecal material should be collected in a disposable container. The specimen should reach the laboratory as soon as possible. In the laboratory, inoculate about 2 g of faeces into 20 ml alkaline peptone water (peptone 10 g, NaCl 10 g, distilled water 1 l, pH 8.6) and incubate for 5–8 h at 37 °C. This will enrich for halophilic vibrios. For *V. cholerae* alkaline peptone water without NaCl is used. At the same time, TCBS is streak inoculated with a heavy load of faecal material.

After 5–8 h incubation from the first alkaline peptone water inoculate, a new alkaline peptone water preparation with 1 ml of fluid from the top of the alkaline peptone water and a second TCBS plate with a loopful from the top and incubate overnight. Look for typical colonies on both TCBS plates (yellow or green colonies about 2 mm in diameter). Inoculate a third TCBS plate from the alkaline peptone water. If no colonies occur on this plate after overnight incubation the sample is probably negative. This schema can be adapted for other specimens.

Identification

Suspicious colonies are streak inoculated onto nutrient agar as a purity check. Vibrios may be identified by the tests summarized in Table 34.5. A small number of basic tests are needed to identify at the genus level.

Oxidase

Colonies grown on nutrient agar should be tested using filter paper impregnated with 1% tetramethyl *p*-phenylene-diamine dihydrochloride. The oxidase test on growth from a plate containing a carbohydrate that is fermented by the organism can give a false negative.

O/129 Sensitivity

This is available as the phosphate (2,4-diamino-6,7-diisopropylpteridine phosphate) from BDH, product number 44169. Disks are prepared containing 10 and 150 Mg and the test performed as for a disk diffusion sensitivity method on nutrient agar – not specialized sensitivity testing agars.

CLED

Cystine-lactose-electrolyte-deficient medium was designed to prevent swarming of proteus. Being electrolyte deficient it is useful for distinguishing the non-halophilic vibrios (e.g. *V. cholerae*), which can grow on it, from the halophilic ones (e.g. *V. parahaemolyticus*), which cannot.

O/F Oxidation/Fermentation (tests)

Media for these tests should have the sodium chloride concentration raised to 1%, which will support good growth of all the pathogenic *Vibrio* spp.

Vibrios can be identified using commercial identification systems such as API 20E or standard laboratory tests when standard peptone water sugars are used. Results are more reliable if these are supplemented by 1% NaCl. Indeed, 1% NaCl is essential as a growth factor for most of the clinically important vibrios. Exceptions to this are *V. cholerae* and *V. mimicus*. O'Hara *et al.* (2003) evaluated six commercially available systems for the identification of the family Vibrionaceae and reported that none of the six systems tested were able to identify isolates to the species level with an accuracy of more than 81%, indicating that care must be taken when using these six commercial kits for the identification of *Vibrio* species.

V. cholerae O1, O139, Non-O1, Non-O139

The definition of the species *V. cholerae* and the relationship of the species to the cholera vibrios that cause cholera has long been a source of confusion. Rather like *E. coli*, *V. cholerae* is a large and diverse species, not all members of which are pathogens. In the past it was customary to speak of cholera vibrios, non-cholera vibrios (NCVs) and non-agglutinable vibrios (NAGs). It is now clear that these organisms are all members of the same species. Taxonomic studies including DNA–DNA homology have shown that *V. cholerae* is a single, relatively homogeneous, closely related species (Citarella and Colwell, 1970). Like other Gram-negative bacteria, *V. cholerae* has a complex cell wall which includes lipopolysaccharides, the carbohydrate components of which are designated as O antigens; there are now 206 somatic antigens in the *V. cholerae* serotyping scheme established by Shimada (Shimada *et al.*, 1994; Faruque and Nair, 2002).

Most of the positive reactions occur during the first 24 h. NaCl 1% is added to the standard medium to enhance growth. Percentages approximate for guidance only. Boxes indicate useful tests.

Most of the strains of *V. cholerae* isolated from cases of cholera belong to the O1 serogroup. Within this serogroup are further subdivisions, three serogroups Inaba, Ogawa and Hikojima. There are also two biotypes, Classical and El Tor. Each biotype may include members of all serotypes. It should be remembered that not all O1 strains cause cholera. Members of serogroups O2 to O206 may cause diarrhoea but are not thought to cause epidemic or endemic cholera. Although serogroups O2 to O206 (excluding O139) are generally recognized to be less pathogenic than the Classical or El Tor biotypes, they can cause symptoms very similar or identical to those of cholera and may cause outbreaks of enteritis. Indeed, they are more commonly isolated in Britain from cases of enteritis than the El Tor or Classical biotypes. Only *V. cholerae* O1 is reportable to the World Health Organisation as cholera. Isolation of the Classical biotype is much less common and the current, seventh, cholera pandemic is caused by the El Tor biotype. Members of the recently isolated O139 serogroup cause a disease clinically indistinguishable from cholera and have been responsible for epidemics (Albert *et al.*, 1993; Bhattacharya *et al.*, 1993; Ramamurthy *et al.*, 1993; Cheasty and Rowe, 1994).

Strains of *V. cholerae* O1 can be divided into the two biotypes on the basis of the tests set out in Table 34.6.

Serotyping

All strains of *V. cholerae* share a common H antigen. There are at least 206 O groups in the extended serotyping scheme of Shimada. Apart from O1 and O139 there is no link between the O group and pathogenicity. The O1 antiserum is available commercially as *V. cholerae* 'polyvalent' antiserum. Subtyping of O1 strains may be done by testing for agglutination with absorbed Inaba and Ogawa antisera (Table 34.7).

Rapid Identification

Rapid methods for the detection of both *V. cholerae* O1 and O139 are available using microscopy for immobilization studies (Benenson *et al.*, 1964) and immunoassays (Hasan *et al.*, 1994; Qadri *et al.*, 1995). Nato *et al.* (2003) described a one-step immunochromatographic dipstick tests for the detection of *V. cholerae* O1 and O139 in stool samples. The dipsticks represent the first rapid test which has been successfully

used to diagnose cholera from rectal swabs, and this would immensely improve surveillance for cholera, especially in remote settings (Bhuiyan *et al.*, 2003). Molecular methods such as PCR and DNA probes for the identification of *V. cholerae* directly from both clinical and environmental samples are also available; however their use in areas of epidemic cholera may not be practicable.

Typing

Further subtyping/molecular analysis of strains has also been reported using such techniques as pulsed-field gel electrophoresis (PFGE), multilocus enzyme electrophoresis (MLEE) and multilocus sequence typing (MLST). Studies using MLEE have grouped the toxigenic O1 El Tor biotype strains into four major electrophoretic types (ET), the Australian type, the Gulf coast type, the seventh pandemic type and the Latin American type, designated ET1–ET4 respectively (Sack *et al.*, 2004). Kotetishvili, Stine and Chen (2003) reported that when investigating strains of *V. cholerae* O1 and O139, MLST using three housekeeping genes *gyrB*, *pgm* and *recA* and three virulence-associated genes *tcpA*, *ctxA* and *ctxB* was more discriminatory than PFGE and additionally provided a measure of phylogenetic relatedness.

Vibrio mimicus

Previously *V. mimicus* had been identified as *V. cholerae*. Organisms that are unable to ferment sucrose produce green colonies on TCBS but which are otherwise phenotypically similar to *V. cholerae* have been isolated from shellfish, brackish water and stools of human beings with diarrhoea in many parts of the world. Studies on more than 50 such organisms showed that they have DNA relatedness to each other at species level but are related only distantly to *V. cholerae* (DNA–DNA homology 20–50%). Thus these bacteria would appear to be distinct species (Davis *et al.*, 1981). *Vibrio mimicus* shares O group serotypes with *V. cholerae*. Only some strains produce enterotoxin.

Vibrio parahaemolyticus

These vibrios are halophilic, i.e. they have an obligate requirement for sodium chloride. *Vibrio parahaemolyticus* is widely distributed in warm coastal and estuarine waters, requires sodium for growth and has been found in gastroenteritis outbreaks associated with the eating of seafoods throughout the world. This vibrio was first identified in Japan as a cause of food poisoning associated with shrimps. Further outbreaks have been associated with the eating of crabs, prawns and other seafoods. In the current *V. parahaemolyticus* pandemic involving eight countries, there is an association with three predominant serotypes O1:K?, O3:K6 and O4:K68 (Bhuiyan *et al.*, 2002).

TREATMENT

The nature of the life-threatening symptoms of cholera results from massive loss of water and salts and without effective treatment the case-fatality rate in cases of severe cholera can be as high as 50%. All other effects are probably consequent on the dehydration. Effective therapy concentrates on the replacement of fluids and prevention of further loss. Both oral and intravenous rehydration have their place in the management of cholera. Many cases of cholera, especially if diagnosed early, can be managed by oral rehydration. However, the volumes of fluid lost in severe cases may be very large. Especially if diagnosis has been delayed, replacement of adequate volumes of fluid by mouth may prove difficult. Fluid losses of up to 20 l per day have been reported. For these reasons, the use of intravenous rehydration methods may prove very valuable and should not be excluded.

Rehydration therapy alone will lead to recovery from cholera (Guidelines for Cholera Control, 1986). However, it may be necessary

to rehydrate for quite a long time. It must be remembered that CT becomes permanently bound to mucosal cells, and thus ion fluxes are probably unbalanced throughout the life of that cell. For this reason, antibiotics are usually added to the treatment regimen. The empirical evidence is that they reduce the time during which rehydration therapy has to be continued. Antibiotics also reduce the load of *V. cholerae* in the intestine. Elimination of the organism by antibiotics prevents the release and binding of more CT, and thus only the limited amount of CT already released before antibiotic therapy is commenced continues to act on the intestine.

Though there is a role for antibiotics in the treatment of cholera, there is no role for antimotility agents. Such agents increase the retention of both vibrios and their attendant CT in the gut, and probably exacerbate the physiological effects. When using antibiotics it is important to remember that *V. cholerae*, like other bacteria, is able to develop antibiotic resistance. *Vibrio cholerae* is also able to acquire antibiotic resistance plasmids and, although they are not as stable hosts of plasmids as are some other organisms, this can be of considerable practical importance (Glass *et al.*, 1983). A number of antimicrobial agents have been used in endemic situations. These include tetracycline, doxycycline, furazolidone, trimethoprim-sulphamethoxazole and norfloxacin. Indeed, extensive use of tetracycline has resulted in many of the endemic strains becoming tetracycline resistant, and since the late 1970s there has appeared in Africa, the Indian subcontinent and South America, strains of multidrug resistant *V. cholerae* (Mhalu, Mmari and Ijumba, 1979; Threlfall, Rowe and Huq, 1980; Threlfall, Said and Rowe, 1993). Thus, although empirical therapy may be necessary, the performance of antibiotic resistance tests should also be a priority. *Vibrio cholerae* strains isolated from individuals undergoing antibiotic therapy should be maintained on media containing the antibiotics. It may be helpful to use a medium containing antibiotics in general use in isolation procedures. This would be in addition to standard media. Such procedures may be helpful in obtaining a more accurate picture of the effective antibiotic resistances in the population of *V. cholerae* in that many plasmids are unstable in *V. cholerae* in the absence of the selective pressure from antibiotics for their maintenance.

PREVENTION AND CONTROL

Cholera Vaccines

The first candidate cholera vaccine was produced within a year of the first isolation of *V. cholerae* by Koch. Since then, a variety of vaccines have been developed and used. The discovery of CT (De, 1959) provided a further stimulus to vaccine development. All types of vaccine have been tried. These include live parenteral vaccines, killed parenteral vaccines, oral killed vaccines, oral subunit vaccines and live oral vaccines. Oral vaccines include those developed by chemical mutagenesis such as Texas Star; those produced by using the techniques of molecular biology to disarm fully virulent strains; and those that use the ability of other organisms such as *Salmonella typhi* type 21A, which has an expression vector for genes encoding relevant *V. cholerae* antigens.

Conventional parenteral vaccines have been of little use in cholera. The level of protection afforded is low, perhaps 40–80% protection during the first 2 to 3 months after administration but no significant protection 6 months after. There is some evidence suggesting that the vaccine may be more effective when administered to the inhabitants of highly endemic areas. However, the vaccine is not at all satisfactory, and the World Health Organisation has recommended that its use be discontinued. The advances in our understanding of the pathogenesis of cholera reawaken interest in oral vaccines. The isolation of the infection from systemic immune systems, and the lack of success from parenteral vaccines, made cholera a prime target for the development of oral vaccines. Studies have focused on the development of a

live oral vaccine, although killed vaccines have also been investigated. Considerable advances have been made and several oral candidate vaccines have been developed and shown to protect in volunteer studies.

The first new vaccine to reach the field test stage was a killed oral vaccine (Clemens *et al.*, 1987). Killed vaccines were tested in an extensive field trial in Bangladesh (Clemens *et al.*, 1986). The basic vaccine consisted of a mixture of heat-killed and formalin-killed cells of *V. cholerae* O1 of both the Ogawa and Inaba subtypes. In this trial, the basic vaccine was administered alone or in combination with the B subunit of CT, and *E. coli* K12 preparation was administered as a control. These vaccines provided good, although short-term, protection against *V. cholerae*, both in the field trial and in adult volunteers. These vaccines needed to be administered and boosted on two occasions by further vaccine. This would have disadvantages for large-scale use. However, their success demonstrated the possibility of a successful vaccination campaign using an oral vaccine.

The use of a live oral vaccine should overcome the problem of the need for multiple vaccine administration. Several such candidate vaccine strains have been developed and tested. The prototype strain of this approach was the vaccine strain Texas Star SR (Levine *et al.*, 1984). This strain, isolated after nitrosoguanidine mutagenesis, produces B subunits only. Texas Star may be considered as establishing the principles by which the development and testing of candidate vaccines were governed. More recent strains have shown greater promise. A number of genetically engineered strains have been developed and tested (Table 34.8) (Levine *et al.*, 1988). Those engineered with attenuated *V. cholerae* strain CVD103 HgR have shown the greatest promise. This strain is a derivative of CVD103 which was itself derived from wildtype O1 classical Inaba strain 56913. Strain 569B is pathogenic for volunteers. A gene coding for mercury resistance was introduced into CVD103 to produce CVD103 HgR. This marker enables us to differentiate vaccine strain from wildtype *V. cholerae* O1. In volunteer studies the efficacy was about 60%. This is better than currently available vaccines. In some groups, effective efficacy was much higher than this: up to 100% in some instances. The vaccine has undergone volunteer studies or clinical trials in the USA (Kotloff *et al.*, 1992), Switzerland, Thailand, Indonesia (Suharyono *et al.*, 1992), Peru (Guttuzzo *et al.*, 1993), Chile and Costa Rica. Apart from initial volunteer studies, most of these have been randomized placebo-controlled double-blind trials. As mentioned above, the vaccine shows good protective efficacy but, perhaps equally important in terms of its large-scale application, there are no side effects. Occasional subjects reported diarrhoea, but this was of no greater incidence than in the control groups. Studies have been undertaken in both adults and children. We now have a vaccine

Table 34.8 Candidate vaccine strains of *V. cholerae*

Strain number	Toxicogenic status	Number	Parent strain	
			Biotype	Serotype
Texas Star SR	A-13'	3083	EI Tor	Ogawa

produced by the methods of molecular biology that is a significant improvement on vaccines produced by other methods and has considerable potential for use in control of cholera. It is likely that future generations of engineered vaccines will be even more useful but, at the present, the claims that molecular biology are able to produce a single-dose, live oral vaccine providing significant immunity after oral administration seem to have been amply fulfilled (Levine and Kaper, 1993).

It is worthwhile noting briefly a few considerations about immunity to cholera. It has long been assumed that the production of local intestinal immunity is what protects against infection. However, the best laboratory correlate with immunity is circulating vibriocidal antibody. The reasons for this are not clear. Nonetheless, field studies have shown that vibriocidal antibody in populations is the best indicator of the susceptibility of individuals to cholera, and further, such vibriocidal antibody is produced as a result of stimulation by effective vaccines (Wasserman *et al.*, 1994). Antibody production is not the only important factor in determining susceptibility to cholera. There is undoubtedly a genetic element. Studies in Bangladesh have indicated that among those developing clinical cholera, there is an excess of persons with blood group O (Levine *et al.*, 1979). The reason for this has not been fully clarified, although it has been suggested that H substance might act as a receptor for the fucose-resistant adhesin of *V. cholerae*.

Two oral vaccines (Dukoral and Orochol) are currently commercially available, Dukoral consisted of heat- and formalin-inactivated *V. cholerae* O1 Inaba and Classical biotype strains in association with recombinant CT B subunit (rCTB). This vaccine claims protection against cholera caused by *V. cholerae* O1 and diarrhoea caused by enterotoxigenic *E. coli*. The second oral vaccine Orochol contains an avirulent mutant *V. cholerae* strain (CVD103 HgR). Other oral vaccines currently under development may well bring further benefits.

Aeromonas and Plesiomonas spp.

Alpana Bose

Centre for Medical Microbiology, Royal Free and University College Medical School, London, UK

INTRODUCTION

The aeromonads and plesiomonads were originally placed in the family Vibrionaceae, which also includes *Vibrio*, *Photobacterium* and *Enhydrobacter*. However phylogenetic studies have indicated that *Aeromonas* is not closely related to vibrios and thus has been transferred to a separate family, Aeromonadaceae (Colwell, MacDonell and De Ley, 1986). It has also been proposed that *Plesiomonas* being closer to the genus *Proteus* should belong to the family Enterobacteriaceae (Ruimy *et al.*, 1994; Janda, 1998).

DESCRIPTION OF ORGANISM

Aeromonas

Members of the genus *Aeromonas* are Gram-negative, non-spore-forming straight rods, which occur singly, in pairs or short chains. They are facultative anaerobes, being both catalase and oxidase positive. The aeromonads break down carbohydrates with the production of acid or acid and gas. Most of the mesophilic species within this genus are motile and have a single polar flagellum. Swarming motility with the production of lateral flagella has also recently been described (Kirov *et al.*, 2002). Although strains of *A. salmonicida* are capable of producing lateral flagella they are non-motile. This is thought to be as a result of inactivation of the *lafA* (flagellin gene), by transposase 8 (IS3 family) (Merino *et al.*, 2003).

The aeromonads can grow at range of temperatures from 5 to 44 °C. The optimum temperature for growth is 22–28 °C. Most isolates of clinical significance will grow readily at 37 °C. The pH range for growth is 5.5–9.0. Growth is inhibited in 6% salt broth. The G+C content of DNA is 57–63%.

Taxonomy

The genus *Aeromonas* was proposed by Kluvyer and van Neil in 1936 (Popoff, 1984). Since then it has undergone a number of taxonomic and nomenclature changes.

Phenotypic Classification: A phenotypic classification system was put forward on the basis of a numerical study by Popoff and Vernon (1976) who divided the aeromonads into two groups. The generally motile mesophiles which grow at 35–37 °C were known as *A. hydrophilia*. The subspecies within this group were known as *hydrophilia*, *anaerogenes* and *sobria*. These are now known as *A. hydrophilia*, *A. caviae* and *A. sobria* respectively and are responsible for the majority of human infections. The non-motile psychrophiles, primarily fish pathogens, and growing at 22–28 °C,

were known as *A. salmonicida*. Further phenotypic distinctions could be made on the basis of motility, production of melanin-like pigment on tyrosine agar and ability to produce indole. Just over a decade later Hickman-Brenner described two further mesophilic phenospecies, *A. veronii* (Hickman-Brenner *et al.*, 1987) and *A. shubertii* (Hickman-Brenner *et al.*, 1988). Since then many other species have been described such as *A. trota*, *A. jandaei*, *A. allosaccharophilia*, *A. bestiarum*, *A. encheilaiae* and *A. popoffi* based on biochemical and genetic analysis (Janda, 1998).

Genotypic Classification: DNA hybridisation studies initially established 12 genomic species or hybridisation groups (HG). Each of the phenotypes was found to contain several genomic species which could be differentiated in some cases by biochemical tests. This has caused considerable confusion, for example, HG3 has been named *A. salmonicida* (Janda, 1991). This genomic species contains the psychrophilic, non-motile strains of phenospecies *A. salmonicida* and the mesophilic strains of phenospecies *A. hydrophilia*. Therefore it is important to specify the system used to classify the species. The discrepancy between the different modes of classification can be further exemplified by considering HG8 and HG10. Although described independently with different phenotypes they are genetically identical. The rules of taxonomic nomenclature mean that the genomic species is known as *A. veronii*. However the phenotypic characteristic is used to describe the biotype: thus HG8 is known as *A. veronii biotype sobria* and HG10 is referred to as *A. veronii biotype veronii* (Hickman-Brenner *et al.*, 1987; Janda, 1991).

Abbott *et al.* (1992) proposed a new classification scheme that aimed to correlate the genomic species and phenospecies (Table 35.1). This scheme includes 13 genospecies ordered in four complexes or phenospecies.

Table 35.1 Hybridisation groups, mesophilic genomic and phenotypic species of *Aeromonas* spp.

Hybridisation group	Genomic species	Phenospecies or complex
1	<i>hydrophilia</i>	<i>hydrophilia</i>
2	Not classified	
3	<i>salmonicida</i>	
4	<i>caviae</i>	<i>caviae</i>
5A, 5B	Media	
6	<i>eucreonophilia</i>	
7	<i>sobria</i>	<i>sobria</i>
8	<i>veronii biotype sobria</i>	
9	<i>jandaei</i>	
10	<i>veronii biotype veronii</i>	
11	Not classified	
12	<i>shubertii</i>	<i>shubertii-trota</i>
13	<i>trota</i>	

Four new species were subsequently described: *A. allosaccharophila* (Martinez-Murcia *et al.*, 1992), *A. encheleia* (Esteve, Gutiérrez and Ventosa, 1995), *A. bestiarum* (Ali *et al.*, 1996) and *A. popoffii* (Huys *et al.*, 1997). Five new species were subsequently described: *A. allosaccharophila* (Martinez-Murcia *et al.*, 1992), *A. encheleia* (Esteve, Gutiérrez and Ventosa, 1995), *A. bestiarum* (Ali *et al.*, 1996), *A. popoffii* (Huys *et al.*, 1997) and *A. culicicola* (Pidiyar *et al.*, 2002). Two additional species, *ichthiosmia* and *enteropelogenes*, appear to be subjective synonyms of previously published species (Janda and Abbott, 1998). Recently a new species, *A. molluscorum* sp. nov., isolated from the bivalve mollusc has been proposed. 16S rRNA gene sequence analysis showed that the strains were similar to *A. encheleia*. Biochemical tests that distinguish this strain from other *Aeromonas* spp. include their negative reactions in tests for indole production, lysine decarboxylase, gas from glucose and starch hydrolysis (Minana-Galbis *et al.*, 2004).

Thus, at least 14 species are considered in the most recent classification (Janda and Abbott, 1998); among them, six are considered pathogen for human, while the rest are non-pathogenic or 'environmental' on the basis of the frequency of isolation from clinical or environmental sources.

Plesiomonas

Like aeromonads the plesiomonads are Gram-negative, non-spore-forming straight rods. However, the plesiomonads are more pleomorphic occurring singly, in pairs, short chains or as long filamentous forms. They are also facultative anaerobes, being catalase and oxidase positive. Carbohydrate is broken down with the production of acid only. The plesiomonads are motile and have several polar flagella.

The optimum temperature for growth is 30–37 °C, although plesiomonads will grow at a range of temperatures between 8 and 44 °C. The pH range for growth is 5–7.7 and growth is inhibited by 6% salt broth. The G+C content of DNA is 51%.

Taxonomy: These organisms were initially described by Ferguson and Henderson in 1947 and were known as C27. The C27 organisms were initially placed in the genus *Pseudomonas* as '*Pseudomonas shigelloides*'. They were subsequently transferred to the genus *Aeromonas* as '*A. shigelloides*'. Habs and Shubert proposed the name *Plesiomonas* in 1962 and the organisms were given their own genus. The name for this genus was chosen from the Greek word for 'neighbour' as it was thought that the organism was closely related to *Aeromonas*. However, *Plesiomonas* spp. have been found to be more closely related to the genus *Proteus* in the family Enterobacteriaceae. *Plesiomonas shigelloides* is the only species in the genus. This species name was chosen, as a minority of strains share a common O-antigen with *Shigella sonnei*. Despite this, the genus *Plesiomonas* still resides in the family Vibrionaceae.

The major characteristics of the genus *Aeromonas* and *Plesiomonas* are summarised in Table 35.2.

PATHOGENESIS

Aeromonas

The pathogenicity of *Aeromonas* spp. is mainly related to tissue adherence and toxin production.

S-Layer

Tissue adherence is mediated by the S-layer composed of single-surface array protein of about 50 kDa. The S-layer can be found in the fish pathogen *A. salmonicida*. Human pathogens *A. veronii* biotype *sobria* and *A. hydrophilia* have also been found to have an S-layer; however, the molecular weight of the protein is 52–58 kDa and sequence analysis shows no homology at the amino terminus

Table 35.2 A summary of the major characteristics of the genera *Aeromonas* and *Plesiomonas*

Characteristics	<i>Aeromonas</i>	<i>Plesiomonas</i>
Gram stain	Gram-negative straight rod	Gram-negative straight rod
Oxygen requirement	Facultative anaerobe	Facultative anaerobe
Biochemical reactions ^a	Oxidase positive	Oxidase positive
	Catalase positive	Catalase positive
	Break down carbohydrates producing acid or acid and gas	Break down carbohydrates producing acid only
Flagella	Single flagellum	Several flagella
Temperature range	5–44 °C	8–44 °C
Optimum temperature	22–28 °C	30–37 °C
pH range	5.5–9.0	5–7.7
Growth in 6% salt broth	Inhibited	Inhibited

^a See Table 35.4 for further biochemical reactions.

(Janda *et al.*, 1987; Dooley and Trust, 1988). The S-layer is thought to promote colonisation of the organisms to gut mucosa. In addition, the S-layer confers surface hydrophobicity, resistance to complement-mediated lysis and enhances interaction with macrophages. The S-layer appears to be anchored by lipopolysaccharide (LPS) in *A. hydrophilia* and *A. veronii* biotype *sobria*.

Fimbriae and Adhesins

Mesophilic strains possess fimbriae (filamentous) and outer membrane, S-layer synonymous adhesins (non-filamentous) with haemagglutinating activity which promote tissue adherence. The production of adhesins is increased in liquid culture at low temperatures (5 °C) (Ho, Sohel and Schoolnik, 1992; Gosling, 1996).

Capsular Layer

During growth in glucose-rich media strains of *A. hydrophilia* and *A. veronii* have been shown to produce a capsular polysaccharide which may contribute to increased virulence of these strains (Martinez *et al.*, 1995).

Extracellular Proteins

The toxins produced by *Aeromonas* spp. include cytotoxins including aerolysin, phospholipases, haemolysins and enterotoxins some of which have haemolytic activity. The mechanism of action of the enterotoxin is similar to that of *Vibrio cholerae* (Merino, Camprubi and Tomàs, 1992; Merino *et al.*, 1995; Tanoue *et al.*, 2005). *Aeromonas* spp. can also produce other substances such as amylase, chitinase, lipase and nuclease that can be released by the organisms and act as extracellular virulence factors (Janda, 1991). In addition, exoenzymes such as proteases have been implicated as virulence factors, as species deficient in proteases show reduced virulence. It has been shown that proteases are also required for the activation of other virulence factors such as aerolysin which form pores in the cell membrane leading to cell lysis (Howard and Buckley, 1985; Abrami *et al.*, 1998).

Endotoxin

Endotoxin or LPS of *Aeromonas* spp. has been implicated as an important virulence factor. It has been shown that strains that possess

O-antigen LPS secrete more exotoxin than strains that do not have O-antigen LPS. The possession of O-antigen LPS has been reported to be temperature dependent with some strains that have LPS becoming more virulent when grown at low temperatures (Merino, Camprubi and Tomàs, 1992). The O-antigen LPS is also used to serotype *Aeromonas* strains (Sakazaki and Shimada, 1984).

Siderophores

Almost all strains of *Aeromonas* spp. produce siderophores. In other Gram-negative organisms siderophores have been associated with establishment of infection. *Aeromonas hydrophila*, *A. caviae* and some strains of *A. sobria* have been shown to produce a new siderophore known as amonabactin (Barghouthi *et al.*, 1989). This is thought to enhance growth in iron-deficient media.

Plesiomonas

Research into elucidating virulence factors of *P. shigelloides* has focused mainly on investigating enteropathogenic mechanisms. The production of enterotoxin in the rabbit ileal loop model has been demonstrated. Both heat-labile and heat-stable enterotoxins have been characterised. The heat-stable enterotoxin is genetically different to that of *Escherichia coli* and *V. cholerae* (Matthews, Douglas and Guiney, 1988). Cytolysins that may cause tissue destruction or inhibition of the normal bacterial gut flora and thus have a role in enhancing colonisation or invasion of epithelial cells have also been identified (Abbott, Kokka and Janda, 1991). Other potential virulence factors such as haemolysin, elastin and plasmids have been detected but their pathogenic significance is uncertain.

EPIDEMIOLOGY

Aeromonas

Bacteria of the genera *Aeromonas* are found in abundance in freshwater, saltwater and chlorinated drinking water. Counts tend to rise with increasing water temperatures, and in the deeper more anoxic layers there may be more than 10^5 per gram mud and greater than 10^5 per litre of surface water. In summer they form majority of the aerobic flora. The organisms can also be isolated from fish, birds and reptiles, raw foods such as fresh vegetables, meat and ready-to-eat products (Hanninen and Siitonen, 1995; Blair, McMahan and McDowell, 1999). More recently a rare species, *Aeromonas culicicola*, has been isolated from the midgut of female *Culex quinquefasciatus* and *Aedes aegyptii* mosquitoes (Pidiyar *et al.*, 2002) and drinking water supply in Spain (Figueras *et al.*, 2005).

Members of the Aeromonadaceae have been implicated in cases of human infection. Aeromonads are also important in veterinary medicine causing an acute or chronic haemorrhagic septicaemia, furunculosis, in fish. They have also been implicated as food-spoilage organisms.

Plesiomonas

The only member of the genus *Plesiomonas*, *P. shigelloides*, is found in aquatic environments primarily freshwater and estuaries within tropical and temperate climates but can also be isolated from seawater in summer months. The organism forms part of the normal bacterial flora of fish, reptiles and amphibians. It has been isolated sporadically from mammals such as wolves, cheetah and Black lemur (Jagger, 2000). *Plesiomonas shigelloides* has been implicated as an uncommon cause of diarrhoea in cats. In humans, extragastrointestinal infection occurs mainly in neonates or in patients with underlying chronic diseases or who are immunocompromised. Diarrhoeal illness may also occur in immunocompetent individuals.

CLINICAL FEATURES

Aeromonas

Despite the explosion in the number of new species only a few have been implicated as human pathogens. Clinically significant strains belong to *A. hydrophila* (HG1), *A. caviae* (HG4) and *A. veronii biotype sobria* (HG8). These account for over 85% of all clinical isolates and are the causative agents of a wide range of extragastrointestinal and systemic infections. In addition, *A. veronii biotype veronii* (HG10), *A. jandaie* (HG9) and *A. shubertii* (HG12) have also been isolated albeit less frequently from clinical samples (Janda, 1991). The remainder of the *Aeromonas* species have been mainly isolated from environmental sources including water, fish, birds, other animals and industrial sources. The pathogenic potential of newer *Aeromonas* species is yet to be determined. Almost all of the recently described mesophilic species have been isolated from faeces and may reflect transient carriage as a consequence of their proliferation in water supplies in the summer months (Janda, 1991). *Aeromonas* species are recovered most commonly from faecal samples followed by samples from wound infections.

Gastroenteritis

There has been considerable debate regarding the enteropathogenic potential of *Aeromonas* species. The clinical presentation is said to vary tremendously, but most cases have been described as watery diarrhoea, associated with vomiting and low-grade pyrexia. The duration of symptoms is less than a week, although they can persist for longer in a minority of cases. In addition, there have also been a few cases of bloody diarrhoea (Gracey, Burke and Robinson, 1982). Evidence in favour of *Aeromonas* spp. as an aetiological agent of gastroenteritis comes from numerous reports linking infection with *Aeromonas* spp. and gastroenteritis. The discovery of enterotoxin produced by many *Aeromonas* strains provided a mechanism by which *Aeromonas* spp. could act as an enteropathogen.

In a Finnish study it was found that *Aeromonas* spp. was the third most common enteropathogen isolated, after *Campylobacter* and *Salmonella*. Furthermore 96% of patients with faecal isolates of *Aeromonas* spp. had gastroenteritis. *Aeromonas caviae* (41%), *A. hydrophila* (27%) and *A. veronii biotype sobria* (22%) were the most frequent isolates (Rautelin *et al.*, 1995). There have also been a number of case reports describing diarrhoeal illness associated with the isolation of *Aeromonas* spp. as well as serological evidence of infection. Champsaur *et al.* (1982) described a case of a patient with 'rice-water' diarrhoea. The stool was culture negative for *V. cholerae* and enterotoxigenic *E. coli* but was positive for *A. sobria*. This strain produced enterotoxin, proteolysin, cytolysin, hemolysin and a cell-rounding factor. Acute and convalescent phase sera showed an increase in neutralising antibodies to enterotoxin, cytolysin and hemolysin. Further evidence supporting a causative role of *Aeromonas* spp. in diarrhoeal disease comes from case reports where there has been improvement in diarrhoea with antibiotics active against *Aeromonas* spp. and resolution of abnormal bowel pathology with the disappearance of the organism from the stool (Roberts, Parenti and Albert, 1987).

Evidence against the view that *Aeromonas* spp. is a human enteropathogen comes from case-control studies that have shown that three main species *A. hydrophila*, *A. veronii* and *A. caviae* could be isolated from symptomatic individuals and healthy controls. Most isolates of *A. hydrophila* and *A. veronii* have been shown *in vitro* to express a cytolytic enterotoxin, β -haemolysin. In addition, human volunteer studies have yielded inconclusive results. In a study by Morgan *et al.* (1985), of fifty-seven healthy adults who were given doses of up to 10^{10} cfu of strains of *A. hydrophila* which produced both cytotoxin and enterotoxin, only two developed mild diarrhoea. It was suggested

that the lack of infectivity was secondary to immunity in the adult population as a result of exposure to strains in the local water supply. The observation that episodes of travellers diarrhoea in Peace Corp volunteers in Thailand were associated with *Aeromonas* spp. in faecal samples whereas the indigenous population from whom *Aeromonas* spp. was also isolated remained asymptomatic seemed to corroborate this view (Pitarangsi *et al.*, 1982). However, there have been reports that suggest that over 40% of individuals with diarrhoea and *Aeromonas* spp. isolated from the stool may have been infected with another recognised pathogen or have a non-infective disease such as bowel malignancy or inflammatory bowel disease (Millership *et al.*, 1986). This together with the lack of an animal model that could be used to fulfil Koch's postulates has failed to convince sceptics.

However, it is difficult to ignore the mounting evidence outlined above, suggesting that *Aeromonas* spp. do have an enteropathogenic role. Several outbreaks have also been described. These have been mainly in long-term care facilities (Bloom and Bottone, 1990) and child daycare centres (de la Morena *et al.*, 1993). Therefore, an alternative view is emerging that certain strains can sometimes produce gastrointestinal disease in predisposed individuals provided that there is a high enough infective dose.

Musculoskeletal and Wound Infections

Aeromonas spp. have been isolated either in pure culture or more often as a mixed culture together with enteric organisms such as *Bacteroides* spp., *Enterococci* and *Clostridia* from clinical samples taken from sites of musculoskeletal and wound infections. Although most clinically significant *Aeromonas* spp. have been recovered from such sites, strains of *A. hydrophilia* account for the majority of clinical isolates. There is a wide spectrum of clinical presentation ranging from mild superficial skin infection to more severe deep infections such as septic arthritis and osteomyelitis (Janda and Abbott, 1998).

Musculoskeletal and wound infections occur most commonly in healthy individuals who participate in recreational or occupational aquatic activities. *Aeromonas* infection is in many cases secondary to penetrating injuries to the lower limbs in aquatic environments. Patients often give a history of striking a submerged object barefoot whilst walking along the banks of a river or lake (Voss, Rhodes and Johnson, 1992). These infections arise almost exclusively as a result of exposure to freshwater as opposed to seawater. This observation is difficult to explain as the bacterial densities in both uncontaminated freshwater and seawater are similar (approximately 10^2 cfu/ml) and *Aeromonas* spp. have been isolated from marine crustaceans (Holmes, Niccolls and Sartory, 1996). Recently an outbreak of *A. hydrophilia* wound infection in people playing 'mud-football' has been reported in Western Australia. The field had been prepared using water from a near-by river (Vally *et al.*, 2004).

The other important environmental source of infection with *Aeromonas* spp. is soil. In a review of 32 infections of the foot, at least 33% were related to trauma secondary to inanimate objects such as broken glass and nails contaminated with soil (Wakabongo, 1995). *Aeromonas* infections as a consequence of severe crush injuries causing compound fractures or extensive burns have also been associated with soil-borne pathogens. In some cases osteomyelitis can occur several months after the event (Voss, Rhodes and Johnson, 1992).

In a minority of patients no history of trauma can be elicited. However these patients have underlying disorders such as chronic ulcers, chronic vascular insufficiency, malignancy and diabetes mellitus (Voss, Rhodes and Johnson, 1992).

Medicinal leech therapy has also been implicated as a significant albeit rare source of infection. Leeches are used by many Plastic Surgeons and other surgical specialists to relieve venous congestion and reduce oedema over skin flaps. *Aeromonas veronii* biotype *sobria* forms part of the normal flora of the leech and is thought to break down ingested erythrocytes and thus aid digestion (Dabb, Malone and

Leverett, 1992). Prophylactic antibiotics are recommended for treatment with medicinal leeches as up to one-fifth of such treatment regimens are associated with Gram-negative infections many of which are secondary to *Aeromonas* spp. (Mercer *et al.*, 1987). The clinical presentation following infection is varied and can range from mild wound infection to myonecrosis and bacteraemia. Recently a case of *Aeromonas veronii* biotype *sobria* meningitis associated with the use of leech therapy has been reported. The leeches were used to salvage a skin flap after surgical excision of a glomus tumour of the central nervous system. The authors advised caution in the use of leech therapy in close proximity to the central nervous system (Ouderkerk *et al.*, 2004).

Hospital-acquired *Aeromonas*-associated wound infections have also been described, but these are more likely to arise as a result of translocation of endogenous gut flora secondary to intervention. There have been rare cases of indwelling catheter-related *Aeromonas* bacteraemia and wound infections post laparotomy (Janda and Abbott, 1998). *Aeromonas* has also been recovered from hospital water supplies. There have been observations of a seasonal variation in nosocomial *A. hydrophilia* infection and in the number of *Aeromonas* spp. in hospital water supplies. A high prevalence of *A. hydrophilia* infection in the summer months correlated with maximal proliferation rates in hospital storage tanks (Picard and Goullet, 1986). Other studies have failed to demonstrate an epidemiological link. Millership, Stephenson and Tabaqchali (1988) investigated the occurrence of *Aeromonas* spp. in hospital water supplies. The isolation rate among hospital patients was 6% compared to 3.6% in individuals from the community. When molecular typing of the isolates was performed, no relationship could be established between water and clinical samples.

Bacteraemia

Aeromonas species that have been isolated from blood cultures include *A. hydrophilia*, *A. veronii* (both biotypes), *A. jandaie* and *A. cavaie* (Janda *et al.*, 1994). There have also been less-frequent case reports of *A. shubertii* bacteraemia (Hickman-Brenner *et al.*, 1988; Abbott *et al.*, 1998). The most common groups of patients who are susceptible to *Aeromonas*-associated bacteraemia are immunocompromised adults and infants under the age of 2 with underlying medical conditions. In these groups of patients *Aeromonas* bacteraemia can occur as a result of haematogenous translocation of the organisms from their gastrointestinal tracts. There are a variety of premorbid conditions that are associated with an increased risk of *Aeromonas* bacteraemia. These include pancreatitis, trauma, anaemia, gastrointestinal disorders, respiratory and cardiac abnormalities. However, in most cases *Aeromonas* bacteraemia is associated with underlying malignancy, hepatobiliary disease and diabetes mellitus. Mortality rates can be as high as 50% in these groups (Janda and Abbott, 1996). Clinical presentations and prognostic factors of 104 cases of monomicrobial *Aeromonas* bacteraemia were analysed by Ko *et al.* (2000) in Taiwan. The majority of infections occurred in patients with hepatic cirrhosis and malignancy. The crude fatality rate at 2 weeks was 32% and the outcome was worse in patients who had secondary bacteraemia where a source of infection could be identified and those with more severe illness at presentation such as septic shock.

The fatality rate is greater than 90% in the subgroup of patients who develop bacteraemia as a result of severe wound infection and myonecrosis secondary to trauma. Infection occurs as a result of exogenous sources such as exposure to freshwater (Janda and Abbott, 1996). In patients who develop bacteraemia secondary to burns the mortality rate approaches 67% (Ko and Chuang, 1995). There is also a smaller subgroup of adults in whom no underlying premorbid condition can be found. These patients do not have a history of exposure to freshwater and the portal of entry cannot be determined (Janda and Abbott, 1996).

Polymicrobial bacteraemias with members of the Enterobacteriaceae family, *Pseudomonas* spp., *Streptococci* spp. and *Enterococci*

spp., have also been reported. Some surveys have found that certain *Aeromonas* species are more likely to participate in polymicrobial bacteraemia in patients with certain underlying medical conditions, for example, in patients with underlying malignancy. In these patients the frequency of polymicrobial bacteraemia involving *A. caviae* is much greater than the other species (Janda *et al.*, 1994).

Respiratory Tract Infections

Although rare, *Aeromonas* spp. have been associated with infections of the upper and lower respiratory tract such as epiglottitis, pharyngitis, pneumonia, empyema and pulmonary abscess formation. Immunocompetent individuals can acquire infection from aspirating freshwater associated with swimming, near drowning or other accidents. Patients with underlying medical problems or who are immunocompromised develop pulmonary infection as a result of haematogenous dissemination from their gastrointestinal tract. Respiratory infections can be associated with concomitant *Aeromonas* bacteraemia (Janda and Abbott, 1998).

The mortality rate is approximately 50% and is not related to the presence of underlying disease. Factors indicative of poor prognosis include pneumonia, haemoptysis, rapidly progressive infection and bacteraemia (Goncalves *et al.*, 1992).

Peritonitis

Peritonitis is an uncommon but serious consequence of *Aeromonas* spp. infection or colonisation with a mortality rate of up to 60%. The majority of cases are associated with bacteraemia. *Aeromonas hydrophila* is predominantly isolated although the other clinically significant *Aeromonas* spp. have also been implicated. In a review of 34 cases, *Aeromonas*-associated peritonitis occurred primarily in patients with underlying chronic hepatic impairment; this was followed by patients with chronic renal failure undergoing chronic ambulatory peritoneal dialysis and those with intestinal perforation (Munoz *et al.*, 1994).

Haemolytic Uraemic Syndrome

Haemolytic uraemic syndrome (HUS) associated with *A. hydrophila* enterocolitis has been reported. This extremely rare condition occurred in a 23-month-old infant who developed HUS 6 days after an episode of abdominal pain and bloody diarrhoea. *Aeromonas hydrophila* was isolated from the patient's stool and produced cytotoxin against Vero cells. A rising titre of cytotoxin-neutralising antibody was demonstrated in the serum (Bogdanovic *et al.*, 1991). In a subsequent study 82 cases of HUS were investigated. There were two cases in which a link to recent *A. hydrophila* infection could be established. It was felt that *Aeromonas* spp. should be recognised as a sporadic cause of HUS secondary to a diarrhoeal illness (Robson, Leung and Trevenen, 1992). The cytotoxin produced by *A. hydrophila* has been shown to be genetically and antigenically unrelated to the shiga toxin produced by *E. coli* 0157:H7 (Janda, 1991).

Other Infections

In addition there have been documented cases of meningitis (Ouder Kirk *et al.*, 2004) and ocular infections including corneal ulceration (Puri *et al.*, 2003), endophthalmitis (Lee, O'Hogan and Dal Pra, 1997) and keratitis associated with contact lens wear (Pinna *et al.*, 2004).

Plesiomonas

Plesiomonas shigelloides has been implicated as an uncommon cause of diarrhoea in humans. Extragastrintestinal manifestations are rare.

Gastroenteritis

Plesiomonas shigelloides has been isolated from stools of patients with diarrhoea. The incidence is higher in tropical and subtropical regions such as the Indian subcontinent and Southeast Asia. In Europe, America and Canada cases of travellers diarrhoea have also been reported. Patients with *P. shigelloides*-associated gastroenteritis present with a variety of symptoms associated with diarrhoea including abdominal pain, tenesmus, nausea, vomiting, lethargy, rigors and headache. The incubation period can range from 1 to 9 days. There have been reports of large-volume secretory diarrhoea as well as of bloody mucoid diarrhoea as a result of invasive disease. Infection can occur in immunocompetent individuals, and the duration of illness in untreated cases is approximately 11 days. In some cases, the bacterium can be isolated from stool samples more than 2 months following the initial diarrhoeal episode suggesting chronic infection. However, there have also been reports of asymptomatic carriage of *P. shigelloides*, and volunteer studies have failed to establish an aetiological link between *P. shigelloides* and gastroenteritis. Evidence to support the view that *P. shigelloides* can act as an enteropathogen comes predominantly from a number of published case reports and case-control studies (Jagger, 2000).

Infection with *P. shigelloides* is acquired mainly through aquatic sources and is often associated with contamination of water sources with sewage. The incidence is higher in the summer months reflecting the increased proliferation of the organisms in warmer temperatures. Infection can also arise as a result of inadequately treated drinking water. This was thought to be the source of an outbreak of *P. shigelloides*-associated gastroenteritis in Japan affecting 978 people (Tsukamoto *et al.*, 1978). In addition there have been reports of *P. shigelloides*-associated diarrhoea in individuals who have been swimming or participating in other recreational activities in fresh- and seawater (Soweid and Clarkston, 1995).

Infection with *P. shigelloides* can also occur as a consequence of eating fish, shellfish and crustaceans. It is thought that inadequate refrigeration or cooking contributes to food-borne infection.

Bacteraemia and Other Infections

Bacteraemia is a rare consequence of infection with *P. shigelloides*. In many cases the source is unknown. The majority of affected individuals are either neonates or immunocompromised adults. The mortality rate can be as high as 62% (Lee *et al.*, 1996).

Other extragastrintestinal infections that have been described include meningitis, endophthalmitis, cellulitis, wound infections and cholecystitis in immunocompromised individuals. Cases of osteomyelitis and septicaemia have also been described in immunocompetent patients (Ingram, Morrison and Levitz, 1987). Recently two cases of peritonitis in patients undergoing chronic ambulatory renal dialysis have been described (Woo *et al.*, 2004).

LABORATORY DIAGNOSIS

Aeromonas spp. and *Plesiomonas* spp. grow well on 5% sheep blood, chocolate and MacConkey blood agars. They also grow well in the broth of blood culture systems and in thioglycollate or brain-heart infusion broths. *Plesiomonas* spp. does not grow so well on thiosulphate citrate bile sucrose media.

On 5% sheep blood agar *Aeromonas* spp. colonies are large, round, raised and opaque. Most colonies are β -haemolytic except *A. caviae*, which is non-haemolytic. In comparison, colonies of *P. shigelloides* appear smooth, shiny, opaque and are generally non-haemolytic.

On MacConkey agar *Aeromonas* spp. and *Plesiomonas* spp. can be lactose fermenters or non-lactose fermenters, although *Plesiomonas* spp. does not ferment lactose on most enteric media.

Selective techniques are often needed to isolate *Aeromonas* spp. and *Plesiomonas* spp. from mixed cultures. Enteric media may inhibit

some members of *Aeromonas* spp., and thus isolation of the bacterium from stool cultures can sometimes be difficult. Either cefsulodin-irgasan-novobiocin agar or blood agar that contains ampicillin (10 or 30 µg/ml) can be used as a selective medium (Janda, Abbott and Carnahan, 1995). The plates can be examined for growth after 24 h. Selective media for the isolation of *Plesiomonas* spp. can be used and includes bile peptone broth and trypticase soy broth with ampicillin (Rahim and Kay, 1988). *Plesiomonas* spp. grow well at 35 °C producing colonies within 24 h.

The oxidase test distinguishes *Aeromonas* spp. and *Plesiomonas* spp. (positive) from other Enterobacteriaceae (negative).

The string test can be used to distinguish *Vibrios* spp. from *Aeromonas* spp. and *Plesiomonas* spp. When the organisms are emulsified in 0.5% sodium deoxycholate, the cells of *Vibrios* spp. are lysed and this can be detected by the subsequent release of DNA which can be pulled into a string using an inoculating loop. The cells of *Aeromonas* spp. and *Plesiomonas* spp. are unaffected.

The vibriostatic test using 0/129 (2,4-diamino-6,7-diisopropylpteridine) impregnated discs has also been used to separate the vibrios which are susceptible from other oxidase-positive glucose fermenters (resistant). However, recently strains of *V. cholerae* 01 have been found to be resistant to 0/129 and hence the dependability of this test is becoming questionable.

Some commercial kits are unable to distinguish between *Aeromonas* spp. and *Vibrios* spp. Hence, the identification of *Aeromonas* spp. and *P. shigelloides* should be confirmed using conventional biochemical or serotyping methods. The biochemical and biophysical features that may be used to differentiate members of the family Vibrionaceae are summarised in Table 35.3. Differentiation between *Aeromonas* spp. and *Plesiomonas* spp. requires further biochemical analysis (Table 35.4).

Most commercial identification systems fail to accurately identify aeromonads to a species level. Thus many systems proceed no further than identification to genus level reporting an *Aeromonas* isolate as 'Aeromonas species' or 'Aeromonas hydrophilia complex'. To solve this problem various methods have been used to identify mesophilic *Aeromonas* spp. to a species level (Table 35.4). For example, *A. hydrophilia* is motile, catalase positive, urease negative and converts nitrate to nitrite.

Abbott *et al.* have recently developed phenotypic identification schemes to species level for *Aeromonas* spp. based on initial Moeller decarboxylase and dihydrolase reactions. Several new tests have also been described to help separate members of the *A. caviae* complex (*A. caviae*, *A. media* and *A. eucreonophilia*) which included utilisation of citrate, DL-lactate, urocanic acid and fermentation of glucose 1-phosphate, glucose 6-phosphate, lactulose and D-mannose (Abbott, Cheung, Janda, 2003).

PCR-based 16S and 23S rRNA gene analysis have also been used to identify *P. shigelloides* and *Aeromonas* spp. to genomic species level (Ruimy *et al.*, 1994; Gonzalez-Rey *et al.*, 2000; Laganowska and Kaznowski, 2004). In addition the rpoD sequence that encodes sigma factor and the gyrB sequence, a gene that encodes the B-subunit of DNA gyrase, have been utilised to establish phylogenetic relationships between *Aeromonas* species. The results corroborate current taxonomic divisions (Yanez *et al.*, 2003; Soler *et al.*, 2004). Furthermore, gyrB sequence analysis was superior to 16S rRNA at identifying different *Aeromonas* species and has therefore been proposed as a useful marker for identification of *Aeromonas* strains (Yanez *et al.*, 2003).

MANAGEMENT

The management of extragastrintestinal infections secondary to *Aeromonas* spp. or *Plesiomonas* spp. relies on prompt diagnosis and treatment with antibiotics to which the organisms are susceptible. Most gastrointestinal infections are short lived and therefore the majority of patients do not require antibiotics.

Aeromonas

A recent study investigated the antibiotic susceptibility pattern of *A. veronii* biotype *sobria*, *A. caviae*, *A. jandaei* and *A. hydrophilia* isolated from faecal specimens from patients with gastroenteritis. All strains were resistant to ampicillin but susceptible to cefotaxime, ciprofloxacin and nalidixic acid. The susceptibility to chloramphenicol, tetracycline and trimethoprim-sulfamethoxazole varied (Vila *et al.*, 2003). *Aeromonas* spp. can possess a conjugative plasmid that confers multiple antibiotic resistance (Chang and Bolton, 1987). *Aeromonas* spp.

Table 35.3 Differentiation of the genera within the family Vibrionaceae (adapted from Blair, McMahon and McDowell, 1999)

Characteristics	<i>Aeromonas</i>	<i>Plesiomonas</i>	<i>Vibrio</i>	<i>Photobacterium</i>	<i>Enhydrobacter</i>
Motility	+ ^b	+	+	+	-

<i>A. veronii</i> biotype <i>veronii</i>	+	+	-	+	-	+	-	+
<i>A. jandaei</i>	+	+	-	-	-	+	+	-
<i>A. shubertii</i>	+	-	-	-	-	+	+	-
<i>P. shigelloides</i>	+	-	-	-	+	+	+	+

+, >90% of strains positive; -, >90% of strains negative.

can also produce chromosomal β -lactamases such as Bush group 2d penicillinase, group 1 cephalosporinase and a metallo-carbapenemase (Walsh *et al.*, 1995). Unlike other known carbapenemases the metallo-carbapenemase found in *Aeromonas* spp. have narrow substrate profile and only hydrolyse carbapenams (Rossolini, Walsh and Amicosante, 1996). Despite this, many isolates of the clinically significant *Aeromonas* spp., with the exception of *A. jandaei* and *A. veronii biotype veronii*, remain susceptible to imipenem, with a minimal inhibitory concentrations observed (Overman and Janda, 1999). In addition to strains in which β -lactamase production may be induced, derepressed mutants for β -lactamase production have been isolated from clinical and environmental specimens (Walsh *et al.*, 1997).

Plesiomonas

P. shigelloides strains are usually susceptible to second- and third-generation cephalosporins, nalidixic acid, quinolones, co-trimoxazole, chloramphenicol and nitrofurantoin. Resistance to aminoglycosides is variable. Most *P. shigelloides* strains produce β -lactamase and are therefore resistant to all penicillins; however these isolates are susceptible to penicillins in combination with β -lactamase inhibitors.

Stock and Wiedemann investigated the natural susceptibility of 74 *P. shigelloides* strains isolated from humans, water and animals to a range of antibiotics. *Plesiomonas* strains were sensitive or displayed intermediate sensitivity to tetracyclines, several aminoglycosides, aminopenicillins in combination with β -lactamase inhibitors, all cephalosporins (except cefoperazone, ceftazidime and cefepime), carbapenems, aztreonam, quinolones, trimethoprim, sulfamethoxazole, azithromycin, chloramphenicol, nitrofurantoin and fosfomicin. Uniform resistance was found to all penicillins, roxithromycin, clarithromycin, lincosamides, streptogramins, glycopeptides and fusidic acid. Variable resistance to streptomycin, erythromycin and rifampicin was detected (Stock and Wiedemann, 2001).

Treatment of *P. shigelloides*-associated infection should be guided by sensitivity testing of the isolate. Quinolones may be used to treat *P. shigelloides*-associated gastroenteritis and in some cases antibiotic treatment has been shown to decrease the duration of diarrhoeal illness.

PREVENTION AND CONTROL

There have been no reports of person-to-person spread of infection; therefore special infection-control procedures are unnecessary. Proper cooking of food will prevent most food-borne infections as the vegetative cells and many of the exoenzymes and exotoxins are destroyed by heat challenge. However both *Aeromonas* spp. and *Plesiomonas* spp. have been shown to produce heat-stable exotoxins.

INTRODUCTION

Early Descriptions

In 1850, Sédillot, a French military surgeon, observed the formation of blue pus in the wound dressings of injured soldiers. Fordos also documented this, in 1860, but it was not until 1882 that Gessard described the organism responsible for the pigmentation, which he named *Bacillus pyocyaneus*. In 1900, Migula adopted the generic name *Pseudomonas* (Greek: 'pseudes', false; 'monas', unit) and called the species *Pseudomonas pyocyanea*. The epithet *aeruginosa* (Latin: aeruginosus, full of copper rust; i.e. green) became widely used and is now the approved species name. (For early references, see Forkner, 1960.)

Taxonomy

Up to 1984, over 100 species were included in the genus *Pseudomonas*. Many of these are plant pathogens, and their names reflect their primary hosts. The genus was subdivided into five groups based on rRNA homology (Palleroni, 1984), and today, only rRNA group I remains in the genus *Pseudomonas* (Table 36.1). It comprises 57

species defined by 16S rRNA phylogenetic analysis and includes the fluorescent species *Pseudomonas aeruginosa*, *Pseudomonas putida* and *Pseudomonas fluorescens* as well as the non-fluorescent *Pseudomonas stutzeri* (Anzai *et al.*, 2000). Organisms that were previously categorized as rRNA group II, 'the pseudomallei group', were transferred to the genus *Burkholderia* by Yabuuchi *et al.* (1992) and include the *Burkholderia cepacia* complex, *Burkholderia mallei*, *Burkholderia pseudomallei* and many plant pathogens. rRNA group III was formerly *Comamonas acidovorans* but is now incorporated into the genus *Delftia* (Wen *et al.*, 1999). Members of rRNA groups IV and V have been reclassified, respectively, as *Brevundimonas* and *Stenotrophomonas*.

DESCRIPTION OF ORGANISMS

The diversity of the pseudomonads makes it difficult to consider their properties as a single group. Furthermore, the bulk of the literature pertaining to *Pseudomonas* concerns specifically *P. aeruginosa*, and less so *B. cepacia* and *B. pseudomallei*, and the literature is relatively sparse for other species. As a result, this chapter deals with each species independently to avoid generalizations that might be inaccurate.

Table 36.1 Key tests for medically important pseudomonads

rRNA homology group	Species	Distinguishing features
I <i>Pseudomonas</i>	Fluorescent on King's B agar	<i>Pseudomonas aeruginosa</i> (oxidase+)
		<i>Pseudomonas fluorescens</i> (oxidase+)
		<i>Pseudomonas putida</i> (oxidase+)
	Non-fluorescent	<i>Pseudomonas alcaligenes</i> (oxidase+)
		<i>Pseudomonas pseudoalcaligenes</i> (oxidase+)
		<i>Pseudomonas stutzeri</i> (oxidase+)
II <i>Burkholderia</i>	<i>Burkholderia cepacia</i> (oxidase+)	
	<i>Burkholderia pseudomallei</i> (oxidase+)	
	<i>Burkholderia mallei</i> (oxidase±)	
	<i>Ralstonia pickettii</i> (oxidase+)	
	<i>Burkholderia gladioli</i> (oxidase-)	
III <i>Delftia</i>	<i>Delftia acidovorans</i> (oxidase+)	
IV <i>Brevundimonas</i>	<i>Brevundimonas diminuta</i> (oxidase+)	
	<i>Brevundimonas vesicularis</i> (oxidase+)	
V <i>Stenotrophomonas</i>	<i>Stenotrophomonas maltophilia</i> (oxidase-)	

Cultural Characteristics of *P. aeruginosa*

Pigments

Pseudomonas aeruginosa grows well on simple bacteriological media, and most strains elaborate the blue phenazine pigment pyocyanin and fluorescein (yellow), which together impart the characteristic blue-green coloration to agar cultures. The production of pyocyanin is unique to the species, and this is enhanced by culture on King's A medium (King *et al.*, 1954), which contains potassium and magnesium salts in sufficient concentration to suppress fluorescein production. The latter, also called pyoverdine, is optimally produced on King's B medium, which contains less of these salts, and is visible under ultraviolet illumination. *Pseudomonas chlororaphis* may be confused with *P. aeruginosa* as it can grow as green colonies on King's A agar. Two other uncommon pigments are pyorubrin (port wine) and the brownish-black pigment pyomelanin, which is best demonstrated on tyrosine agar. This pigment should not be confused with the brown discoloration of blood agar by some weakly haemolytic strains.

Colonial Forms and Biochemistry

On agar culture at 37 °C, most isolates form flat diffuse colonies with an irregular edge (type 1), and some are coliform in appearance (type 2). Other colony types are generally rare. They include the dry, pepper-corn (type 3), mucoid (type 4), rugose (type 5) and dwarf colonies characteristic of type 6. Many cultures produce an ester-like odour owing to the formation of trimethylamine.

Pseudomonas aeruginosa is a Gram-negative rod of variable length, motile by means of a single polar flagellum, molecular oxygen being necessary for motility. Anaerobic growth is possible only in the presence of an alternative terminal electron acceptor such as nitrate or arginine. Motility tests in conventional Craigie agar tubes are therefore inappropriate. It grows over a wide temperature range (10–44 °C), but growth is optimal at around 35 °C. It will not grow at 4 °C, which distinguishes it from the psychrophilic species *P. putida* and *P. fluorescens*, but isolates will grow over three successive subcultures at 42 °C, while the latter do not.

In keeping with other pseudomonads, most strains utilize a range of single organic compounds as energy sources. The species metabolizes glucose and other sugars by an oxidative pathway. Acid is formed in peptone–water sugars by young cultures, but this is neutralized by alkali released by the breakdown of peptone. Sugar utilization is therefore best demonstrated in an ammonium salt-based medium. All strains produce a cytochrome oxidase enzyme that is detected in the oxidase test with Kovac's reagent. Other common features of *P. aeruginosa* are reduction of nitrate to nitrogen gas and the formation of ammonia from arginine.

PATHOGENICITY

Virulence-Associated Factors

Pseudomonas aeruginosa produces a wide array of cell-associated and secreted factors, some of which have been closely linked with disease-producing potential. These include exotoxin A (ETA), phospholipase, proteases, pyocyanin, pili, flagella and lipopolysaccharide (LPS). Nevertheless, in the absence of impairment of host defences, the species has low intrinsic virulence for humans and, to cause disease, must be introduced into the tissues, or systemically, in sufficient numbers to overwhelm the host defences. This feature probably explains some of the conflicting experimental evidence concerning the role of different virulence factors. Several animal models such as the burned mouse, neutropenic mouse (induced with cyclophosphamide or anti-neutrophil monoclonal antibodies) and the murine

corneal scratch model have been used by different investigators. Certain isolates infect a broad range of host organisms from plants (*Arabidopsis*), nematode worms (*Caenorhabditis elegans*) to humans, and a universal genetic mechanism underlying the pathogenic process has been proposed (He *et al.*, 2004).

Like many Gram-negative bacteria, *P. aeruginosa* utilizes a type III secretion system that enables the organism to secrete and inject virulence factors into the cytosol of the host eukaryotic cells. The type III secretion system of *P. aeruginosa* transports four effector proteins (ExoS, ExoT, ExoU and ExoY), and the genes encoding these are present in nearly all clinical and environmental isolates, although individual isolates and populations from distinct disease sites differ in their effector gene complement (Feltman *et al.*, 2001). An additional protein, PcrV, which is a structural analogue of the *Yersinia* V antigen LcrV, is involved in the translocational process of the type III secretion system. Production of PcrV has been associated with strains from acute infections, and the risk of mortality was reported to be sixfold higher in patients infected with strains producing ExoS, ExoT, ExoU or PcrV, suggesting that these strains have increased virulence and that their presence is a predictor of poor clinical outcome (Roy-Burman *et al.*, 2001).

Adherence

Injury to the epithelial mucosa by viral infection or previous colonization by other bacteria predisposes tissue to the attachment of *P. aeruginosa*. The organism grows naturally as a biofilm either on a surface or attached to large glycoproteins such as those found in respiratory mucins. Adherence properties vary from strain to strain and the attachment matrix used, but four main groups of adhesins have been identified which mediate the attachment of *P. aeruginosa* to host tissues and mucins. They are pili, mucin-binding outer membrane (OM) protein F, surface lectins and mucoid exopolysaccharide (alginate).

The contribution of each class of adhesin to the attachment of strains of *P. aeruginosa* to different tissues is difficult to quantify. However, nearly all strains produce pili under favourable conditions. The main pilus adhesin is the type IV pilus, and they are responsible for motility of the bacteria across a solid surface (twitching motility) and for the binding and entry of some bacteriophages. They are the protein polymers (pilin) of a single gene *pilA*, but their assembly and function involves a large number of genes. Many studies have shown that pili are necessary for strain virulence at several sites of infection, and they may also be involved in cytotoxicity. *Pseudomonas aeruginosa* synthesizes two surface lectins termed PA-IL, binding to galactose, and PA-III (binds to fucose), which appear to function as adhesins similar to the fimbrial adhesins of uropathogenic *Escherichia coli*. They interact with the ABO(H) and P blood group glycosphingolipid antigens and, through this, contribute to tissue infectivity and pathogenesis of the species (Gilboa-Garber *et al.*, 1994).

Transcription of alginate biosynthetic genes is induced upon attachment of the pseudomonas cell to a surface, and increased alginate production ensues. The consortium of alginate and bacterial cells (microcolonies) is the basis of the biofilm mode of growth and protects the bacteria from the external environment, complement and antibiotics. Flagella and type IV pili do not appear to be necessary for biofilm formation, but they have a role in biofilm development (Klausen *et al.*, 2003). Exotoxin S also functions as an adhesin and is found on the cell surface, where it interacts with glycosphingolipid receptors.

Flagella

The loss of flagella by strains is strongly correlated with a decrease in virulence in the experimental animal. Flagella are therefore considered to be a significant virulence factor, in that they promote chemotaxis and motility during invasion of the tissues. The flagellin protein binds to respiratory mucins, and this facilitates the clearance of the

organism from the airways via the normal mucociliary escalator. They can also function as ligands for macrophages and other phagocytic cells. Thus, although they are important in the establishment of respiratory tract infection and may tether the cell to epithelial membranes, flagella may also contribute to the host clearance mechanisms and the elimination of the organism (Feldman *et al.*, 1998). Most isolates of *P. aeruginosa* from patients with cystic fibrosis (CF) lack flagella and are generally resistant to macrophage phagocytosis, and so they may promote the establishment of chronic infection in these patients.

Lipopolysaccharide

The cell envelope of *P. aeruginosa*, as with other Gram-negative bacteria, is composed of an external unit membrane (OM), a layer of peptidoglycan and an inner cytoplasmic membrane. The latter is mainly composed of phospholipids with randomly intercalated molecules of proteins. *Pseudomonas aeruginosa* produces two chemically distinct types of LPS, a serotype specific (B-band) and a common antigen (A-band). The B-band LPS consists of three basic units: lipid A, core polysaccharide and O-specific side chain which determines the O-serotype of the organism. A-band LPS is antigenically uniform (Lam *et al.*, 1989). The relative expression of A-band and B-band LPS in *P. aeruginosa* may enable alteration of surface characteristics to survive under extreme conditions or to evade the host immune response. The levels of the two LPS species are influenced by the dissolved oxygen tensions, with the B-band variety being mostly absent from cells grown in reduced oxygen concentrations, which may explain the loss of O-serotype of isolates recovered from the near-anaerobic conditions found in biofilms of *P. aeruginosa* growing in the CF patient's lungs (Worlitzsch *et al.*, 2002).

The LPS of *P. aeruginosa* has a lower intrinsic toxicity for mammalian cells compared with the LPS of the Enterobacteriaceae. It plays a major role in protecting the cell from the complement-mediated bactericidal action of normal human serum. Most isolates of *P. aeruginosa* from clinical samples are resistant to serum, and the highest frequency of resistance is found in isolates from blood. However, isolates from chronic infection, in particular CF and bronchiectasis, and, less frequently, persistent urinary tract infection in paraplegics, are often sensitive to serum. LPS-deficient mutants are invariably serum sensitive and avirulent in the experimental animal. Furthermore, antibody to LPS is protective not only in animal models but also in humans. Evidence suggests that antibodies specific to O-antigens of *P. aeruginosa*, particularly the high-molecular-weight O-polysaccharide, can protect against mucosal surface colonization by the organism, and this is achieved through circulating antibody alone rather than by induction of local immunoglobulin A (IgA) antibodies (Pier, Meluleni and Goldberg, 1995).

Extracellular Polysaccharides

All strains of *P. aeruginosa* elaborate an extracellular slime that aggregates loosely around the cell. More than 50% of the dry weight of slime is composed of polysaccharide, chiefly of the sugars glucose, rhamnose and mannose, with galactosamine, glucuronic acid, nucleic acids (20%) and proteins as a minor fraction (Brown, Foster and Clamp, 1969). The alginate polysaccharide is hyper-produced by mucoid strains of *P. aeruginosa* and is composed of β -1,4-linked D-mannuronic acid and L-guluronic acid, the ratio of which confers the degree of viscosity on the polymer and hence the physical appearance of the mucoid colony. Mucoid strains are almost exclusively isolated from the sputum of patients with CF or those with bronchiectasis, but few strains (<2%) from other sources may grow mucoid on first isolation. The frequency of these forms may be higher for isolates from the urine of spinal injury patients who have had repeated urinary tract infections. Isolates elaborate mucoid exopolysaccharide best on glycerol-containing agar but often throw off non-mucoid colonies on

subculture. Increased oxygenation of the medium favours the mucoid phenotype. Conversion of a non-mucoid strain to mucoid can be engineered by exposure of the organism to hydrogen peroxide and oxygen by-products of polymorphonuclear leucocytes (Mathee *et al.*, 1999). Alginate production by other species is rare, but *Azotobacter vinelandii* and some pseudomonads (*P. fluorescens*, *P. putida* and *Pseudomonas mendocina*) can manufacture the polymer.

Exoenzymes

The lethal toxin of *P. aeruginosa*, ETA, is produced by approximately 90% of the species and is closely related to diphtheria toxin. Both toxins catalyse the transfer of the ADP-ribosyl moiety of oxidized NAD (NAD⁺) to elongation factor 2 (EF2). This reaction inactivates EF2, terminates peptide chain elongation and leads to the inhibition of protein synthesis and cell death. The toxin is composed of two fragments. Fragment A is of molecular weight 21 000 Da and has enzymic activity. Fragment B is 37 000 Da and acts as the binding moiety. ETA is optimally produced in iron-limited conditions and is encoded by a single copy of a structural gene, *toxA*, and regulated by two genes *regA* and *regB* on an operon (Wick *et al.*, 1990). It is highly toxic for mammalian cells (LD₅₀ for mice <0.01 mg/kg) and enters the cell via a receptor-mediated endocytic pathway. ETA also has activity as a T-cell mitogen and interleukin-1 (IL-1) inducer (Nicas and Iglewski, 1986).

Pseudomonas aeruginosa produces another ADP-ribosyl transferase, exoenzyme S. It catalyses the transfer of ADP-ribose from NAD⁺ to other eukaryotic proteins, and it is more resistant to heat and is not neutralized by antibodies to ETA. Exoenzyme S activity is also partially destroyed by the reducing agents urea and dithiothreitol, which potentiate ETA activity. Strains lacking only the *exoS* gene are less virulent in animal models, but 94% and 80% of CF and non-CF isolates, respectively, are reported to carry the gene (Lanotte *et al.*, 2004).

Two distinct haemolysins have been identified in *P. aeruginosa*: a heat-labile phospholipase C (PLC) and a heat-stable rhamnolipid. PLC is believed to be exclusive to the species and is found in almost all strains. It degrades phospholipids containing quaternary ammonium groups such as phosphatidylcholine, the major phospholipid component of lung surfactant. PLC is therefore a potential virulence factor particularly for strains colonizing the human lung. Rhamnolipid also degrades phospholipids because of its detergent action and, in high concentrations, attracts and lyses leucocytes and has ciliostatic action (Woods and Vasil, 1994).

Most strains of *P. aeruginosa* produce a range of proteolytic enzymes that are active against a variety of substrates such as gelatin, casein, elastin, collagen and fibrin. Three classes of protease have been identified: a general protease, elastase and alkaline protease. They are distinguishable by their optimum pH of activity, substrate specificity and physical properties (Woods and Vasil, 1994). The general protease is lysine specific and has a limited range of activity. Alkaline protease has not been widely studied but has activity against a wider range of substrates and has been implicated in corneal damage in *P. aeruginosa* eye infections. Elastase degrades many proteins such as human lung elastin, Igs, complement factors, basement membrane constituents and mucins. Elastolytic activity is the result of at least two proteins, LasA and LasB, under the control of the gene *lasR*. Elastase production by strains is controlled, at the translational level, by the levels of zinc and iron in the environment. Exoenzyme production has been associated with a pathogenic role in *P. aeruginosa*. A recent study of a large number of CF isolates found that isolates from patients with good clinical status often had higher elastase and neuraminidase activities than isolates from patients with worse clinical scores. In contrast, PLC activity was higher in isolates from patients with poor clinical status (Lanotte *et al.*, 2003).

Most *P. aeruginosa* organisms produce a cytotoxin that is localized to the periplasmic space as an inactive form, but is activated by

proteases, including an endogenous elastase. Cytotoxic activity may be linked to the observed lack of leucocytes during sepsis due to *P. aeruginosa* and the fall in the granulocyte count in some patients. Experimental studies of the action of the cytotoxin in a leukopenic mouse model showed that challenge with a high cytotoxin-producing strain caused earlier and a significantly greater mortality than that observed for a cytotoxin-deficient strain. Moreover, pretreatment of mice with a cytotoxin-specific antibody decreased the mortality following challenge with the cytotoxic strain (Baltch *et al.*, 1994).

Siderophores

To obtain iron, an essential requirement for the establishment and maintenance of bacterial infection, *P. aeruginosa* excretes iron chelators such as pyochelin and the fluorescent yellow-green pigment pyoverdine (Poole and McKay, 2003). It is also able to use many heterologous siderophores of fungal and bacterial origin, and together, they play a key role in the growth and virulence of the species in iron-limited conditions. Pyochelin is poorly water soluble and of low molecular weight (325 Da), whereas pyoverdine (approximately 1500 Da) is highly soluble in water and more active. Three structurally different pyoverdine compounds have been identified in *P. aeruginosa* by isoelectric focusing (De Vos *et al.*, 2001).

Pyocyanin

The phenazine pigment pyocyanin and its colourless precursor 1-hydroxyphenazine are highly toxic for human respiratory epithelial cilia. They induce, at low concentrations, ciliary dyskinesia and later disrupt the integrity of the epithelial surface. Pyocyanin causes a fall in intracellular cyclic adenosine mono phosphate (amp), and ciliary beat can be restored by agents such as the β_2 -adrenoceptor agonists salmeterol and isoprenaline. Pyocyanin is bactericidal for many species including *E. coli*, *Staphylococcus aureus* and *Mycobacterium smegmatis*. Other activities of pyocyanin include the production of reactive nitrogen intermediates and promotion of elastase–anti-elastase imbalance by increasing the release of neutrophil elastase and enhancing the oxidative inactivation of α_1 -protease inhibitor (Ran *et al.*, 2003).

Quorum Sensing

Pseudomonas aeruginosa produces small diffusible signal molecules, acyl homoserine lactones (AHLs), during growth in an environment, and these molecules can be detected by surrounding organisms. When the concentration of AHLs accumulates in the environment because of increasing numbers of bacteria, intracellular levels of AHLs are then sufficiently high to induce the activation of transcriptional regulators, thus enabling the bacteria to act as a community in the coordinated regulation of gene expression. This process is known as quorum sensing, and two different systems have been described: the *las* system and the *rhl* system (Smith and Iglewski, 2003). These systems are the target for therapeutic compounds in the hope that the latter will attenuate the virulence of the organism and potentially assist the host in clearing the infection. Cell-to-cell signalling is considered an essential requirement for the establishment of biofilms, and AHLs have been detected in the lungs of CF patients infected with *P. aeruginosa* (Favre-Bonté *et al.*, 2002).

EPIDEMIOLOGY

Pseudomonas aeruginosa is widespread in the natural environment and can adapt to habitats ranging from surface waters to disinfectants. It can multiply in distilled water, presumably by the utilization of gaseous dissolved nutrients, but is rarely isolated from sea water (except from sewage outfalls and polluted river estuaries). It is not

associated with disease in fish. The species is present in soil and the rhizosphere and, as a result, may be frequently recovered from fresh vegetables and plants (Rhame, 1980). In the hospital environment, sinks, taps and drains are invariably colonized by *P. aeruginosa* and other pseudomonads. In contrast, the domestic household environment is rarely contaminated, with the exception of washing machines, where the organism may reside in water traps.

Natural carriage by humans is infrequent. In healthy subjects, faecal carriage rates vary between 2% and 10% (possibly higher in vegetarians). Faecal colonization appears to be transient in healthy people, and there is a rapid turnover of strain types. *Pseudomonas aeruginosa* dies rapidly on dry healthy skin, but in conditions of superhydration, such as in divers undergoing long-term saturation dives, the frequency of skin colonization is increased and accompanied by infections, particularly otitis externa (Alcock, 1977).

Clinical and environmental strains of *P. aeruginosa* form a coherent taxonomic group with few distinguishing characteristics. Environmental isolates are able to utilize gasoline supplied in the gas phase as the sole carbon source, but clinical strains do not share this property (Foght *et al.*, 1996).

Despite the apparent ubiquity of *P. aeruginosa* in the natural environment and the vast array of potential virulence factors, the incidence of community-acquired infections in healthy subjects is relatively low. However, in the hospital environment, particularly in immunosuppressed, debilitated and burns patients, the incidence of *P. aeruginosa* infection is high. The frequency of faecal carriage is sharply increased in hospitalized patients (Stoodley and Thom, 1970), possibly because of ingestion of contaminated food and the widespread use of antibiotics. The salivary carriage rate is similar in hospital patients and normal controls (approximately 5%), but skin colonization in burns patients may reach 80% by the ninth day following the burn (Holder, 1977).

Almost any type of hospital equipment or utensil has been implicated as a reservoir for *P. aeruginosa*, including disinfectants, antiseptics, intravenous fluids and eyewash solutions. These sources may serve as foci for the dissemination of the organism in common-source outbreaks, and this usually is the result of poor sterilization. Widespread contamination of the inanimate ward environment such as sink traps and taps has been cited by many workers as a potential infection hazard particularly for the contamination of the hands of personnel, but not all studies have supported this conclusion (Beck-Sagué, Banejee and Jands, 1994). Many surveys have concluded that *P. aeruginosa* accounts for approximately 10% of all hospital-acquired infections, but its prevalence in various body sites and hospital units varies from study to study. It is among the most frequent causes of hospital-acquired pneumonia, and prevalence rates of 15–25% have been reported from some centres. The species was by far the most common, and dangerous, microorganism recovered from burn wounds in the 1960s and 1970s. Today, the number of serious infections in burns patients caused by *P. aeruginosa* has declined considerably (in the developed world), owing to improvements in burn management and treatment.

INFECTIONS DUE TO *P. AERUGINOSA*

Skin and Eye

Pseudomonas aeruginosa rarely causes disease in the healthy individual unless introduced into the tissues in relatively large numbers. Prolonged exposure to contaminated water [$>10^9$ colony-forming units (CFU)/mL] may lead to skin infections such as folliculitis, soggy dermatitis of the interdigital spaces or otitis externa. Folliculitis due to *P. aeruginosa* is characterized by a diffuse maculopapular or vesiculopustular rash and usually follows immersion in contaminated swimming pools, spas and hot tubs (Schlech *et al.*, 1986). The condition is usually self-limiting, but topical treatment or, rarely, systemic antibiotics may be required. *Pseudomonas aeruginosa* is a common cause of

superficial otitis externa, but it may also cause an invasive form, sometimes in diabetics, which fails to respond to topical antibiotic therapy. This malignant infection can lead to erosion through the external auditory canal and involvement of cranial nerves, with a mortality of 20%.

Pseudomonas aeruginosa is probably the most devastating of bacterial pathogens for the human eye, in particular the cornea, where it produces ulceration or keratitis. Other infections include conjunctivitis, endophthalmitis and orbital cellulitis. The most common sources of the organism are contact lens fluids, ocular medications and mascara which have been become contaminated with *P. aeruginosa* (Zloty and Belin, 1994). Septicaemic spread of the organism from an orbital focus accompanied by pneumonia and ecthyma gangrenosum has been described in an immunocompromised individual (Maccheron *et al.*, 2004).

Burns

Pseudomonas aeruginosa is a common cause of infections in burns, established through colonization of the burn wound by the patient's own flora or from the environment. Most fatalities (usually arising from septicaemia) are associated with full-thickness burns, and there is a strong correlation with the percentage area of the burn (Smith, 1994). The most commonly used anti-pseudomonal topical agent is silver sulphadiazine, which is most effective when used prophylactically. The addition of cerium increases its antibacterial properties as well as its persistence in the eschar. Topical silver nitrate also reduces mortality in patients with extensive burns, and methylated sulphonamide (mafenide) cream has good burn eschar penetration. Patients with burns infected with *P. aeruginosa* have an increased mortality rate and longer hospital stays compared to non-infected patients. They also have an increased number of surgical procedures and higher associated antibiotic costs (Tredget *et al.*, 2004).

Wounds

Pseudomonas aeruginosa is a common isolate from surgical wounds, and its frequency is related to the site and extent of the surgery and the underlying clinical state of the patient. Data from the National Nosocomial Infection Surveillance (NNIS) survey in the United States showed an incidence in surgical wounds of about 7% in ward areas compared with 10% in intensive care patients (Beck-Sagué, Banejee and Jands, 1994).

Bones and Joints

Bones and joints can be infected either by direct injection in puncture wounds (rare) or by haematogenous spread in intravenous drug abusers and diabetic subjects, resulting in chronic osteomyelitis. Removal of the focus as well as the surrounding soft tissue is necessary if antibiotic therapy is to be successful. Septic arthritis is unusual, and many patients have a history of drug abuse or a predisposing condition (Mader *et al.*, 1994). Infection of the temporal bone by *P. aeruginosa* (mastoiditis) is a common complication of otitis media, particularly in children.

Blood and Cerebrospinal Fluid

Reports of *P. aeruginosa* bacteraemia are relatively rare in the early literature, but owing to the increased susceptibility of the hospitalized population, frequencies of *P. aeruginosa* bacteraemia today vary from 5% to 20% in many studies and septicaemia is most common in the immunocompromised, in particular granulocytopenic patients and the elderly. The mortality rates associated with *P. aeruginosa* bacteraemia range from 17% to 78%, and attributable mortality has been estimated at 34–48%, although it is often difficult to distinguish mortality due directly to bacteraemia from mortality due to underlying disease. A study by Blot *et al.* (2003) of matched cohorts in 53 intensive care unit

(ICU) patients with *P. aeruginosa* bacteraemia found that patients with the organism had a higher incidence of acute respiratory failure, haemodynamic instability and longer ICU stay and ventilator dependence with a 62% mortality rate compared with 47% for controls. Attributable mortality was therefore 15%. Multivariate survival analysis found the APACHE II score to be the only variable independently associated with mortality. A minority of patients exhibit ecthyma gangrenosum, and if untreated, necrosis of deep tissue can occur. The primary sources of bacteraemia are the gastrointestinal tract, the respiratory tract and skin. Early treatment is critical, particularly in the immunocompromised, and combination therapy with an aminoglycoside and a β -lactam is usual.

Infection of the central nervous system (CNS) with *P. aeruginosa* is uncommon. Nevertheless, the risk is increased for neonates, for those undergoing neurosurgery or transplantation or for those with a chronic underlying condition. *Pseudomonas aeruginosa* may be isolated from a minority of intracranial abscesses, but the incidence rises in patients with chronic otitis media and mastoiditis. Nosocomial transmission can occur in neurosurgical ICUs, particularly in patients with percutaneous external ventricular catheters to monitor cerebrospinal fluid pressure. The application of a sterile occlusive dressing may decrease the risk of pseudomonas ventriculitis in these patients (Trick *et al.*, 2000).

Urinary Tract

Primary urinary tract infection acquired in the community because of *P. aeruginosa* is rare except in those patients with anatomical abnormalities and spinal cord injuries. The great majority of urinary tract infections are of nosocomial origin and are invariably the consequence of long-term catheterization. Rates of approximately 5% have been reported. Haematogenous spread from a primary focus is uncommon. Paraplegic patients in institutional care are especially at risk, and reservoirs of contaminated urine such as drainage bottles and bed pans are probably the major sources for the organism. The infection is usually resolved by the removal of the catheter or other predisposing factor, but prostatic infections in the presence of calculi are exceedingly difficult to treat (Kunin, 1994).

Respiratory Tract (Non-Cystic Fibrosis)

Community-acquired pneumonia due to *P. aeruginosa* is rare and usually presents in patients with an underlying disease such as malignancy or chronic pulmonary disease or with a history of intravenous drug abuse. In intubated hospitalized patients, the organism frequently colonizes the lower respiratory tract, particularly those with a tracheostomy who have been exposed to contaminated inhalation equipment. Few of these patients progress to pneumonia. A large recent study reported that the incidence of *P. aeruginosa* was 7%, with a mortality of 28%, which is higher than that reported by other surveys (Arancibia *et al.*, 2002). This study also showed that fluoroquinolone therapy was associated with the emergence of multiresistant strains, and the presence of an underlying disease affecting immune function was linked to the presence of such strains. In most patients without anatomical abnormalities or prolonged immunosuppression, infection is relatively transient and specific treatment is not indicated. A diagnosis of ventilator-associated pneumonia is problematic, with variable sensitivity and specificity for the range of methods employed. The reader is referred to the comprehensive review of Chastre and Fagon (2002) for further detail.

Elevation of the pro-inflammatory cytokine IL-1 is believed to be associated with the outcome of *P. aeruginosa* pneumonia, and an absence of or reduction in IL-1 improves the host defence against the organism. In contrast, IL-18 (gamma interferon) appears to impair the host response to *P. aeruginosa* (Schultz *et al.*, 2003).

Pseudomonas aeruginosa is commonly recovered from the lower airways of patients with non-CF bronchiectasis, and in a minority, a chronic infected state is established, which is seldom relieved by therapy. Isolates from these patients may exhibit some of the features normally associated with CF, such as mucoid alginate production and colonial variation. Diffuse panbronchiolitis is an idiopathic inflammatory condition largely restricted to Japan that is characterized by suppurative and obstructive airway disease. Many of these patients are co-infected by *P. aeruginosa* and *Haemophilus influenzae*, and mortality is high if left untreated. Erythromycin is the drug of choice, although its effectiveness appears to be due to mechanisms other than antibacterial activity (Koyama and Geddes, 1997).

There have been many reports of *P. aeruginosa* respiratory infections in acquired immune deficiency syndrome (AIDS) patients. Most infections appear to be community acquired, and the organism is often present in pure culture. Morbidity and mortality are difficult to define accurately as many patients have advanced human immunodeficiency virus (HIV) disease, but mortality may reach 40%. Risk factors identified include advanced HIV immunosuppression and use of systemic *Pneumocystis* prophylaxis and/or broad-spectrum antibiotics.

Cystic Fibrosis

Until the 1970s, most CF patients who succumbed to bacterial infection were infected with *S. aureus*, and *P. aeruginosa* infection was relatively rare. Since that time, there has been an inexorable rise in the number of patients who harbour *P. aeruginosa*. Today, in some centres, as many as 30% of children aged 2–5 years and 80% of adult patients are colonized by or infected with this organism. Its presence and persistence in the lungs correlates with clinical decline, and until recently, it was seldom eradicated once colonization was established. The gut does not appear to be the principal source of the organism, as respiratory tract colonization often precedes the recovery of the organism from the faeces of CF patients. Oropharyngeal swabs have relatively poor sensitivity (46%) for *P. aeruginosa* in the lower airway but are quite specific for the organism. Thus, a negative oropharyngeal culture indicates that isolation of the organism from the lower airway is unlikely, but a positive culture does not predict lower airway infection. Similar findings were shown for bronchoscopic sampling of the lower airways to detect early infection in neonates (Saiman, 2004).

As *P. aeruginosa* is ubiquitous, CF patients may acquire it from a variety of sources in the environment. This is corroborated by the fact that patients are, with the exception of siblings, usually colonized by genetically different strains. Most individuals are colonized by a single strain and often retain this strain for their lifetime, but a minority may harbour two, three or more different strain genotypes. There is a reported risk of cross-infection with *P. aeruginosa* among CF patients, and this is highest when non-colonized patients come into contact with chronically infected patients in hospitals, CF centres or summer holiday camps (Govan and Nelson, 1992). A recent survey indicated that cross-infection with highly transmissible strains has occurred both within and across different CF centres in England and Wales. The study found that about 20% of all strains examined from many centres fell into two prevalent genotypes (Scott and Pitt, 2004).

An explanation for the apparent predilection of *P. aeruginosa* for the CF respiratory tract was proposed by Pier (2002). In Pier's (2002) scenario, *P. aeruginosa* may be killed early in the lung by antimicrobial factors such as host cationic peptides (defensins) and nitric oxide or bound by the CF transmembrane conductance regulator (CFTR). This serves as an epithelial cell receptor for *P. aeruginosa*, and binding occurs through the conserved core oligosaccharides of the bacterial OM. Binding of CFTR to *P. aeruginosa* results in the internalization of the bacterium by the epithelial cells, and these cells are shed into the airway surface liquid and removed by the mucociliary escalator. The airway surface fluid of CF patients is dehydrated because of CFTR dysfunction, which combined with hypersecretion

of abnormal mucus and a slow ciliary escalator provides the conditions where persistent colonization and subsequent infection can occur. Increased numbers of asialo GM₁ molecules, a receptor for various bacteria, have been reported on CF epithelia, and *P. aeruginosa* apparently binds to this compound via surface structures such as pili and flagella; however, the specificity of this mechanism has been questioned by Schroeder *et al.* (2001). It has been suggested that *P. aeruginosa* grows in a biofilm in the viscous mucus layer in near-anaerobic conditions, and this triggers the emergence of mucoid cell types. However, growth of *P. aeruginosa* biofilms in the presence of reactive oxygen species such as hydrogen peroxide can also trigger the emergence of mucoid cells (Ratjen and Doring, 2003). The selection of *P. aeruginosa* in the CF lung is therefore probably multifactorial, but it is evident that a cycle of inflammation and tissue damage is established and accompanied by an extended and exaggerated response to bacterial and viral invaders. This heightened inflammatory state over time results in an environment where high bacterial loads (often in excess of 10⁸ CFU/g of sputum) prove refractory to lung clearance mechanisms and antimicrobial therapy.

There is pronounced antibody production in response to colonization by *P. aeruginosa* in CF patients. This humoral response is associated with a poor prognosis. IgA and IgG antibodies are significantly elevated in CF compared with normal subjects, while IgM is not. Precipitating antibodies against *P. aeruginosa* are significantly elevated in at least 30% of patients, and these antibodies are always detectable when the mucoid phenotype of *P. aeruginosa* is present in the sputum. Indeed, the rise in precipitins is much more evident with chronically colonized patients as opposed to those with intermittent colonization.

Pier *et al.* (1987) suggested that the survival of CF patients to adulthood without being colonized by mucoid *P. aeruginosa* was related to the presence of specific serum antibodies against the mucoid exopolysaccharide. These antibodies were termed opsonic killing and were significantly more common in older CF patients not colonized by *P. aeruginosa*. Chronically colonized patients also had high titres of these antibodies, but they were not specific for the exopolysaccharide. This suggested that the opsonic-killing antibodies against alginate protected patients against chronic colonization with mucoid *P. aeruginosa*. An enzyme-linked immunoadsorbent assay (ELISA) which measures antibody to the lipid A, core oligosaccharide and O-polysaccharide of *P. aeruginosa* LPS revealed that the systemic antibody response is increased to all parts of the molecule (Kronborg *et al.*, 1992). Furthermore, antibodies in sputum are mainly anti-lipid A and anti-O-polysaccharide of the IgG and IgA isotypes. The determination of serum antibody by ELISA is of value, particularly in paediatric CF patients, where it may help detect *P. aeruginosa* infection at an early stage and aid the differentiation between early infection and colonization as well as monitor disease progression. In general, positive serum IgG antibody titres do not predate isolation of *P. aeruginosa* from sputum in CF patients but in some are present soon after acquisition of the organism. A positive titre indicates significant exposure to *P. aeruginosa* and may be useful to detect infection in sputum-negative patients and possibly indicate the effect of early treatment. It is paradoxical, however, that CF patients with high titres of antibodies, which supposedly protect against infection, are often those who are chronically colonized by *P. aeruginosa*. It is clear, therefore, that elevated antibodies against *P. aeruginosa*, which may protect against septicaemia, are insufficient to eliminate the bacterium from the lungs of CF patients. West *et al.* (2002) claimed that a positive serum antibody response to *P. aeruginosa* antigens (ETA, a cell lysate and elastase) preceded culture positivity by 6–12 months and argued that such diagnostic markers provided an opportunity for transforming the treatment strategy of neonates with CF. This work has yet to be independently confirmed by others.

Many isolates of *P. aeruginosa* from CF have an altered LPS structure in their cell envelope. This involves loss of all or part of the polysaccharide side chain (O-antigen) and results in the absence of

a specific O-serotype reaction for most strains (Hancock *et al.*, 1983). By electron microscopy, LPS-deficient strains exhibit outer layers characterized by atypical extrusions (lipophilic blebs) from the cell wall. These strains are also invariably serum sensitive, which requires the action of both the classical and alternative complement pathways. Both LPS-deficient and LPS-complete strains can activate complement, but only in the deficient form is the terminal complement complex able to anchor stably in the OM. Serum-sensitive strains should not survive in the bloodstream, and this is consistent with the extremely rare finding of *P. aeruginosa* septicaemia in CF patients.

Many isolates of *P. aeruginosa* from CF patients are auxotrophic (i.e. require specific growth factors). The most common requirement is for methionine, but other amino acids such as leucine, arginine or ornithine are less commonly required. Auxotrophic and prototrophic (wild-type) *P. aeruginosa* isolates colonizing the same CF patient invariably constitute an isogenic group, and it is most likely that auxotrophs are selected from the prototrophic population during the course of pulmonary infection (Barth and Pitt, 1995).

LABORATORY DIAGNOSIS AND STRAIN TYPING

Media

Pseudomonas aeruginosa grows readily on simple media. It is relatively resistant to quaternary ammonium compounds, in particular cetyltrimethyl ammonium chloride (cetrimide) and benzalkonium chloride. Cetrimide resistance has been exploited as a selective feature for the isolation and presumptive identification of the species from clinical specimens, and cetrimide-containing media combined with nalidixic acid are commercially available. Irgasan is also selective for *P. aeruginosa*. However, a minority of isolates from CF patients may exhibit hypersensitivity to both compounds and thus fail to grow on these media. Enrichment in acetamide broth has been recommended for the isolation of *P. aeruginosa* from faeces.

Typing Methods

That *P. aeruginosa* is one of the most diverse of bacterial pathogens is not surprising, given its metabolic versatility and its ability to adapt to a wide variety of habitats. The species is characterized by a superficially clonal population structure, with frequent genetic recombination leading to the emergence of highly successful epidemic clones (Pirnay *et al.*, 2002). No single method is sufficient for the unequivocal identification of strain types of *P. aeruginosa* in epidemiological studies, and combinations of two or more methods are recommended to ensure efficient discrimination between strains. Many of the early methods used for typing such as pyocin typing, phage typing and serotyping are seldom performed today and have been largely replaced by molecular techniques to define genotypes. For details of the early methods, see the first edition of this book.

Pseudomonas aeruginosa is serologically heterogeneous, and a scheme of 17 O-antigen groups is recognized internationally (Liu *et al.*, 1983). The scheme was subsequently extended to 20 serotypes. Isolates are typed by slide agglutination with live cultures from agar plates or in microtitre trays with boiled suspensions. The percentage typeability of O-serotyping for most isolates of *P. aeruginosa* (excluding CF isolates) is approximately 90%, and the reproducibility of the technique is high. Two serotypes, O6 and O11, predominate in clinical material (20% and 15%, respectively), with O11 being particularly frequent in hospital outbreaks. The loss of serotype specificity in the LPS of CF isolates drastically reduces their typeability with O-antisera, and usually less than 20% of these isolates are able to be serotyped. Many CF isolates exhibit polyagglutination with antisera to unrelated serotypes. At the time of writing, O-typing antisera can be

obtained commercially from the Institut Pasteur, Paris, France and Denka-Seiken, Tokyo, Japan.

Rare cutting restriction endonucleases, in particular *SpeI* and *XbaI*, have been widely utilized for DNA macrorestriction analysis and for generating fragments in the size range of 50–2000 kb, which are separated by pulsed-field gel electrophoresis (PFGE). Isolates with approximately 80% genomic similarity by the Dice coefficient (differ by three or fewer bands) are considered to be of the same clone, while four-to-seven-band difference implies probable relatedness. PFGE has excellent discriminatory power for *P. aeruginosa* and is the gold standard technique against which other molecular techniques are compared (Grundmann *et al.*, 1995). Amplified fragment length polymorphism (AFLP) is a PCR-based technique that randomly samples a small fraction of the entire genome and has been successfully applied to the typing of *P. aeruginosa* and gives a similar level of discrimination as PFGE (Speijer *et al.*, 1999). Other approaches to genetic typing of strains include ribotyping with *PvuII* restriction, specific gene probes (Grundmann *et al.*, 1995), various DNA targets by PCR (repetitive elements, consensus sequences and random priming) and DNA sequencing of specific genes encoding OM proteins (Pirnay *et al.*, 2002).

ANTIBIOTIC RESISTANCE AND THERAPY

Compared with the Enterobacteriaceae, *P. aeruginosa* is relatively resistant to many antibiotics. However, there are many compounds with good-to-excellent activity against the species. They include the semisynthetic penicillins (e.g. ticarcillin), ureidopenicillins (piperacillin), carboxypenicillins (carbenicillin), third-generation cephalosporins (ceftazidime), carbapenems (imipenem and meropenem), monobactams (aztreonam), aminoglycosides (gentamicin and amikacin), fluoroquinolones (ciprofloxacin) and polymyxins (polymyxin B and colistin). To improve outcomes, an aminoglycoside has often been combined previously in treatment regimens with a β -lactam, third-generation cephalosporin, monobactam or carbapenem. This requirement for combination therapy has been challenged in several studies (Paul *et al.*, 2004). Monotherapy with an appropriate antibiotic may be as effective if given early and in suitable doses.

A variety of antibiotic resistance mechanisms exist in *P. aeruginosa*. These include the following:

1. low cell-wall permeability conferring intrinsic resistance;
2. the production of extracellular chromosomal and plasmid-mediated β -lactamases, aminoglycosidases and cephalosporinases;
3. an alteration in antibiotic-binding protein sites;
4. an active efflux mechanism which pumps out antibiotic from the cell.

The development of resistance to β -lactams *in vivo* during treatment is often the result of derepression of chromosomal β -lactamase expression. Some antibiotics, in particular cefoxitin, are potent inducers of these enzymes and may select out subpopulations resistant to other cephalosporins such as ceftazidime. Resistance emerging from therapy with β -lactam antibiotics may also be due to the modification of the penicillin-binding proteins of *P. aeruginosa*. Most impermeability mediated resistance is due to an efflux pump mechanism, MexAB–OprM, which removes a very wide range of antimicrobials including β -lactams, chloramphenicol, fluoroquinolones, macrolides and various dyes and detergents. Indeed, a combination of upregulated efflux, loss of the major porin OprD and impermeability to aminoglycosides confers resistance to every known anti-pseudomonal drug class except the polymyxins (Livermore, 2002).

Pseudomonas aeruginosa from the natural environment and from non-CF patients are generally susceptible to the above-mentioned agents. Resistance rates have changed little over the last two decades and today remain around 12% for these agents (Henwood *et al.*, 2001). Similar studies from Europe have also shown little variation in

resistance rates; however, in some parts of southern Europe, Southeast Asia and South America, resistance rates may be as high as 50% for many anti-pseudomonal agents. Nevertheless, a survey of isolates from British CF patients attending regional treatment centres revealed disturbingly high levels of resistance. It showed that only 38% of isolates were susceptible to all of the six agents tested but almost 50% were resistant to gentamicin, 39% to ceftazidime, 32% to piperacillin, 30% to ciprofloxacin, 10% to tobramycin and 3% to colistin. Approximately 40% were resistant to two or more compounds (combinations of ceftazidime, gentamicin, piperacillin or ciprofloxacin). These resistance rates were generally similar to those reported for CF patients in the United States and, less so, in Germany (Pitt *et al.*, 2003). Despite this background of resistance, these and other antibiotics continue to be used with clinical success in CF patients. Part of the explanation for this is that the minimum inhibitory concentration (MIC) of some antibiotics may vary by 80-fold within the same specimen and the result obtained is greatly influenced by the colony chosen for test. To overcome this, mixed morphotype testing has been advocated, and studies have shown good agreement between multiple colonies tested singly and mixed morphotypes. Morlin *et al.* (1994) examined the correlation of the MIC of an agent for mixed colonies with the MIC for the most resistant morphotypes in sputum samples and found that the former correctly predicted the highest MICs for isolated colonies. On 90% of occasions, the MIC for mixed morphotypes predicted susceptibility, but for resistance it was only just over half of the cases.

Many antimicrobial compounds, some of which have negligible anti-pseudomonal activity, can, at concentrations as low as 1/20th and 1/50th of their MIC for a particular organism, suppress the synthesis of pseudomonas aggressins, such as elastase, phospholipase and exotoxins, and in this way reduce the inflammatory state in the lung and improve lung function. The MIC of macrolide antibiotics for *P. aeruginosa* exceeds their achievable peak serum concentrations, but clinical experience supports their anti-inflammatory action in the CF lung (Saiman *et al.*, 2003).

In the course of infection in the CF lung, *P. aeruginosa* accumulates many mutations, and these are expressed in the variety of phenotypes of the organisms recovered from sputum. Recently, hypermutable strains of *P. aeruginosa*, which have mutations in genes controlling their DNA repair systems, were reported to be exclusive to CF, and approximately one-third of CF patients in a survey in Madrid were shown to harbour these strains (Oliver *et al.*, 2000). Mutation rates of 100- to 1000-fold higher than the normal mutation rate (approximately $1 \times 10^{-8}/10^{-9}$) were found, and antibiotic resistance was most associated with hypermutating strains. The clinical significance of hypermutators over non-mutator strains is unknown, but there is speculation over whether antibiotic therapy drives the process of the selection of these strains. However, it is noteworthy that while organisms with more resistance are most likely to be hypermutators, some hypermutators may exhibit little or no resistance to anti-pseudomonal agents.

A recent study that analysed data from a placebo group in an inhaled tobramycin trial found that the *in vitro* susceptibility tests for the most resistant strains did not correlate with clinical improvement and questioned the validity of standard susceptibility methods to guide therapy in CF patients (Smith *et al.*, 2003). This was addressed by Moskowitz *et al.* (2004) who speculated that the response to antibiotic exposure of stationary-phase, microaerophilic *P. aeruginosa* growing as biofilms in the clinical laboratory may better predict the response of CF patients to antimicrobial therapy. They devised an assay that gave reproducible results and found that biofilm inhibitory concentrations (BICs) were much higher than the corresponding conventionally determined MIC for the β -lactam antibiotics but were similar for meropenem, ciprofloxacin and the aminoglycosides. Azithromycin had good anti-biofilm activity, but all isolates were uniformly resistant in the standard method. Clinical trials are clearly needed to compare the efficacy of therapy based on biofilm susceptibility testing with standard testing.

CF patients may require long-term maintenance antibiotics and additional treatment of acute exacerbations of infection. The primary aim for long-term maintenance antibiotic therapy against *P. aeruginosa* in CF is to reduce the severity and frequency of acute exacerbations. Eradication of the organism is difficult, but there are occasional reports of success with different regimens. Early aggressive antibiotic treatment is widely practised using a combination of inhaled colistin with oral ciprofloxacin or inhaled colistin or inhaled tobramycin alone. Long-term follow-up of patients treated with inhaled tobramycin (80 mg twice a day for 1 year after initial colonization) showed that it not only postponed chronic infection but also led to eradication of the bacteria from the sputum in 14 of 15 treated patients (Ratjen, Doring and Nikolaizik, 2001). Aminoglycosides are suitable agents for nebulization, and there is increasing evidence of their efficacy in CF, although not in other groups of patients.

PREVENTION AND CONTROL

Vaccines

Pseudomonas aeruginosa expresses many antigenic surface structures and extracellular products, many of which have been investigated for their potential to induce protective antibodies. Native LPS is poorly immunogenic, and it is best bound to a carrier protein such as ETA or tetanus toxoid, to stimulate an antibody response in the subject. An alternative approach is the use of high-molecular-weight polysaccharide polymers from culture supernatants that are highly antigenic and free of the toxicity of native LPS.

Many clinical trials with *O*-polysaccharide-based vaccines have been reported, and the results vary with the type and quality of the preparations (Cryz, 1994). The first whole-cell vaccines reduced mortality rates in burns patients when compared with controls, but it was not until the development of heptavalent LPS vaccine, Pseudogen, that large-scale studies in different patient groups were undertaken. The vaccine gave little or no protection to cancer patients against *P. aeruginosa* and was also ineffective in intensive care patients and in CF. Another LPS-based vaccine, PEV-01, entered clinical trials, and initial results in burns patients were promising, although this has been questioned on the grounds of poor study design (Cryz, 1994). An octavalent *O*-polysaccharide-toxin A conjugate vaccine was shown to be safe in volunteers and patient groups and elicited functional anti-LPS and antitoxin A antibodies following immunization. Lang *et al.* (2004) reported a 10-year retrospective analysis of clinical outcomes with this vaccine in a cohort of 30 CF children with mean age 7 years, 26 of whom were followed up. The patients were given yearly vaccine boosters, and results were compared with a closely matched control group who did not receive the vaccine. The time to infection with *P. aeruginosa* was longer in the vaccinated group compared with controls, and fewer vaccinated patients than controls became chronically infected (32% versus 72%; $P < 0.001$). This was associated with better preservation of lung function. Vaccinated patients gained more weight during the study period, a possible indication of an improved overall health status.

Pseudomonas alginate is poorly immunogenic, but both the high-molecular-weight polysaccharide moiety and alginate combined with toxin A elicit opsonizing antibodies in humans. It has been shown that the larger the polymer size, the more immunogenic is the alginate vaccine. At a dose of 100 pg of alginate, long-lasting opsonic antibodies are formed in humans which enhance the deposition of C3 onto mucoid cells and mediate the killing of the challenge strain (Garner, Desjardins and Pier, 1990).

Recent research in immunotherapy has focused on the use of DNA vaccines in which animals are immunized with plasmid DNA that expresses bacterial proteins in eukaryotic cells. DNA immunization with flagellin B, OM protein F and ETA has been shown to be effective at protecting animals challenged with virulent strains of

P. aeruginosa. Variation in effectiveness is probably a consequence of the choice of bacterial protein and the route of administration. The type III secretion system proteins have also been investigated for their potential as vaccine targets. Active and passive immunization with a purified type III translocation protein, PcrV, enhanced survival of mice challenged with a lethal dose of *P. aeruginosa* (see review by Holder, 2004).

Normal human serum contains *P. aeruginosa*-specific antibodies, and in the past, pools of normal IgG have proved successful for the reduction of septicaemia and mortality of burns patients infected with *P. aeruginosa*. There were therefore great expectations for passive immunotherapy with hyperimmune plasma, but it proved disappointing in clinical use. Many aspects of passive immunotherapy such as their prophylactic value, the type of patient most amenable to treatment, the duration of treatment and the most reliable clinical indicators of therapy remain contentious. Both murine and human monoclonal antibodies have been prepared against specific LPS, and other antigens of *P. aeruginosa*, including toxin A, have performed with varying success in animal challenge models (Holder, 2004).

OTHER PSEUDOMONAS SPP.

Pseudomonas fluorescens and *P. putida* are both fluorescent pseudomonads. They grow poorly at 37°C, and most strains will grow at 4°C. This property contributes to the fact that these species, in particular *P. fluorescens*, are able to multiply in stored refrigerated blood and blood products and may give rise to fatal reactions when injected intravenously owing to the release of endotoxin. They are both of low pathogenicity in humans but have been isolated from urine, faeces, sputum and occasionally the blood of immunosuppressed patients. Hospital outbreaks of infection are rare, but *P. fluorescens* is often recovered from hospital sites such as floors and sink traps, in environmental screens.

Pseudomonas stutzeri has a characteristic appearance on agar and colonies may grow 'rough', 'smooth' or intermediate even in pure cultures. The rough colonies may be confused with *B. pseudomallei*, and older cultures may appear light brown in colour. The species is actively denitrifying, and large volumes of gas are produced in nitrate broth. Most strains will grow at 41°C. *Pseudomonas stutzeri* has been widely reported from hospital-acquired infections, but these are usually self-limiting. Isolates are sensitive to β -lactams, colistin and gentamicin.

BURKHOLDERIA SPP.

BURKHOLDERIA CEPACIA COMPLEX

Taxonomy

This species was first described by Burkholder in 1950 as the agent of slippery skin in onions, and the genus *Burkholderia* is named after him. Subsequent to this first description, it became known as '*Pseudomonas multivorans*' and '*Pseudomonas kingii*', but later the epithet *Pseudomonas cepacia* was adopted. However, Yabuuchi *et al.* (1992) proposed the transfer of seven species of rRNA homology group II, including *P. cepacia*, to the new genus *Burkholderia*. *Burkholderia cepacia* is not a homogeneous species but forms a complex of phenotypically similar, genetically distinct, genomovars within the genus *Burkholderia*. It was the pioneering work of Vandamme *et al.* (1997) using polyphasic taxonomic methods that revealed a complex of five genomovars among strains isolated from various clinical and environmental sources. Today, the *B. cepacia* complex comprises nine genomovars: *B. cepacia* (I), *Burkholderia multivorans* (II), *Burkholderia cenocepacia* (III), *Burkholderia stabilis* (IV), *Burkholderia vietnamiensis* (V), *Burkholderia dolosa* (VI), *Burkholderia ambifaria* (VII), *Burkholderia anthina* (VIII) and *Burkholderia pyrracinia* (IX).

The individual genomovars cannot be identified by their phenotypic properties or reactions in biochemical tests. Classification of *B. cepacia* complex clinical isolates to genomovar level is best achieved by the amplification of the *recA* gene to assign the isolate to the complex. Restriction fragment length polymorphism (RFLP) analysis with *HaeIII* restriction enzyme is then used to generate genomovar-specific patterns (Mahenthalingam *et al.*, 2000), and these are then confirmed with specific PCR tests.

PATHOGENICITY

Strains of *B. cepacia* from animal or plant sources are relatively avirulent (LD₅₀ 1 × 10⁸ CFU) for normal mice, but they persist in high numbers in a burned mouse model. The species produces a variety of extracellular putative virulence factors that may contribute to its pathogenicity for plant and animal hosts. These include lipases, haemolysins and proteases. Invasion of host cells and intracellular survival are fundamental to its establishment of disease. *Burkholderia cepacia* invades cultured respiratory epithelial cells and progresses into the cytoplasm where they are enclosed by membrane-bound vacuoles. It is also able to penetrate, survive and grow in *Acanthamoeba*, which may suggest a symbiotic relationship between the bacteria and free-living amoebae, with the latter perhaps acting as a reservoir for the organism and even possibly serving as a vehicle for its transmission to CF patients.

Using immunohistological techniques, Sajjan *et al.* (2001) were able to localize *B. cepacia* in the lungs of CF patients with cepacia syndrome in the exudates within bronchial lumens and between airway epithelial cells. The organisms were diffusely distributed in patients with chronic infections, but in acute infections the distribution was more focal, with the bacteria located on injured airway surfaces and in abscesses. In the progression from the chronic state to invasive infection, *B. cepacia* migrates across the epithelial barrier to invade the lung parenchyma and capillaries, thereby initiating septicaemia.

EPIDEMIOLOGY

Nosocomial Infections

A common feature of infections in humans with *B. cepacia* is the association of infusion of contaminated fluids. Numerous nosocomial outbreaks have been documented involving contamination of antiseptics, infusion fluids, tubing for irrigation and pressure-monitoring devices, but in general, outbreaks are rare and can usually be curtailed by the recognition and removal of the source. Infections also tend not to be severe, and systemic sepsis is uncommon. Patient-to-patient spread is unusual, and prolonged carriage by individuals (with the exception of CF) has not been documented. An association between *B. cepacia* and chronic granulomatous disease has been reported (O'Neil *et al.*, 1986). Phagocytic cells from these patients do not produce peroxides necessary for the intracellular killing of bacteria.

Cystic Fibrosis

Burkholderia cepacia infection was first recognized in CF patients in the mid-1970s, but it was 10 years later when its prevalence rose to nearly 40% of patients in a major centre in Toronto, Canada (Isles *et al.*, 1984), and elsewhere in the United States. The clinical outcome of *B. cepacia* infection in CF patients may vary from asymptomatic carriage through a gradual but accelerated decline to a rapidly fatal fulminant septicaemia in a minority of cases, the latter condition being termed cepacia syndrome. The contribution of *B. cepacia* to clinical deterioration and lung damage in most patients is unclear. Some early studies reported no significant difference in inflammatory markers

and lung function between *B. cepacia* colonized and non-colonized patients, but more recently, a clear excess of mortality has been demonstrated in patients colonized with an epidemic strain of *B. cepacia* (Ledson *et al.*, 2002).

The frequency of *B. cepacia* complex organisms among all CF patients is generally low (approximately 5% of patients in UK centres), but this may increase dramatically if transmissible strains are implicated. Infections are more common in adult (>15 years) than paediatric patients. Segregation of *B. cepacia*-positive CF patients from others who do not harbour the organism is now widely practised, and this, combined with efficient infection control measures, reduces acquisition of the organism by new patients. However, a 6-year review of *B. cepacia* genotypes from patients referred to a North American transplantation centre showed that patient-to-patient spread was rare, and no evidence was found that they represented a major source of *B. cepacia* strains found in the resident CF clinic population (Heath *et al.*, 2002). This may be due to the fact that almost all the strains examined lacked the *cblA* gene which is almost unique to strains of the ET12 clonal lineage. This highly transmissible lineage probably originated in Ontario and spread through northeastern centres in the United States to the United Kingdom, apparently carried by CF patients returning from summer camp holidays, and at its peak was found in almost one-third of United Kingdom and Ireland patients colonized with *B. cepacia* (Pitt *et al.*, 1996).

Burkholderia cepacia can be transmitted between CF patients both in and out of hospitals (Govan *et al.*, 1993) and between non-CF and CF patients. Guidelines for the management and control of *B. cepacia* infections in patients and their carers have been published by CF associations in Europe and North America and have been reviewed recently (Saiman and Siegel, 2004). Apart from practical infection control advice, they also highlight the importance of regular sensitive and specific bacteriological screening to establish the colonization status of patients.

Most *B. cepacia* complex isolates from CF patients are of genomovar III (60–70%). *Burkholderia multivorans* (genomovar II) is the second most common, with reported frequencies of approximately 5–37%; the other genomovars are uncommon (Mahenthiralingam, Baldwin and Vandamme, 2002). Accordingly, most outbreak isolates are genomovar III. Although genomovar II strains may occasionally be transmitted between patients, most strains appear to be genotypically unique. Some genomovar III strains may superinfect patients already colonized with other genomovars. This is clinically important, as the former are universally associated with clinical decline and a higher mortality. Patients infected with *B. cepacia* complex organisms present an additional problem in their selection for heart–lung transplantation as long-term survival is influenced by genomovar status. Outcomes are variable, with some 1-year mortality rates of between 50% and 100%, but survival rates greater than 75% have also been reported. However, the highest mortality is associated with genomovar III-colonized patients (De Soyza *et al.*, 2001).

Three transmissibility genetic factors have so far been described in *B. cepacia*: *cblA* which encodes for thick bundles of peritrichous (cable) fimbriae, an insertion sequence hybrid IS1356/IS402 and the *B. cepacia* epidemic strain marker (BCESM), a 1.4-kb sequence containing an open-reading frame with homology to transcriptional regulatory genes. These markers have strong association with the prevalent epidemic strain (ET 12) in the United Kingdom, and some authors have suggested that strict segregation of patients might only be appropriate for those harbouring this genotype (Clode *et al.*, 2000).

Burkholderia cepacia can be detected by air sampling after physiotherapy of CF patients has taken place and may persist for short periods after the room is vacated. Some strains of *B. cepacia* are able to survive in respiratory droplets on environmental surfaces, and it is also a common contaminant of dental water systems. It is relatively common in the domestic environment but is infrequent in salads and fresh foods. The risk posed by the natural environment as a reservoir for infection of CF patients is therefore probably low, but the patho-

genic potential of environmental strains is unclear. A comparison of the traits related to virulence and transmissibility in large numbers of isolates from Italian CF patients with isolates from the maize rhizosphere (Bevivino *et al.*, 2002) found that genomovar III isolates comprised most of the strains in both groups. The clinical strains were more resistant to antibiotics, but most strains were equally as able as environmental strains to rot onion tissue. There is a potential danger to CF patients from the widespread application of strains for biodegradation and biocontrol purposes to the agricultural environment. Most rhizosphere isolates have closest affinity with *Burkholderia* spp. with known bioremediation and biocontrol capabilities and are unrelated to plant or human pathogenic strains. Nevertheless, the finding of a genomovar III strain from agricultural soil in the United States by LiPuma *et al.* (2002) suggests that human pathogenic strains are not necessarily distinct from environmental strains and that patients may acquire them on occasion direct from the environment.

LABORATORY DIAGNOSIS

Cultural Characteristics

Burkholderia cepacia complex organisms are slender motile rods. They grow well aerobically on nutrient agar but often prefer temperatures of 25–35 °C for 48 h for optimal growth. Most strains grow at 41 °C but not at 42 °C, and none grows at 4 °C. Stored cultures survive poorly on refrigerated agar slopes, and viability is better maintained as suspensions in sterile tap water and in frozen suspensions in glycerol on beads. Colonies on nutrient agar are opaque and vary in appearance from greyish-white, through yellow to a reddish-purple or deep brown colour. Members of the complex do not form ammonia from arginine and are lysine and ornithine decarboxylase positive. The oxidase reaction is slow and nitrate is not reduced; some strains produce a melanin-like pigment on tyrosine agar. Automated biochemical identification assays, such as Vitek and Microscan, give a reasonable level of identification, but the API 20NE system is reliable for identifying members of the complex, except *B. stabilis*.

Selective media are necessary to optimize isolation of the species from clinical and environmental specimens. Most selective media exploit the biochemical diversity and intrinsic resistance of the complex to antibacterial agents. They include an oxidation–fermentation agar base supplemented with lactose, polymyxin B and bacitracin; a commercially available agar containing crystal violet, bile salts, ticarcillin and polymyxin B; and a medium containing the selective agents 9-chloro-9-(4-diethylaminophenyl)-10-phenylacridan and polymyxin B. Henry *et al.* (1999) reported that a medium containing lactose and sucrose in an enriched casein and yeast extract with polymyxin, gentamicin and vancomycin was superior to oxidation–fermentation agar and the commercially available selective medium for the recovery of *B. cepacia* from CF sputum. For the optimal isolation of *B. cepacia*, sputum should be liquefied and diluted in saline or water and selective agar plates incubated at 37 °C for 48 h and then at room temperature for up to 5 days. Many pseudomonads and other polymyxin-resistant Gram-negative species are able to grow on *B. cepacia* selective media, and the identity of isolates should be confirmed by additional tests. A liquid enrichment medium (Malka broth) supplemented with polymyxin B is recommended for isolating the organism from environmental swabs and soils (Butler *et al.*, 1995).

Typing Methods

Many typing methods have been described for *B. cepacia*. They include biotyping, serotyping of O and H antigens, bacteriocin production/sensitivity, plasmid profiling, chromosomal DNA analysis and multilocus enzyme electrophoresis (Wilkinson and Pitt, 1995). The methods vary in their discriminatory power, reproducibility and

typeability, and therefore, a combination of them is recommended. Ribotyping using the restriction enzyme *EcoRI* has been widely applied to epidemiological studies of *B. cepacia*, and at least 50 different patterns were identified among strains from British CF patients (Pitt *et al.*, 1996). Various PCR methods have been used to detect polymorphisms in the intergenic spacer regions of rRNA, random DNA targets, flagellin genes and insertion sequences as a means of strain identification. PFGE of *XbaI* chromosomal DNA digests offers the highest level of discrimination. Multilocus restriction typing (MLRT) which indexes variation at five chromosomal loci by restriction analysis of PCR-amplified genes was described by Coeyne and LiPuma (2002). Most clusters delineated by MLRT corresponded closely to those defined by PFGE.

Antibiotic Susceptibility and Treatment

Burkholderia cepacia is intrinsically very resistant to many antimicrobial agents, and resistance is even more common in clinical isolates from CF patients who have previously received antibiotics. *Burkholderia cepacia* is generally resistant to the antibiotics active against *P. aeruginosa*. Nearly all strains are resistant to the aminoglycosides, polymyxin, ticarcillin and azlocillin, while variable sensitivity is shown to aztreonam, ciprofloxacin, tetracyclines and carbapenems. A proportion of strains remain relatively susceptible to trimethoprim-sulphamethoxazole and chloramphenicol. Pitt *et al.* (1996) found that about three-quarters of CF isolates were susceptible to ceftazidime, piperacillin (+tazobactam) and meropenem but usually at only high breakpoint levels. However, the MICs for individual antimicrobials vary widely within genomovars (Nzula, Vandamme and Govan, 2002). Combinations of two, three or even four agents may show *in vitro* synergy against *B. cepacia*, but Manno *et al.* (2003) found that less than half of *B. cepacia* complex isolates tested were susceptible to combinations of ciprofloxacin-piperacillin and rifampicin-ceftazidime. They also showed that rates of antagonism for cotrimoxazole and chloramphenicol in combination with β -lactams were higher than those observed for ciprofloxacin plus β -lactams. Interpretation of these synergy tests is difficult; data are lacking on the relationship with clinical response. As a result, particularly where patients have been treated previously, combination antibiotic regimens are often tailored to individual patients (Jones, Dodd and Webb, 2001; Conway *et al.*, 2003).

Resistance to β -lactams is a consequence of a combination of low permeability of the OM and inducible β -lactamases. β -Lactam resistance may also be mediated by a class A β -lactamase very similar to the chromosomal β -lactamase of *Klebsiella oxytoca* (Trepanier, Prince and Huletsky, 1997). Multidrug resistance efflux pumps have been described and may contribute to high-level resistance to tetracycline and nalidixic acid. Plasmids can be detected in a minority of *B. cepacia* strains, but their contribution to overall resistance is unknown. Conjugative transfer of plasmid DNA from *P. aeruginosa* to *B. cepacia* and from *B. cepacia* transconjugants to other strains of the same species has been demonstrated.

BURKHOLDERIA PSEUDOMALLEI

INTRODUCTION

Burkholderia pseudomallei is the causative agent of melioidosis, which is a glanders-like disease of humans and animals. The species has been known by many names in the past and was for a long time classified among the genus *Pseudomonas* but was transferred to *Burkholderia* by Yabuuchi *et al.* (1992). *Burkholderia pseudomallei* and *B. mallei* formed a distinct group within *Pseudomonas* RNA group II because of their phenotypic and genetic similarities; they share 92–94% DNA–DNA homology and have identical 16S rRNA sequences.

EPIDEMIOLOGY

Burkholderia pseudomallei is a free-living saprophyte in soil and water in tropical areas where melioidosis is endemic, mainly Southeast Asia and northern Australia. Sporadic cases have also been reported from other parts of the world including the Indian subcontinent, the Pacific Islands, Central Africa, Caribbean islands and Central and South America (Dance, 1991). The organism persists in soil during the dry season and spreads through the surface with the rains; the number of bacteria in the soil probably affects the incidence of melioidosis in these areas. It has been recovered from a wide variety of sources within endemic areas, but the relationship between environmental contamination and the incidence of melioidosis is unclear. Furthermore, the species is able to survive well in conditions of nutrient depletion, and this may be relevant to its persistence in the environment.

Infection is acquired through wounds and skin abrasions and by inhalation and rarely through ingestion. The organism may also enter the body through mucosal membranes of the eye and nose. Human-to-human transmission is considered to be extremely rare. Venereal spread of melioidosis has been described in humans, and intrauterine and mammary infection in goats. Early studies postulated that an insect vector was involved in the transmission of the organism, but this is now refuted. Although *B. pseudomallei* may infect a wide range of animals and birds, transmission of infection from animal to humans is rare, and cross-infection between people is very uncommon. There have been occasional reports of infection through contaminated injections as well as accidental exposure in the laboratory.

Regular contact with soil and water appears to be the primary risk factor for acquiring melioidosis, hence the frequency of the disease among rice farmers in Southeast Asia and Aborigines in Australia. Several thousand cases are thought to occur each year in Thailand, and melioidosis accounts for approximately 18% of community-acquired septicaemia in endemic areas of the country (Suputtamongkol *et al.*, 1994a). In Thailand, the peak incidence of infection is in the 40-to-60-year age group, but all ages are affected with a male:female ratio of 3:2. Most (75%) cases present during the rainy season, but incubation periods varying from 2 days to 26 years have been documented. Particular risk factors for developing disease are the presence of other underlying diseases such as diabetes mellitus, renal failure and alcoholism (White, 2003).

PATHOGENESIS AND INFECTION

Early work suggested that *B. pseudomallei* produces two heat-labile toxic constituents, both of which are lethal for mice when injected intraperitoneally but only one of which is dermonecrotic. Proteins with cytotoxic activity of approximately 31 kDa and 3 kDa have been purified from culture filtrates of isolates of *B. pseudomallei* from different sources, but it is unclear whether these toxins represent those described originally. An acidic rhamnolipid of 762 Da was also identified in heated culture filtrates of *B. pseudomallei* with toxicity for various cell lines, and it also lysed mouse, sheep and human erythrocytes (Häubler *et al.*, 2003).

Most strains of *B. pseudomallei* produce protease, lipase, PLC and haemolysin but not elastase. A type II secretion gene cluster controls the secretion of protease, lipase and PLC, but there is no direct correlation between the level of protease activity and the virulence of *B. pseudomallei* for mice. Another cluster of genes has been identified in the species which is homologous to, and in the same order as, a group of genes in *Ralstonia solanacearum* which in the latter are located in a type III secretion system-associated pathogenicity island. These genes were present only in the *ara*⁻ phenotype and absent from *ara*⁺ strains (see *Burkholderia thailandensis*), suggesting that they have a role in virulence (Winstanley and Hart, 2000). The species obtains iron from serum and cells through a hydroxamate siderophore, malleobactin, which is optimally produced under iron-deficient conditions.

As with *B. cepacia*, *B. pseudomallei* adheres to, penetrates and survives in a variety of mammalian cells. Structurally intact bacteria can be demonstrated within macrophages in experimental melioidosis that, despite an augmented cellular immune response, results in intracellular survival and growth. Phagocytes containing *B. pseudomallei* remain viable and retain their capacity to produce an oxidative burst for the first hour of incubation. The occurrence of latency and the tendency for melioidosis patients to relapse are also consistent with the organism surviving intracellularly. Harley *et al.* (1998) investigated intracellular survival of the species by studying the uptake of a test strain by fresh mouse peritoneal macrophages and cultured cells by electron microscopy. They found that *B. pseudomallei* appeared initially in phagosomes with intact membranes, but fusion with lysosomes was not observed. Loss of the membrane occurred rapidly, and the organisms escaped into the cytoplasm. However, fusion of phagocytic and non-phagocytic cells occurs when infected with *B. pseudomallei*, leading to the formation of multinucleated giant cells. The latter have been reported in the tissues of patients with melioidosis (Wong, Puthuchery and Vadivelu, 1995). *Burkholderia pseudomallei* has a specific high-affinity binding site for human insulin, and this feature has been postulated to be related to the predisposing influence of diabetes mellitus for melioidosis.

Presentation and Diagnosis of Melioidosis

Melioidosis varies greatly in clinical presentation (White, 2003). Patients may be asymptomatic but seropositive, present with mild localized infections, or may have a fulminating rapidly fatal septicaemia. The disease is characterized by pneumonia (either primary or secondary) and the widespread development of abscesses, particularly in the skin, liver, spleen, lung and prostate gland. Large joints are often involved. Among hospitalized adult cases, approximately 60% will have positive blood cultures. Children often present with localized, unilateral parotid gland swelling. Chronic suppurative infections also occur, and the disease may be easily mistaken for tuberculosis. The overall in-hospital mortality remains high, at approximately 40%.

Latency and relapse are also prominent features of this disease (Chaowagul *et al.*, 1993). A chronic state is established in many patients after acute infection, and relapse may occur after the apparent cure or remission of primary infection. The definitive diagnosis of melioidosis is made by the isolation of *B. pseudomallei* from tissues or body fluids, such as blood, urine and sputum. The organism is relatively easy to isolate on conventional media, and selective broth-enrichment media increase diagnostic sensitivity. Every attempt to aspirate samples of pus should be made. In Gram-stained smears, the organism may be present in only small numbers and bipolar staining may not be observed. Culture of throat swabs has a high predictive value (Wuthiekanun *et al.*, 2001). An immunofluorescence antibody test, ELISA latex agglutination test and PCR have all been used for rapid diagnosis. Serodiagnosis of melioidosis is based on the demonstration of a rising antibody titre to reference strains of *B. pseudomallei*. The indirect haemagglutination assay (IHA) is probably the most widely used, but high background titres in non-infected patients from endemic areas reduce its effectiveness. IHA titres of 40–80 in non-infected adults in endemic areas are not unusual, but titres of 640 or above are considered strongly indicative or diagnostic of the disease. ELISA tests for detecting both specific IgG and IgM antibody to *B. pseudomallei* have been proposed, with claims of high specificity and sensitivity. The ELISA is comparable in performance with an IgG immunofluorescence assay and is more sensitive than the IHA test.

LABORATORY DIAGNOSIS

Both *B. pseudomallei* and *B. mallei* are classified, by the UK Advisory Committee on Dangerous Pathogens (ACDP), as Hazard Group 3 organisms, and therefore, their culture and manipulation presents a

risk to laboratory personnel. All procedures involving live cultures must be performed within a Laboratory Containment Level 3 facility. Both organisms are considered to be potential biological warfare agents.

Burkholderia pseudomallei grows well on nutrient agar at an optimum temperature of 37 °C (range 15–43 °C). Colonial morphology is best observed after 48 h at 37 °C, although growth is visible after 24 h. Colonies may be smooth and opaque or wrinkled; the latter is enhanced by glycerol. The growth has a characteristic musty odour (**sniffing of cultures is discouraged**), and on blood agar there may be weak haemolysis. Variation between rough and smooth colonial forms is frequent, and purified colonies may not breed true on subculture. Cells exhibiting bipolar staining are apparently associated with the rough colonial form. Mucoid isolates are rare. No extracellular pigments are formed. Colonial morphology is best observed on Ashdown's medium, which is a simple agar containing crystal violet, glycerol and gentamicin (Ashdown, 1979). Colonies concentrate the dye from this medium and grow rugose or smooth.

Burkholderia pseudomallei oxidizes glucose in Hugh and Leifson's medium, produces ammonia from arginine and degrades poly- β -hydroxybutyrate, starch, gelatin and Tween 80. Dance *et al.* (1989b) recommend that an oxidase-positive Gram-negative rod showing bipolar or irregular staining should be tested for resistance to colistin 10 μ g and gentamicin 10 μ g discs and subcultured on Ashdown's medium and incubated for 48–72 h. Presumptive isolates from this medium (resistant to both antibiotics) should be screened by API 20NE, which is highly efficient for confirmation of the identity of *B. pseudomallei*, although false identification of some other pseudomonads may occur. *Burkholderia pseudomallei* may be misidentified as *B. mallei*, *B. cepacia*, *P. stutzeri* or *Flavobacterium* spp.; *B. cepacia* is arginine negative and lysine decarboxylase positive, and *B. mallei* is not motile and arginine negative. A latex agglutination test can be used to confirm the presence of the LPS antigen of *B. pseudomallei*, which is conserved throughout the species.

Various PCR assays targeting 16S or 23S rDNA and other DNA sequences have been described for the identification of *B. pseudomallei* either in pure culture or in clinical specimens. They vary considerably in their performance characteristics but generally are disappointing in their specificity, although reported sensitivities range from 40% to 100% with spiked samples. The protocol of Hagen *et al.* (2002) is probably the most efficient for the rapid and specific detection of *B. pseudomallei*. They used a seminested PCR assay targeting a genus-specific sequence of the ribosomal protein subunit 21 (rpsU) and a nested PCR to amplify the filament-forming flagellin gene (*fljC*). The combination of PCR and sequencing of the amplicons resulted in high sensitivity and specificity in fixed tissue sections and avoided the need for culture of the organism.

Typing Methods

Until the advent of molecular typing techniques, relatively few methods were applied to the epidemiological type identification of *B. pseudomallei*. There is little, if any, serological heterogeneity to be exploited for antigenic typing schemes. The immunodominant epitope of the OM, LPS, is structurally and antigenically conserved, and there is minimal variation in OM and cellular proteins. The flagella are antigenic, but no H-typing scheme has been described. A capsule-like exopolysaccharide has been identified, but this is also antigenically uniform throughout the species.

Ribotyping using *Bam*HI digests of chromosomal DNA was the first molecular typing method used for studies of the epidemiology of *B. pseudomallei*. A survey of 350 isolates of *B. pseudomallei* recovered over 71 years from 23 countries revealed 44 ribotypes. Two ribotypes together accounted for almost half of the collection, and one of these was statistically associated with an Asian origin (Pitt, Trakulsomboon and Dance, 2000). PFGE of *Xba*I DNA macrorestriction digests gives optimal discrimination between strains and has been utilized for many studies.

Other techniques applied to strain typing include random amplified polymorphic DNA (RAPD) analysis, multilocus enzyme electrophoresis and multilocus sequence typing (MLST). The latter technique has similar discriminatory power to PFGE (Godoy *et al.*, 2003).

ANTIBIOTIC SUSCEPTIBILITY AND TREATMENT

In general, *B. pseudomallei* is susceptible *in vitro* to carbapenems (imipenem and meropenem), anti-pseudomonal penicillins (such as piperacillin and azlocillin), tetracyclines such as doxycycline, amoxicillin plus clavulanic acid (co-amoxiclav), ticarcillin plus clavulanic acid, ceftazidime, ceftriaxone, cefotaxime, aztreonam, cefoperazone plus sulbactam, chloramphenicol and trimethoprim-sulphamethoxazole. Quinolones such as ofloxacin and ciprofloxacin have intermediate activity. *Burkholderia pseudomallei* is resistant to penicillins, aminopenicillins and many early cephalosporins, including cefuroxime. It is also resistant to macrolides, clindamycin and rifampicin. Aminoglycoside resistance is uniform, although 60% of strains may be sensitive to kanamycin. Sulphamethoxazole and trimethoprim sensitivity tests may be unreliable because of poorly defined endpoints (Dance *et al.*, 1989a). Resistance to ampicillin is mediated by a clavulanate-susceptible β -lactamase, three different mechanisms of β -lactam resistance being identified in *B. pseudomallei* (Godfrey *et al.*, 1991).

High-dose ceftazidime, with or without additional co-trimoxazole, has been shown to halve the mortality of severe melioidosis compared with the previously used conventional regimen (see below) and is the drug of choice for severe infections. Co-amoxiclav (Augmentin) is a good alternative (Suputtamongkol *et al.*, 1994b), particularly for empirical treatment of severe sepsis in endemic areas, because of its broad spectrum of activity. Imipenem plus cilastatin was shown to be equivalent to ceftazidime alone in a single large trial (Simpson *et al.*, 1999), and meropenem might be expected to have equivalent efficacy. Cefotaxime and ceftriaxone are poorly active *in vivo* despite good *in vitro* activity (Chaowagul *et al.*, 1999). Before 1987, the conventional treatment for melioidosis was chloramphenicol, doxycycline and trimethoprim-sulphamethoxazole, in combination. This regimen, given intravenously, was associated with poor outcomes in acute disease. However, it may be the only option in severe β -lactam allergy.

Prolonged oral eradication therapy, following successful treatment of acute disease, is required to reliably limit disease relapse. The four-drug conventional regimen has been shown to be superior to co-amoxiclav for this purpose and remains the eradication regimen of choice. Doxycycline, as a single agent, and fluoroquinolones (ciprofloxacin and ofloxacin) have each proved to be unsatisfactory (White, 2003). The need for chloramphenicol in the oral eradication regimen has been questioned (Chetchotisakd *et al.*, 2001) and is the subject of further clinical trials. Trimethoprim-sulphamethoxazole alone has been used successfully in Australia (Currie *et al.*, 2000), but as yet there are no clinical trial data to support its use. For children and pregnant women, prolonged courses of co-amoxiclav are recommended for eradication.

BURKHOLDERIA THAILANDENSIS

In recent years, it has become apparent that some environmental isolates of *B. pseudomallei* are of a different phenotype to those from disease. This phenotype was first characterized by their ability to assimilate arabinose; in contrast, all clinical isolates were unable to assimilate this sugar. These newly defined strains, termed ara⁺, were non-virulent in mice compared with the highly virulent ara⁻ clinical strains. They were also distinguishable by ribotype and had sufficient differences in 16S rRNA encoding genes to allow Brett *et al.* (1998) to propose the new species name of *Burkholderia thailandensis*. Isolates from the environment should therefore be screened for arabinose assimilation for the presumptive identification of this species. At the time of writing, there

has been only one unconfirmed report of human infection because of this organism, and its clinical relevance remains in doubt. Antibiotic susceptibility patterns are similar to those of *B. pseudomallei*.

BURKHOLDERIA MALLEI

Burkholderia mallei is an obligate animal parasite (particularly of equine species) that was at one time widespread in the world. It is exceedingly rare today and restricted to a few foci in Asia, Africa and the Middle East. Most interest in this organism now arises from its theoretical potential for use as a biological warfare agent.

Cells are straight or slightly curved rods arranged singly, in pairs end to end, in parallel bundles or in Chinese-letter form; they may stain irregularly owing to granular inclusions. It does not produce a capsule and flagella are absent. *Burkholderia mallei* is aerobic and on nutrient agar forms smooth, grey translucent colonies 0.5–1 mm in diameter in 18 h at 37 °C. It is non-motile, does not grow on MacConkey or cetrimide agar, does not form pigments and is catalase positive, and few are oxidase positive. All strains reduce nitrate but not nitrite. Gelatin hydrolysis, urease activity and production of lecithinase is variable; almost all hydrolyse tyrosine, but without the formation of pigment. All strains break down arginine but not lysine or ornithine.

Data on the antibiotic susceptibilities of *B. mallei* are scanty. The few strains reported appear to be sensitive to sulphonamides and usually also to streptomycin, tetracycline and novobiocin; some are sensitive to chloramphenicol. Kenny *et al.* (1999) examined 17 strains from reference culture collections and reported the following MICs in broth dilution tests for 90% of the strains tested: >64 μ g/mL for ampicillin, 16 μ g/mL for piperacillin, 8 μ g/mL for amoxicillin-clavulanate, >64 μ g/mL for cefuroxime, 8 μ g/mL for ceftazidime, 0.25 μ g/mL for imipenem, >64 μ g/mL for chloramphenicol, 2 μ g/mL for doxycycline, 8 μ g/mL for ofloxacin, 8 μ g/mL for ciprofloxacin, 0.5 μ g/mL for gentamicin, 4 μ g/mL for azithromycin, 16 μ g/mL for rifampin, >64 μ g/mL for sulphamethoxazole, 32 μ g/mL for trimethoprim and >64 μ g/mL for co-trimoxazole. They concluded that the superior tissue penetration of azithromycin over gentamicin made this a possible candidate antibiotic for treating glanders, but there is virtually no clinical experience with this agent.

There are no contemporary accounts in the literature of glanders in humans with the exception of the report of a laboratory-acquired case in a military researcher working with *B. mallei* (Srinivasan *et al.*, 2001). The individual was diabetic and had not worn gloves when handling the live organism. His illness closely resembled melioidosis, with initial axillary lymphadenopathy followed by a systemic illness with liver and splenic abscesses. He was effectively cured by treatment with imipenem plus doxycycline followed by azithromycin plus doxycycline for a total of 6 months. In view of the lack of experience of treating glanders in recent times, treatment of cases should follow regimens that are suitable for melioidosis.

BURKHOLDERIA GLADIOLI

Burkholderia gladioli was previously known as *Pseudomonas marginata* but is closely related to *B. cepacia*. Strains grow readily on polymyxin-containing selective media, and they can be differentiated from *B. cepacia* by their negative reactions for oxidase enzyme and utilization of maltose and lactose. The species may also be confused with *Oligella ureolytica* because of its variable urea-hydrolysing properties. It is most often isolated as an opportunist in the CF lung where it may cause a primary invasive infection, but it has also been recovered from patients with chronic granulomatous disease. Multiresistant isolates with shared phenotypic properties of *B. cepacia* and *B. gladioli* have been reported from CF patients by Baxter *et al.* (1997) who found the 'Edinburgh epidemic strain' of *B. cepacia* to give equivocal

reactions in biochemical tests and fatty acid analysis. A PCR assay for the species based on 23S rDNA sequences was shown by Whitby *et al.* (2000) to have a sensitivity of 96% and to be 100% specific. Human clinical cases have been reviewed previously (Graves *et al.*, 1997).

OTHER PSEUDOMONADS

STENOTROPHOMONAS MALTOPHILIA

The work of Swings *et al.* (1983) placed strains of the species *Pseudomonas maltophilia* into the genus *Xanthomonas*. However, many strains of the former did not form the bright-yellow colonies of many *Xanthomonas* strains, and hence a new genus *Stenotrophomonas* (a unit feeding on few substrates) was proposed by Palleroni and Bradbury (1993) to accommodate the single species *maltophilia*. *Stenotrophomonas maltophilia* forms opaque grey-green yellowish colonies on nutrient agar at 37°C and often has a lavender hue on blood agar. It has several polar flagella and gives a variable weak oxidase reaction. Most strains require methionine for growth. Maltose, glucose and xylose are utilized in ammonium salt-based media and nitrate is reduced.

Stenotrophomonas maltophilia is widely distributed in the natural world and has been isolated from various environments (soil, water and milk). After *P. aeruginosa*, it is probably the most frequently isolated pseudomonad in the clinical laboratory. It is an occasional cause of bacteraemia, endocarditis and pneumonia and has been recovered from many other disease states. Nevertheless, the clinical significance of *S. maltophilia* is unclear. Although it can cause severe and fatal infections, in many patients, particularly those with wound infections, infection is often trivial and self-limiting. However, mechanically ventilated patients receiving antimicrobials in the Intensive Therapy Unit (ITU) and neutropenic patients are at increased risk of *S. maltophilia* infection or colonization. Establishing the importance of isolates from ITU patients can be very difficult, particularly if the organism is a common isolate from patients in that unit. Contamination of monitoring equipment possibly contributes to its spread, although carriage on the hands of hospital workers in outbreaks is uncommon. The hospital sources from which the organism has been isolated include sinks, nebulizers, transducers, disinfectants, defrost water baths and ice-making machines. *Stenotrophomonas maltophilia* has been reported as the most common contaminant identified from embryos and semen samples stored in liquid nitrogen, and the organism was further shown to suppress significantly fertilization and embryonic development *in vitro* (Bielanski *et al.*, 2003). Human carriage is variable; faecal carriage rates have been reported to be as high as 33% in patients with haematological malignancy but only 3% in a control patient group (Denton and Kerr, 1998).

Stenotrophomonas maltophilia has been increasingly isolated from the sputum of CF patients. Talmaciu *et al.* (2000) reported that since 1993 the incidence of *S. maltophilia*-positive patients increased from 2.8% to 6.2% in 1997. Their data suggest that colonized patients had worse growth parameters, clinical scores and spirometric values than *S. maltophilia*-negative patients, and there appeared to be a higher incidence of colonization with *S. aureus* among those patients who grew *S. maltophilia*. Considerable variation has been reported in the prevalence of the species in CF centres worldwide, 19% in a British centre and over 30% in a Spanish centre (Denton and Kerr, 1998), and this may be attributable to, among other factors, the wider use of carbapenems and longer duration of hospitalization of patients. Cross-infection between patients does not appear to be significant. *Stenotrophomonas maltophilia* will often grow reasonably well on *B. cepacia* selective media containing polymyxin B.

Many typing methods have been applied to epidemiological studies of *S. maltophilia*. O-Serotyping is poorly discriminatory owing to the disproportionate frequencies of three of the 31 types described, and the technique has not been widely used. Other methods proposed

for typing include protein profiles, bacteriocins and pyrolysis mass spectrometry. Ribotyping is highly discriminatory for the species, and PFGE of *Xba*I chromosomal DNA digests is able to resolve genetically distinct strains. Arbitrarily primed PCR is slightly less discriminatory than PFGE but offers the advantage of speed and less labour. Typing of isolates from apparent outbreaks usually reveals the presence of multiple strains, with small clusters of patients sharing the same strain. Indeed, the diversity of genotypes identified in *S. maltophilia* incidents argues against clonal spread of resistant hospital strains, and the marked genetic distance between strains may lead to further examination of the homogeneity of the species.

Stenotrophomonas maltophilia is intrinsically resistant to imipenem owing to the production of a zinc-dependent carbapenemase, which may explain in part its prevalence in intensive care and neutropenic patients. Most strains are sensitive to co-trimoxazole, doxycycline, minocycline, ticarcillin/clavulanic acid, cefotaxime and ceftazidime. Co-trimoxazole is the antibiotic of choice for therapy. Synergy, *in vitro*, has been observed for combinations of co-trimoxazole with many agents, including carbenicillin, rifampicin and gentamicin. There may be significant differences in sensitivity test results of strains after incubation at different temperatures. Strains are more resistant to aminoglycosides at 30°C and more sensitive to colistin at 37°C. There is also considerable discrepancy between disc diffusion susceptibility values for strains and broth dilution MICs (Denton and Kerr, 1998). This makes the interpretation and reporting of susceptibility tests results problematic.

RALSTONIA SPP.

Ralstonia pickettii is a non-pigmented pseudomonad, formerly a member of the genus *Burkholderia*, which grows well at 37°C and less so at 41°C. The species is synonymous with the organism earlier described as *Pseudomonas thomasii* and resembles *B. cepacia* biochemically, as it does not attack arginine. Most strains are resistant to aminoglycosides and colistin but are generally susceptible to chloramphenicol, co-trimoxazole and cephalosporins. *Ralstonia pickettii* is an occasional cause of nosocomial infections in hospital patients and has been recovered from the ward environment as well as contaminated antiseptic and disinfectant solutions. It has also been associated with pseudobacteraemia. Three other species of *Ralstonia*, *Ralstonia gilardii*, *Ralstonia paucula* and *Ralstonia mannitolilytica*, have rarely been associated with human infections (Coeyne, Vandamme and Lipuma, 2002).

BREVUNDIMONAS SPP.

Brevundimonas diminuta and *Brevundimonas vesicularis* are closely related species that were previously classified as rRNA homology group IV within the genus *Pseudomonas*. They grow rather slowly on ordinary nutrient media and require pantothenate, biotin and cyanocobalamin for optimal growth; *B. diminuta* also requires cysteine or methionine. *B. vesicularis* gives only a weak oxidase reaction, forms yellow or orange colonies and acidifies glucose and maltose in ammonium salt media. Both species are rare in pathological specimens and of doubtful clinical significance, although occasional serious infections may occur.

DELFTIA ACIDOVORANS

Delftia acidovorans was previously classified as a member of the genus *Comamonas* (Wen *et al.*, 1999). It has been isolated on many occasions from hospital patients and their environment and is a common contaminant of dental unit water lines and has been occasionally reported as a cause of eye infections. The organism is able to degrade polyurethane, a widely used industrial polymer, and utilize certain herbicides. Some isolates are able to grow on polymyxin-containing agar and may be misidentified as *B. cepacia* in sputum

specimens from CF patients. It acidifies mannitol but not ethanol, glucose or maltose in ammonium salt media and is generally asaccharolytic. Isolates are usually resistant to gentamicin and susceptible to the ureidopenicillins, tetracyclines, quinolones and co-trimoxazole.

PANDORAEA SPP.

These organisms were originally classified as CDC weak oxidizer group 2 but were recently assigned to the genus *Pandoraea*, which is a close relative of *Burkholderia*. They are nonfermentative Gram-negative rods isolated predominantly from soil and the sputum of CF patients. Four species have been named, *Pandoraea apista*, *Pandoraea pulmonicola*, *Pandoraea pnomenusa* and *Pandoraea sputorum*; *Burkholderia norimbergensis* has also been reclassified as a new *Pandoraea* species. Members may be differentiated from each other by specific PCR assays (Coeyne *et al.*, 2001). The few isolates tested were resistant to ampicillin, extended-spectrum cephalosporins and aminoglycosides but varied in their susceptibility to ciprofloxacin.

Legionella spp.

T. G. Harrison

Health Protection Agency, Systemic Infection Laboratory, Centre for Infection, London, UK

INTRODUCTION

In July 1976 a dramatic outbreak of an acute, febrile respiratory illness occurred in the city of Philadelphia among approximately 4400 Legionnaires (veterans of the US army) who had gathered to attend the 58th convention of the Pennsylvania Branch of the American Legion. There were a total of 182 convention-associated cases of whom 29 died and, as most of the victims were military veterans, the outbreak aroused considerable media interest. The newspapers used colourful names to describe the illness: 'Philly Killer', 'Legion Fever', 'Legion Malady' and 'Legionnaires' disease (LD)'. Surprisingly the latter of these was adopted by the scientific community, and this name has, in part, helped to perpetuate media interest in this uncommon form of pneumonia ever since.

The search for the cause of the Philadelphia outbreak was exhaustive, and only after more than 6 months of investigations was the isolation of the causative organism reported (McDade *et al.*, 1977). In order to isolate the organism, these investigators had inoculated guinea pigs with autopsy material from an LD patient. Tissues from the guinea pigs that developed fever were used to inoculate embryonated hens' eggs. Using these rickettsial isolation techniques McDade and colleagues (1977) were able to demonstrate the presence of Gram-negative bacilli in preparations of the infected eggs. Convalescent sera from patients (91%) identified in the outbreak reacted with antigens prepared from these bacteria in an indirect immunofluorescent antibody test. These results were consistent with the view that the bacterium was the aetiological agent of LD.

Investigators at the Centers for Disease Control, Atlanta recognised epidemiological similarities between the Philadelphia outbreak, where an air-conditioning system was implicated as the source of infection, and several earlier outbreaks of illness including one in Washington DC during 1965, one in Pontiac, Michigan during 1968 and one in the same Philadelphia hotel in 1974 which occurred amongst delegates to a convention of the Independent Order of Odd Fellows. Retrospective examination of stored sera collected from patients during these outbreaks revealed that these outbreaks had also been caused by this organism (McDade *et al.*, 1977; Terranova, Cohen and Fraser, 1978). Thus although newly recognised, LD was clearly not a new illness. Outbreaks of LD have now been recognised to have occurred since the 1940s.

The realisation that a hitherto unrecognised bacterium was responsible for an illness with significant morbidity and mortality led to period of intense interest in all aspects of the organism. It was quickly appreciated that in addition to air-conditioning systems, water-distribution systems were also important sources of infection. It was also established that legionellae occur widely in both natural and artificial aquatic environments. As knowledge of the habitat expanded so did the number of legionellae-like organisms identified.

DESCRIPTION OF THE ORGANISM

Taxonomy

The causative agent of LD was initially designated the Legionnaires' Disease Bacterium (McDade *et al.*, 1977). DNA/DNA homology studies on the few clinical and environmental isolates then available revealed that they were members of a distinct species, and the family Legionellaceae and the genus *Legionella* were subsequently defined in 1979 for a single species *Legionella pneumophila* (Brenner, Steigerwalt and McDade, 1979).

The decision, taken at that time, to create a new family was based on phenotypic evidence: *L. pneumophila* was distinct from other Gram-negative bacteria in nutritional requirements and cell-wall composition. Since this time 48 other species of *Legionella* have been identified (Park *et al.*, 2003) (Table 37.1), and the validity of the family Legionellaceae has been substantiated both phenotypically and phylogenetically. However classification at the genus level has been controversial. The generally held view is that all the species are phenotypically very similar and hence should all be placed into the genus *Legionella*. On the basis of limited phenotypic evidence (e.g. colony autofluorescence) and a different interpretation of DNA homology data, some workers maintain that the family should be divided into three genera: *Legionella*, *Fluoribacter* and *Tatlockia*. Alternative names have been formally proposed and consequently *L. bozemanii*, *L. dumoffi*, *L. gormanii*, *L. micdadei* and *L. maceachernii* may be found cited in the literature as *Fluoribacter bozemanii*, *F. dumoffi*, *F. gormanii*, *Tatlockia micdadei* and *T. maceachernii* respectively (Garrity, Brown and Vickers, 1980; Fox and Brown, 1993).

More recent phylogenetic studies (Harrison and Saunders, 1994; Ratcliff *et al.*, 1997) have again demonstrated that the species of the family Legionellaceae are monophyletic, showing no significant discrete divisions. Furthermore if the family were to be divided on the basis suggested by Fox and Brown (1993) many genera with only one or two species would be created. The phenotypic data do not support this view, as although identification of members of the genus is relatively simple, distinguishing between many of the species is very difficult and often requires the application of molecular techniques (Table 37.1).

Definition

Legionellae are nutritionally fastidious, pleomorphic Gram-negative, non-spore-forming organisms. *In vivo* they are short rods or coccobacilli measuring 0.3–0.9 µm in width and 2.0–6.0 µm in length; on artificial media they may be seen as rods or occasionally as filamentous 6.0–20.0 µm or more in length. They are motile with a single monopolar

^a Evidenced by isolation of the organism, unless otherwise indicated.

^b *L. erythra* serogroup 2 is serologically indistinguishable from *L. rubrilucens*.

^c This species was originally designated as LLAP (see *Growth Requirements* for details).

^d *L. pneumophila* comprises three subspecies: subsp. *pneumophila*; subsp. *fraseri* and subsp. *pascullei*.

^e *L. sainthelensi* Sgp 2 is serologically indistinguishable from *L. santicrucis*.

flagellum although non-motile strains do occur. Branched-chain fatty acids predominate in the cell wall which also contains major amounts of ubiquinones with more than ten isoprene units in the side chain. L-Cysteine and iron salts are required for growth *in vitro*, carbohydrates are not fermented or oxidised and nitrate is not reduced to nitrite. Legionella are urease negative, catalase positive and give variable results in the oxidase test. The legionellae have a genome size

of approximately 2.5×10^9 Da (3.9 Mb) and a guanine-plus-cytosine content of 38–52 mol%, the exception being *L. gresilensis*, which has a reported G + C content of 33 mol%.

PATHOGENICITY

As discussed below legionellae are primary pathogens of protozoans, which can from time to time give rise to infection in humans and possibly other animals. It appears that the pathogenic mechanisms that have evolved to enable legionellae to survive in their protozoal host also enable them to multiply in mammalian alveolar macrophages.

Infection in humans follows inhalation of fine aerosol (<5 µm particle size) containing organisms that are both viable and virulent. Once within the alveoli the legionellae are taken up by alveolar macrophages where they multiply. Two modes of entry into macrophages have been observed. The first termed 'coiling phagocytosis', in which long phagocytic pseudopods coil round the organism, was extensively studied by Horwitz and colleagues (Horwitz and Silverstein, 1980; Horwitz, 1983; Horwitz and Maxfield, 1984; Shuman and Horwitz, 1996). Although initially thought to be highly significant, workers have since reported that other strains of *L. pneumophila* are taken up by conventional phagocytosis (Rechnitzer and Blom, 1989). Phagocytosis is mediated by a three-component, receptor ligand-acceptor molecule, system comprising complement receptors on phagocytes (CR1 and CR3), fragments of the complement component C3 fixed on the bacterial surface as ligand, and the major outer membrane protein (MOMP), which acts as the C3-acceptor molecule, in the bacterial outer membrane (Payne and Horwitz, 1987). During phagocytosis the plasma membrane is remodelled with components of the phagocyte being sorted into, or out of, the nascent phagosome: the CR3 receptors are concentrated within the phagosome, while class I and class II MHC molecules are excluded from it. This mode of entry appears to limit the oxidative burst of the phagocyte and hence enhances intracellular survival of the legionellae. A less well-characterised opsonin-independent mode of entry has also been reported (Stone and Abu Kwaik, 1998). Once within the macrophage legionellae are able to reprogram the phagocyte endocytic pathway to escaping killing by inhibiting acidification of the nascent phagosome and preventing phagosome/lysosome fusion. Subsequently the phagosome recruits smooth vesicles, mitochondria and rough endoplasmic reticulum, and within 4–8 h a ribosome-lined replicative vacuole is formed. Multiplication of the legionellae proceeds by binary fission with a doubling time of approximately 2 h. During the late replicative phase the legionella-containing phagosome merges with lysosomes, but replication continues until the host cell is packed with organisms and finally disrupts releasing bacteria to infect further host cells. The actual killing and lysis of the phagocytes appears to occur in a biphasic manner. In the early stages of infection legionellae induce apoptosis, a process that is mediated by the activation of caspase-3 (Gao and Abu Kwaik, 1999), but once bacterial replication ceases, the legionellae cause necrosis of their host cell probably by inducing a pore-forming toxin (Alli *et al.*, 2000).

The host limits infection primarily by cell-mediated immune mechanisms. Once activated by cytokines macrophages are poor hosts for legionellae; phagocytic activity is reduced by about 50%, possibly through decreased expression of CR1 and CR3, and intracellular iron is decreased by downregulation of the transferrin receptor expression (Bellinger-Kawahara and Horwitz, 1990). Studies, using polymorphonuclear leucocyte (PMN)-depleted guinea pigs, suggest that PMNs also play an important role in host defence. Although this observation is consistent with the large numbers of PMNs seen in histology specimens from LD patients, *in vitro* studies have not been able to elucidate the mechanism by which this occurs. Although a strong humoral response accompanies infection, this appears to provide little protection and possibly may be detrimental, promoting the uptake of *L. pneumophila* by macrophages (Horwitz and Silverstein, 1981).

Virulence Factors

In recent years a number of genetic loci have been identified in *L. pneumophila* that are required for its intracellular survival. Many, but not all, of these loci are necessary for the infection process in both mammalian and protozoan cells. The first virulence-associated gene of *L. pneumophila* to be identified was the macrophage infectivity potentiator (*mip*) gene that encodes a 24-kD protein surface protein (Mip). Mip is a prokaryotic homologue of the FK506-binding proteins and exhibits peptidyl-prolyl *cis/trans* isomerase (PPIase) activity. *mip*-like genes have been detected in all other species of legionella and some other bacteria. Cianciotto *et al.* (1990), using a pair of isogenic strains (one of which was deficient in Mip), demonstrated that Mip was required for the full expression of virulence by *L. pneumophila*. It appears that Mip is required either for optimal internalisation of the legionellae by macrophages or for resistance to the bactericidal mechanisms active shortly after phagocytosis. It is, however, noteworthy that although much less efficiently, the Mip-deficient mutant did multiple in macrophages and did produce illness in guinea pigs. Clearly Mip can only contribute in part to the virulence of a strain.

The Dot/Icm system of *L. pneumophila* is encoded by genes located in two 20-kb regions of the chromosome which may, at least in some strains, constitute a single pathogenicity island (Vogel and Isberg, 1999; Brassinga *et al.*, 2003). The *dot* (defective in organelle trafficking) and *icm* (intracellular multiplication) loci were independently identified by two different laboratories so the majority of the 24 genes so far identified have two designations. The Dot/Icm system shares homology with type IV transporters of other pathogenic bacteria such as *Bordetella pertussis*, *Agrobacterium tumefaciens*, *Helicobacter pylori* and *Brucella* species. Type IV systems, which are thought to have evolved from systems involved in conjugative transfer of DNA, are critical for the pathogenic process as they export important virulence factors across bacterial membranes. Hilbi *et al.* (2001) showed that the Dot/Icm system is required for stimulation of uptake of the bacteria upon contact with the host cell. Two proteins, DotA and RalF, which are secreted by Dot/Icm have been identified. DotA previously thought to be an inner membrane protein may actually be a pore-forming protein that is inserted into the host membrane (Nagai and Roy, 2001). RalF is required for the localisation of the ADP-ribosylation factor on phagosomes containing *L. pneumophila* (Nagai *et al.*, 2002).

In addition to those mentioned above, a number of other genes have been investigated. *Legionella pneumophila* contains a type II secretion system that is required for the expression of type IV pili (Liles, Viswanathan and Cianciotto, 1998). The system is known to transport several molecules including the 38- to 42-kD Zn-metalloprotease. This enzyme, variously called tissue-destructive protease, zinc metalloprotease and major secretory protein, has been studied in detail and has been shown to be cytotoxic and haemolytic. Experimentally it causes pulmonary lesions which closely resemble those seen in infection (Conlan, Williams and Ashworth, 1988; Szeto and Shuman, 1990; Williams *et al.*, 1993). The type II secretion system is dependent on the *pilBCD* genes that are involved in the biogenesis of temperature-regulated type IV pili (Stone and Abu Kwaik, 1998). Two genes have been studied in detail: *pilE* (pilin protein) and *pilD* (prepilin peptidase). The *pilE* gene/pilin is not required for intracellular growth but may be involved in attachment to the host cells. However the prepilin peptidase is essential for pilus production and type II secretion of proteins. Other genes that promote various stages of intracellular infection, but which are less well studied included the *pmi* (protozoan macrophage infectivity) gene and *mil* (macrophage-specific infectivity) gene.

Cellular Constituents

The cell wall of legionellae is typical of a Gram-negative organism being trilaminar with an outer membrane, peptidoglycan layer and cytoplasmic membrane; however the composition of the cell wall is unusual.

The subunits of peptidoglycan are extensively cross-linked, producing a highly stable layer which confers some resistance to degradation by lysozyme (Amano and Williams, 1983). The lipopolysaccharide (LPS) composition of legionella has also been shown to be unusual, the monosaccharide and the fatty-acid composition being particularly complex in structure (Sonesson *et al.*, 1989). The LPS comprises a Lipid A part with 16–24 amide-linked 3-hydroxy fatty acids, 5–11 ester-linked non-hydroxy fatty acids and long-chain ester-linked (ω -1)-oxo fatty acids and (ω -1)-hydroxy fatty acids. These features appear to be unique and characteristic of *Legionella* species (Sonesson *et al.*, 1994a,b). It is thought that these unusually long-branched-chain fatty acids may inhibit binding of the CD14 LPS receptor on macrophages, thus reducing the endotoxic activity of *Legionella* LPS by approximately 1000-fold compared to that of salmonella LPS (Wong *et al.*, 1979; Neumeister *et al.*, 1998). The LPS core oligosaccharide lacks the heptose of classic LPS but contains abundant 6-deoxy sugars and is highly o-acetylated. The O-chain polysaccharide of the *L. pneumophila* serogroup 1 LPS is an α (2–4)-linked homopolymer of the 5-*N*-acetimidoyl-7-*N*-acetyl derivative of 5,7-diamino-3,5,7, 9-tetraoxynon-2-ulosonic acid, termed legionaminic acid.

Legionella contain large amounts (>80%) of branched-chain fatty acids and only small amounts of hydroxy acids. Although qualitatively similar, the fatty-acid profiles of some *Legionella* species show marked and consistent quantitative differences. In addition all species contain unusual members of the ubiquinone group of respiratory isoprenoid quinones which contain nine to 15 isoprenyl unit side chains. The combination of fatty-acid profiling and ubiquinone analysis has proved a valuable, although not routine, tool for the identification of legionellae (Wait, 1988; Diogo *et al.*, 1999).

As noted above the *L. pneumophila* LPS is unusual in composition and has little endotoxic activity in comparison with typical LPS. However it has been suggested that differences in LPS structure between strains might account for differences in virulence in humans. Monoclonal antibodies (mAbs) have been used extensively to differentiate between strains of *L. pneumophila* serogroup 1. Dournon *et al.* (1988) were the first to notice that strains (designated MAB2⁺) which reacted with one such mAb, directed against an LPS epitope (Petitjean *et al.*, 1990), were more likely to be isolated from patients than were strains which did not react (MAB2⁻ strains). This has led to the widely held view that MAB2⁺ strains are more virulent than MAB2⁻ strains. There is some evidence that MAB2⁺ strains infect human monocytes less well than do MAB2⁻ strains; however some recent studies have not confirmed this (Edelstein and Edelstein, 1993). An alternative suggestion is that the LPS of mAb2-positive strains is more hydrophobic than mAb2-negative LPS, resulting in better survival of mAb2-positive strains in aerosols which, in turn, makes it more likely that they will be inhaled in a viable state by a susceptible individual than will be mAb2-negative strains. Data from two studies support this hypothesis. First, Dennis and Lee (1988) showed that mAb2-positive strains survived significantly better than did mAb2-negative strains in a laboratory-generated aerosol held at a suboptimal relative humidity of 60%. Second, Luck *et al.* (2001) isolated an mAb2-negative mutant from an mAb2-positive wildtype parent strain. Analysis showed that mAb2-negative strain had a point mutation in the active site of O-acetyltransferase and consequently its LPS contained legionaminic acid that lacked 8-O-acetyl groups: earlier work by the same group had shown that increased 8-O-acetylation of legionella LPS resulted in increased hydrophobicity of the organism (Zahringer *et al.*, 1995).

EPIDEMIOLOGY

Normal Habitat

Extensive environmental studies indicate that legionellae are ubiquitous organisms occurring over a wide geographical area in river mud, streams, lakes, rivers, warm spa water, water in hydrothermal areas,

numerous other natural bodies of water and, most recently, subterrestrial groundwater sediments (Fliermans *et al.*, 1981; Verissimo *et al.*, 1991; Fliermans and Tyndall, 1993). Legionellae have also been isolated from diverse artificial habitats including air-conditioning systems, potable water supplies, ornamental fountains and plumbing fixtures and fittings in hospital, shops and homes (Tobin, Swann and Bartlett, 1981; Colbourne *et al.*, 1988; Redd *et al.*, 1990; Hlady *et al.*, 1993).

Early studies indicated that legionellae could be detected by immunofluorescence (IF) in most natural bodies of water examined but could only be isolated and cultured from a few of these (Fliermans *et al.*, 1981). Initially, because of the questionable specificity of the reagents used in the IF, only the isolation rate was considered to be an accurate indication of the likely prevalence of legionellae. The isolation rate is, in part, dependent on the temperature of the body of water examined: legionellae can be readily isolated and cultured from water between about 20 and 40 °C but are rarely isolated from colder sources. It is now known that at low temperatures, in common with many environmental organisms, legionellae enter a 'dormant state' where they remain viable but non-culturable (VBNC) (Colbourne *et al.*, 1988; Steinert *et al.*, 1997; Ohno *et al.*, 2003). Hence isolation rates probably give a poor estimate of the true prevalence of legionellae which are very clearly widely distributed, being found in almost all natural bodies of fresh water although they may be present at only low numbers and possibly in a VBNC state.

The ubiquitous nature of legionellae, even in low-nutrient environments, appears to contrast with exacting requirements for culture and isolation of the organism in the laboratory. The explanation seems to be that naturally legionellae grow in association with other micro-organisms. Tison *et al.* (1980) first demonstrated that *L. pneumophila* could grow in mineral salts medium at 45 °C in association with cyanobacteria (*Fischerella* sp.). In the same year Rowbotham (1980) observed that when legionellas were phagocytosed by *Acanthamoeba* trophozoites *in vitro*, they could survive and multiply within the amoebal vacuole. It has subsequently been shown that other protozoa such as species of *Hartmanella*, *Naegleria* and *Valkampfia*, *Tetrahymena* and *Cyclidium* can also be parasitised (Breiman *et al.*, 1990), and it is now widely acknowledged that these host-parasite relationships are central to the propagation and distribution of legionellae within the environment. Indeed it has been suggested that legionellae may not be free-living bacteria *per se* (Fields, 1996). This close association has several potential benefits for legionellae such as the provision of adequate concentrations of nutrients in otherwise nutrient poor conditions, the protection from adverse external conditions within, for example, amoebal cysts (Kilvington and Price, 1990) and possibly a mode of distribution with the amoebal cyst acting as a carrier.

In common with most other aquatic bacteria legionellae colonise surfaces at the aqueous/solid interface. Here together with their protozoal hosts, other bacteria and algae, they form a complex consortium of organisms loosely termed 'biofilm'. It is believed that biofilm formation provides nutritional advantages and protection from adverse environmental influences to its constituent organisms compared to their planktonic counterparts.

In humans legionella infection can vary in severity from a mild flu-like illness to acute life-threatening pneumonia. There is no evidence of person-to-person spread, infection being acquired primarily by inhalation of aerosol containing virulent organisms. The pneumonic form of the disease, LD, is well characterised, but the mild non-pneumonic form is ill defined and encompasses any condition that is not LD but where there is some evidence of legionella infection. The term 'Pontiac Fever' is sometimes used interchangeably with non-pneumonic legionellosis; however it is more appropriately applied specifically for those cases characterised by a self-limiting, flu-like illness with a high attack rate and short incubation period. The data presented below relate only to LD; that is where there is clear evidence of pneumonia and the criteria for laboratory diagnosis have been met (Anonymous, 1990).

Incidence and Risk Factors

Cases of LD have been reported from countries throughout the world. However reported incidence varies considerably ranging, for example, from 0.0 to 34.1 cases per million population in 2002 for 31 European countries (Joseph, 2004). This variation may in part be a reflection of genuine differences in incidence but is probably due to considerable under-ascertainment in many countries.

In England and Wales surveillance is organised through a voluntary reporting scheme where about 300 laboratories report cases to the HPA Communicable Disease Surveillance Centre (CDSC). In the 23 years from 1980 to 2002 a total of 4391 cases of LD were reported to CDSC, an average of 191 cases per year (range 112–367) giving an incidence of approximately 3.6 cases per million per year. However prospective studies in the UK and elsewhere indicate that about 2.0–5.0% of cases of all pneumonia cases requiring admission to hospital are LD (Woodhead *et al.*, 1986; Marston *et al.*, 1997; Lim *et al.*, 2001). This equates to between 2000 and 5000 cases per annum in England and Wales, suggesting that 10% or less of LD cases are recognised and reported each year. Estimates from the United States suggest that <5% of LD cases are reported to their national surveillance scheme (Benin, Benson and Besser, 2002).

LD is seen in patients of all ages (1–92 years) but is most frequent in adults over 40 years old and very rare in children. There are many more cases among males than among females (ratio for England and Wales of 2.8:1). Significant risk factors include a compromised immune system, recent surgery, congestive heart failure, chronic bronchitis, liver cirrhosis, renal insufficiency and heavy smoking. Not surprisingly, therefore, in certain patient groups, such as organ transplant patients, the incidence is much higher than 5%, and LD may even be the main cause of lung infections. The overall mortality is 13% for England and Wales, but this can be much higher in immunocompromised patients. Recent data suggest that overall the rate is falling in some countries. In the United States the average mortality was 20% between 1980 and 1998 falling from a high of 34% in 1985 to 11.5% in 1998 (Benin, Benson and Besser, 2002). Similarly in Europe mortality fell from 13% in 1998 to 6% in 2002. While there is some evidence that the decline is due to improvements in speed of diagnosis, and hence the initiation of appropriate therapy (Heath, Grove and Looke, 1996; Formica *et al.*, 2000), improved ascertainment of less-severe cases probably accounts for most of the fall (Benin, Benson and Besser, 2002). In support of this view mortality rates appear to be low in outbreaks of LD that are investigated using urinary antigen assays compared with those seen in outbreaks where this sensitive and rapid technology was not used. For example in the Central London outbreak of 1988 the mortality was 3/79 (3.8%) (Westminster Action Committee, 1988) and in the Murcia outbreak of 2001, the largest to date, the mortality was only 5/449 (1.1%) (Garcia-Fulgueiras *et al.*, 2003). In contrast in the Stafford Hospital outbreak, which occurred in 1985 before urine assays were available, 22/68 (32%) patients died (O'Mahony *et al.*, 1990) and in the 1999 'Flower show' outbreak in the Netherlands 21/188 (11%) patients died. In this latter case although urinary antigen testing was available it was rarely used in the Netherlands prior to the outbreak (Den Boer *et al.*, 2002).

A seasonal variation in the incidence of LD has been recognised in many parts of the world, with a peak incidence in late summer and early autumn in both the Northern and Southern hemispheres (Joseph *et al.*, 1999; Benin, Benson and Besser, 2002). However there have been several major outbreaks during the winter and early spring following periods of unseasonably warm weather (Westminster Action Committee, 1988; Watson *et al.*, 1994). Although highly publicised, outbreaks of LD are uncommon and only account for 25% of cases. There is, however, some evidence to suggest that many of the remaining 75% of cases are associated with a common source of infection although this is not recognised at the time (Bhopal *et al.*, 1991). Cooling towers have been identified as the source in most of

the major outbreaks of LD, but overall water-distribution systems are the most frequently implicated sources.

Travel-Associated LD

Travel-associated LD is now recognised as a significant problem worldwide. In the UK almost half the annual cases of LD, both sporadic and epidemic, are travel associated, the majority being linked to Mediterranean holiday resorts. Where investigations have been undertaken, hotel water systems have been most frequently identified as the likely source. The incidence of cases appears to be highest in those countries and areas where the tourist industry is still developing or where preventative action is poorly enforced. Although countries such as Spain, with long-established tourist industries, account for the highest numbers of cases, the actual rate of infection has declined from about six per million visitors in 1989–1991 to about three per million visitors in 2002. This contrasts with countries such as Turkey where the rate of infection has remained high at >10 per million visitors over the same period.

Nosocomially Acquired LD

Hospitals often have large and complex water-distribution systems and a population of susceptible patients. It is not therefore surprising that nosocomially acquired LD is a significant problem, accounting for 888 (9%) of cases in Europe in 2000–2002 (Joseph, 2004). Although overall this represents only a small number of cases annually the mortality in this group of patients is disproportionately high at approximately 30% (Benin, Benson and Besser, 2002). A second feature of nosocomial LD is that very much larger proportion of infections is caused by non-*L. pneumophila* serogroup 1 strains than is reported overall. Both these observations probably reflect the immunocompromised status of most patients in the nosocomial group.

Legionella spp. Able to Cause Human Infection

To date 21 species have been reported as pathogenic for humans (Table 37.1). However infections caused by species other than *L. pneumophila* are rare and almost always seen in patients who are immunocompromised (Dournon, 1988; Benin, Benson and Besser, 2002; Muder and Yu, 2002). One exception to this is *L. longbeachae* serogroup 1 which is now recognised to be a major cause of community-acquired pneumonia in Australia. Between 1996 and 2000 42% of notified cases of LD in Australia were caused by *L. longbeachae* (Li, O'Brien and Guest, 2002). The reservoir for this organism is thought to be potting mixes prepared from composted indigenous wood where it is found growing in association with amoebae (Hughes and Steele, 1994). Cases of *L. longbeachae* infection associated with potting composts have recently been reported outside Australia (Anonymous, 2000).

The majority of sporadic, and almost all outbreak-associated, cases of LD are caused by a subset of so-called 'virulent' strains of *L. pneumophila* serogroup 1. These strains are characterised by their reaction with a particular mAb and are referred to as MAB2⁺ (Dournon *et al.*, 1988) or MAB3/1⁺ (Helbig *et al.*, 2002), depending on the origin of the antibodies being used. These antibodies recognise a virulence-associated epitope on the LPS of *L. pneumophila* serogroup 1 strains. Strains of *L. pneumophila* serogroup 1 that are MAB2⁻ or MAB3/1⁻, together with strains of other *L. pneumophila* serogroups, account for most remaining cases (Joseph, 2004). With a few exceptions *Legionella* species other than *L. pneumophila* are only seen as the cause of rare sporadic cases of LD or persistent endemic problems in large hospitals (Muder and Yu, 2002). It does, however, seem probable that under the appropriate circumstances any *Legionella* species could cause infection as no consistent differences have been observed

between the virulence traits of the various species examined to date (O'Connell, Dhand and Cianciotto, 1996; Alli *et al.*, 2003).

CLINICAL FEATURES

Legionnaires' Disease

Although overall an uncommon form of pneumonia, in the context of severe community-acquired pneumonias, LD is much more significant, probably being the second most common form accounting for 14–37% of cases (Hubbard, Mathur and Macfarlane, 1993). LD has no special features that clearly distinguish it from other pneumonias, but the clinical picture is usually suggestive of the diagnosis (Mayaud and Dournon, 1988).

The onset of LD is generally more insidious than in typical pneumococcal pneumonia, with fever, headaches and malaise being the first manifestations. In about half of the cases gastrointestinal abnormalities are present. Respiratory signs often only appear later in the course of the disease. A cough is rare and if present it is generally non-productive early in the illness although later small amounts of purulent, and sometimes bloody sputum, may be expectorated. Lung examination usually reveals abnormalities at this stage of the disease, with at least rales and very often lung consolidation being evident. A small pleural effusion, sometimes suspected from the presence of thoracic pains, is present in about one-third of patients but is difficult to recognise on clinical examination. Progression of the lung infection may be rapid and be responsible for increasing dyspnoea and acute respiratory failure (Mayaud and Dournon, 1988).

A frequently reported but non-specific feature of LD is the presence in many cases of gastrointestinal symptoms or neurological signs. In the series studied by Mayaud and colleagues (1984), diarrhoea was present in about 50% cases and appeared early in the course of the disease. Nausea, vomiting or right lower abdominal pain with tenderness were each seen in 20–30% patients. Nervous system manifestations, which were dominated by alterations of the mental status such as disorientation and confusion, were found in about 25% cases.

Routine laboratory findings are not particularly helpful. Liver abnormalities are frequently found with elevated serum levels of transaminases and/or alkaline phosphatase or, in some cases, of bilirubin. Proteinuria, haematuria and renal insufficiency are infrequent in patients receiving early treatment. Elevation of creatinine phosphokinase and aldolase blood levels, suggestive of muscle damage, is seen in some patients.

The prognosis for patients treated with appropriate antibiotics within 7 days of onset is good and they usually recover even if they are immunocompromised (Mayaud *et al.*, 1984). In contrast the prognosis is poor in patients not treated before acute respiratory failure and shock develop. This is usually late in the course of the illness. In such cases rhabdomyolysis, acute renal failure, pancytopenia, disseminated intravascular coagulation, icterus or coma are not infrequent (Mayaud *et al.*, 1984). However, in most instances patients die from the respiratory distress syndrome and not from the extrapulmonary manifestations of the disease.

Pontiac Fever

Pontiac fever is an acute, non-pneumonic, flu-like illness which is usually self-limiting (Glick *et al.*, 1978). The attack rate is usually very high (>90%) and the disease affects previously healthy, and often young, individuals. The incubation period is short, varying from a few hours to 2–3 days, and the illness resolves spontaneously usually within 2–6 days. Outbreaks of Pontiac fever have been reported to be caused by *L. pneumophila*, *L. feeleii*, *L. micdadei* and *L. anisa* (Glick *et al.*, 1978; Goldberg *et al.*, 1989). Although the subject of considerable speculation, the explanation for the differences between LD and Pontiac fever remains unclear.

DIAGNOSTIC METHODS

Although in most instances the clinical picture of LD allows sufficient suspicion of the diagnosis for appropriate treatment to be initiated evidence from laboratory tests are essential for a definitive diagnosis. There are three approaches to the laboratory diagnosis of legionella infections: (i) culture of the causative organism; (ii) demonstration of the organism, its components or products in clinical specimens; and (iii) demonstration of significant levels of antibody directed against the organism in patient sera.

Specimens for Culture

Culture of legionellae from clinical specimens is relatively easy and, in situations where clinical awareness is high, has a sensitivity of 50–80% (Dournon, 1988; Winn, 1993). Furthermore diagnosis by culture and isolation has several advantages over any other approach. First, isolation of a *Legionella* sp. provides definitive proof of the diagnosis as colonisation without infection has not been demonstrated (Bridge and Edelstein, 1983). Second, isolation may be the only way to establish a diagnosis, for example if the patient does not produce antibodies or if there are no reagents available to detect the infecting species/serogroup. Third, isolation of the infecting strain allows subtyping to be undertaken, providing valuable epidemiological data for the control and prevention of further cases of infection.

Given these clear advantages it is perhaps surprising that overall only 12% of cases reported to CDSC between 1980 and 2002 were confirmed by isolation of the organism. The explanation for this disappointing observation is not entirely clear but may in part be due to the fact that the diagnosis of legionellosis is often only considered after both the initiation of antibiotic therapy and the failure to identify more common pathogens.

Specimens for culture should be taken as early as possible and ideally before antibiotic treatment is initiated. Lower respiratory tract specimens are most likely to yield positive results, but sputa are quite satisfactory provided the specimens are pre-treated (Dournon, 1988). The pre-treatments used to reduce contaminants exploit the property that legionellae are generally more tolerant to heating and resistant to low pH exposure than are other organisms found in the respiratory tract. Isolation is usually attempted using buffered charcoal yeast extract (BCYE) agar with and without selective antibiotics; dilution of the specimen may also help. Many combinations of antibiotics have been tried but for the culture of strains from clinical specimens a mixture of polymyxin, vancomycin, cefamandole and anisomycin has proved very effective.

Microscopic and Colonial Appearance

A bacterium which is Gram-negative, catalase positive and grows on complete BCYE agar but not on the same medium lacking supplemental L-cysteine can be presumptively identified as a *Legionella* sp. Colonies usually first appear after 3–6 days of incubation but may be visible in about 36 h from specimens where large numbers of legionellae are present with few contaminating organisms. Growth tends to be delayed by about 12–24 h where selective agars are used.

Colonies of legionella are convex, have an entire edge, glisten and have a characteristic granular or 'ground glass' appearance which is most pronounced in young colonies. Colony colour varies considerably and in large part depends upon the thickness and formulation of growth medium used. In general however coloration varies from blue/green when the colonies are first visible to pink/purple as they grow larger. As the colonies age they become less characteristic, being white/grey and smoother; however the pink/purple coloration can still be seen at their edges. As the name suggests the colonies of *L. erythra* have a slight red coloration.

Almost all species of *Legionella* are weakly motile having one polar flagellum. Flagella can be easily demonstrated by one of the

many described 'silver-plating stains', based on Fontana's stain for spirochaetes. Furthermore the flagella from all species share common antigens and can be visualised using a suitable anti-flagellar serum. Expression of flagellae appears to depend on the growth phase (most abundant in late log-phase), the temperature of incubation and the 'passage' history of the isolate.

Growth Requirements

Legionellae will grow in the temperature range of 29–40 °C with an optimum of 35 °C. However they will withstand considerably higher temperatures, of 50 °C and above, for a considerable time (>30 min), a characteristic which is exploited in their culture and isolation from clinical and environmental specimens (Dennis, 1988). They grow well aerobically on BCYE agar, particularly when supplemented with alpha-ketoglutarate. The function of the charcoal in the medium seems to prevent superoxide formation. Amino acids such as arginine, threonine, methionine, serine, isoleucine, valine and cystine form the major sources of energy for the organism. Legionellae show an absolute requirement for L-cysteine, although *L. oakridgensis* appears not to require L-cysteine as a culture medium supplement after primary isolation. Trace metals such as calcium, cobalt, copper, magnesium, manganese, nickel, vanadium and zinc enhance growth. Although legionellae do not appear to require iron in greater amounts than do other organisms, the presence of soluble iron stimulates growth.

Studies by Rowbotham (1993) have shown that some legionellae originally described as *Legionella*-like amoebal pathogens (LLAPs) can be obtained from environmental and clinical samples by co-cultivation with amoebae but cannot be isolated using standard legionella culture media such as BCYE. Subsequent work has shown that these LLAPs are *Legionella* spp. and most can be grown, albeit poorly, on BCYE provided a reduced incubation temperature of 30 °C is used (Adeleke *et al.*, 2001).

Differentiation of Species

There are a number of simply demonstrated phenotypic characteristics that allow the Legionellaceae to be subdivided into groups of species, or in some cases into individual species (Table 37.2). As in most cases these characteristics have been determined using small numbers of strains of each species, or even a single isolate, the stability of these phenotypic markers is uncertain. Identification of an isolate should, therefore, always be confirmed by an alternative method such as chemical analysis of cellular components, serological identification or molecular analysis (Table 37.2).

Antigenic Properties

Legionellae can be subdivided into serogroups (Sgp) by their reaction with hyperimmune antisera-containing antibodies directed against the somatic LPS or O-antigens. To date 70 serogroups have been recognised among the 49 species, although in the cases of *L. erythra* Sgp 2 and *L. sainthelensi* Sgp 2 these are indistinguishable from *L. rubrilucens* and *L. santicrucis* respectively (Table 37.1). There is considerable antigenic overlap between some of the serogroups, particularly within the blue–white autofluorescent species complex, and therefore hyperimmune antisera require extensive absorption to render them serogroup specific. There is also significant antigenic heterogeneity within many serogroups. Thus strains of one serogroup may react to different degrees with a serogroup-specific antiserum. Thomason and Bibb (1984) examined this phenomenon in detail using five cross-absorbed polyclonal antisera and 176 *L. pneumophila* Sgp 1 strains. They identified 17 subsets that fell broadly into three subgroups. Serogroup heterogeneity is most clearly revealed using mAbs, which identify type-specific epitopes. Panels of such mAbs

Table 37.2 Summary of phenotypic characteristics and biochemical reactions helpful in differentiating between *Legionella* species (modified from Harrison and Saunders, 1994)

Test	Result	Relevant species	Comment
Subculture onto BCYE Subculture onto BCYE-Cys	Supports growth Does not support growth	All species ^a	Blood agar is not a suitable substitute for BCYE-Cys, particularly for environmental specimens, as non-legionellae may grow on BCYE but not on blood agar
Gram's stain	Gram-negative	All species	Legionellae will readily counterstain with 0.1% basic fuchsin
Catalase test	Positive	All species (<i>L. pneumophila</i> only weakly)	Some species possess a peroxidase rather than a catalase but they still give a positive result in the test if 3% H ₂ O ₂ is used
Oxidase test	Negative	All species	Positive results are sometimes recorded but this is probably due to contamination with BCYE medium
Hippurate hydrolysis	Positive Negative	<i>L. pneumophila</i> positive All other species negative	Some strains, particularly of subsp. <i>fraseri</i> , are said to be negative in this test
Colony autofluorescence under long-wavelength UV (approximately 365 nm)	Red fluorescence Blue-white fluorescence No fluorescence	<i>L. erythra</i> , <i>L. taurinensis</i> and <i>L. rubrilucens</i> <i>L. anisa</i> , <i>L. bozemanii</i> , <i>L. cherrii</i> , <i>L. dumoffii</i> , <i>L. gormanii</i> , <i>L. gratiana</i> , <i>L. parisiensis</i> , <i>L. steigerwaltii</i> , <i>L. tucsonensis</i> All other species	Red fluorescence may only be seen after prolonged or reduced temperature (approximately 30 °C) incubation Many of these species are phenotypically and antigenically very similar to others in the group
Bromocresol-purple spot test	Positive Negative	<i>L. micdadei</i> , <i>L. maceachernii</i> positive. All other species negative	These species are serologically distinct

^a Except some of the so-called LLAPs which only grow very poorly on BCYE (see *Growth Requirements* for details).

have been used extensively to subgroup strains of *L. pneumophila* Sgp 1 for epidemiologic purposes (Helbig *et al.*, 2002).

In addition to O-antigens legionella have flagellar antigens. As noted above flagella from all species so far investigated share common antigens, a property that can be useful in the identification of new or unknown strains of legionella. It has also been shown that legionella flagella can be subtyped using panels of mAbs (Saunders and Harrison, 1988).

Alternatives to Culture

Despite the many advantages of culture the time taken to obtain results by this method is measured in days. In contrast the direct demonstration of legionella antigen or nucleic acids in clinical specimens can be achieved within a few minutes of specimen collection. Furthermore a diagnosis may be established by visualisation or detection of the organism in tissue even when they are no longer viable, after antibiotic therapy or retrospectively in fixed tissues.

Microscopy

Bacteriological stains such as Gimenez and modified Warthin–Starry have been used successfully to detect legionellae in clinical material. However such stains may reveal any bacterial species and hence a specific diagnosis cannot be established. Immunofluorescence using rabbit hyperimmune antisera has been used to diagnose LD since legionellae were first recognised, but initially the poor sensitivity and, particularly, the poor specificity of this method severely limited its use. Subsequently the problem of specificity has been overcome by using reagents derived from mAbs, the most widely used of these being directed against the *L. pneumophila* MOMP (Gosting *et al.*, 1984). This reagent reacts with all the serogroups of *L. pneumophila* and hence obviates the need for repeated testing of a specimen with several different

antisera. The clinical utility of this reagent has been evaluated (Edelstein *et al.*, 1985), and the specificity has been found to be excellent allowing a diagnosis to be confidentially established very rapidly. The sensitivity is, however, still considerably lower than that of culture.

Antigen Detection

It is now well established that the use of enzyme immunoassays (EIAs) for the detection of *L. pneumophila* antigen in urine allows diagnoses of LD to be established early in the course of infection (Birtles *et al.*, 1990; Hackman *et al.*, 1996; Harrison *et al.*, 1998). Until the early 1990s the use of such assays was restricted to those few reference laboratories able to develop and maintain in-house EIAs (Sathapatayavongs *et al.*, 1982; Birtles *et al.*, 1990), but commercially produced kits are now widely available. Currently available kits have been shown to be highly specific and reliable in routine use (Dominguez *et al.*, 1999; Harrison and Doshi, 2001), and legionella urinary antigen detection has become the single most widely used diagnostic methodology. The limitation to this method is the poor sensitivity that the kits have for LD caused by any legionellae other than the 'virulent' (mAb2-positive) *L. pneumophila* serogroup 1 strains. Practically this means that while the sensitivity is approximately 90% for the diagnosis of community-acquired LD, it is <50% for nosocomially acquired LD (Helbig *et al.*, 2003).

Attempts to overcome this limitation led to the development of a 'broad-spectrum' EIA that uses hyperimmune serum raised against a pool of *Legionella* species and serogroups to capture the soluble antigen (Tang and Toma, 1986). Unfortunately this method of producing the capture antiserum is not amenable to standardisation and this methodology has not been translated into a commercial assay. An alternative approach is to use reagents prepared against defined *L. pneumophila*, or preferably *Legionella* genus, common antigens. While the successful detection of common protein

antigens such as *momp* or *mip* in urine has not been reported, preliminary studies suggest that a *Legionella* genus common 19-kDa peptidoglycan-associated lipoprotein target is detectable in the urine of experimentally infected guinea pigs (Kim *et al.*, 2003). Whether or not this is also true for humans with a natural infection remains to be seen.

Molecular Methods

Methods for the detection of legionella nucleic acid have been available since the early 1980s when Kohne and colleagues (1984) developed a radiolabelled DNA probe complementary to regions of the ribosomal RNAs of all 20 *Legionella* species known at the time. A commercial nucleic acid hybridisation test, based on this work, and intended for the detection of legionellae in clinical samples, was introduced soon after. This kit was shown to be reasonably sensitive performing similarly to IF, but was less sensitive than culture (Pasculle *et al.*, 1989; Finkelstein *et al.*, 1993). Furthermore questions concerning the kit's specificity (Laussucq *et al.*, 1988) and its use of radioisotopes limited the kit's utility and it was subsequently withdrawn from the market.

The theoretical sensitivity of PCR (i.e. detection of one copy of target sequence) quickly led to widespread use as an alternative to direct probing, which typically requires large number of organisms. Furthermore, as alternatives to radioisotope labelling are now available which have at least equivalent sensitivity and none of the inherent disadvantages, PCR is now seen as the molecular method of choice, promising advantages of both specificity and sensitivity. Development of PCR-based assays for legionellae has focused on three main targets. Assays designed to detect *L. pneumophila* typically use primers directed against the *mip* gene, while those targeting *Legionella* species use primers for either the 5S rRNA or 16S rRNA genes (Starnbach, Falkow and Tompkins, 1989; Mahbubani *et al.*, 1990; Lisby and Dessau, 1994; Jonas *et al.*, 1995; Fry and Harrison, 1998; Ballard *et al.*, 2000). Where lower respiratory tract samples are used, PCR appears to be at least as sensitive as culture (Jaulhac *et al.*, 1992; Jonas *et al.*, 1995; Cloud *et al.*, 2000). However this does not seem to be the case for detection of legionellae in environmental samples, where the sensitivity is consistently lower than culture (Ballard *et al.*, 2000; Riffard *et al.*, 2003). The difference is probably due to the concentration steps, typically a 100-fold, which are integral to the processing of environmental samples. *Legionella* DNA has been detected in non-respiratory samples such as serum and urine and leucocyte samples, but with a lower sensitivity than culture (Lindsay, Abraham and Fallon, 1994; Murdoch *et al.*, 1996; Helbig *et al.*, 1999). At present the status of PCR for the diagnosis of LD is much the same as applied to urinary antigen detection in 1980s, which is confined to a few specialist and reference laboratories able to use it in conjunction with the full range of other diagnostic approaches. Until validated commercial kits are available, the real impact of PCR will not be known.

Diagnosis by Estimation of Antibody Levels

For more than 20 years the primary method for the diagnosis of LD was by serology and although now displaced by urinary antigen testing, estimation of antibody levels against killed preparations of legionellae is still a very commonly employed method for the diagnosis of LD. It is an important tool for case finding during outbreak investigations and for late or retrospective diagnosis. However this approach does not often allow a diagnosis to be established during acute illness, and hence has little value in patient management or in the early detection of outbreaks.

Historically the indirect immunofluorescent antibody test (IFAT) was the method used in 1977 to establish that *L. pneumophila* was the causative agent of LD (McDade *et al.*, 1977). Since this time several

variants of this test have been comprehensively evaluated for the diagnosis of infection caused by *L. pneumophila* serogroup 1, and the IFAT became the reference test for LD diagnosis (Wilkinson, Cruce and Broome, 1981; Harrison and Taylor, 1988). The test used in the UK and parts of Europe until the late 1990s employed a formalised yolk-sac antigen and FITC-labelled anti-human conjugate capable of detecting IgG, IgM and IgA. This test was both sensitive (approximately 80%) and was with a high specificity (>99%) (Bornstein *et al.*, 1987; Harrison and Taylor, 1988), the latter being particularly important in a disease of low prevalence such as LD, if a positive result is to have any real significance. Reagents for this IFAT are no longer available, but various commercially produced IFAT reagents, typically using agar-grown antigens, can be obtained. Reagents for IFATs to detect infection caused by species and serogroups other than *L. pneumophila* serogroup 1 are also commercially available; however it should be emphasised that the sensitivity and specificity of IFAT using these reagents are largely unknown.

In addition to the IFAT several other methods for antibody detection such as microagglutination (Farshy, Klein and Feeley, 1978; Harrison and Taylor, 1982) and indirect haemagglutination (Edson *et al.*, 1979; Lennette *et al.*, 1979) have been devised. As EIAs are widely used in microbiology several have been developed for *L. pneumophila* (Wreghitt, Nagington and Gray, 1982; Herbrink *et al.*, 1983; Barka, Tomasi and Stadtsbaeder, 1986). Reagent manufacturer's market diagnostic kits using this methodology, but these typically incorporate antigens prepared from pools of *L. pneumophila* serogroups 1–6. None of these assays use purified antigens and hence the EIA plates are coated with a complex mixture of bacterial proteins and LPS. The use of such crude pooled antigens may in part be responsible for the poor performance of these assays (Elder *et al.*, 1983; Harrison and Taylor, 1988; Malan *et al.*, 2003).

MANAGEMENT

Legionellae are susceptible to a wide range of antibiotics *in vitro*, but these findings are not necessarily predictive of their *in vivo* efficacy. As legionella are facultative intracellular organisms, some antibiotics that are active *in vitro* are not active *in vivo* because their intracellular penetration is poor. Furthermore the media used to culture legionellae inhibit the activity of some antibiotics, making a valid determination of MICs and MBCs difficult (Edelstein and Meyer, 1980; Dowling, McDevitt and Pasculle, 1984).

The antimicrobial agents that show the best activity against legionellae are those that are concentrated within the phagocytic cells such as macrolides and quinolones, and these antibiotics form the basis of recent treatment guidelines (Bartlett *et al.*, 2000; British Thoracic Society, 2001). Although erythromycin is the traditional drug of choice, studies reveal that it is only inhibitory, and reversibly so, in its activity against intracellular legionellae (Horwitz and Silverstein, 1983). In addition it is often poorly tolerated by many patients and treatment failures are not infrequent (Edelstein, 1998). In contrast azithromycin is bactericidal even at quite low concentrations (Edelstein and Edelstein, 1991), is highly effective in preventing disease in an aerosol-infected guinea pig model (Fitzgeorge, Lever and Baskerville, 1993) and is well tolerated by patients. Azithromycin is only licensed for oral use in some countries and is not suitable for treatment of severe legionellosis in this form. Although clarithromycin is significantly less active than azithromycin, it is more active than erythromycin and hence is recommended in some guidelines (British Thoracic Society, 2001). Most fluoroquinolones are more active than erythromycin *in vitro*, and some have been shown to be highly effective in both animal and cell-culture models of infection (Dournon *et al.*, 1986; Rajagopalan-Lavasseur *et al.*, 1990; Edelstein *et al.*, 1996).

PREVENTION AND CONTROL OF INFECTION

Five essential elements must be in place if legionellae are to give rise to infection: (i) A virulent strain must be present in an environmental reservoir; (ii) conditions must be such that it can multiply to significant numbers; (iii) a mechanism must exist for creating an aerosol containing the organisms from the reservoir; (iv) the aerosol must be disseminated and finally a susceptible human must inhale the aerosol. Prevention of infection depends upon breaking this 'chain of causation'.

As discussed above legionellae can be found in low numbers in almost all aquatic environments. It is probably not possible to eradicate legionellae from such a system because of regrowth from residual biofilm or reseeded from other environmental sources. However it is feasible to ensure that the numbers of organisms remain at a low level, and it is the aim of most preventative procedures to break this link of the chain. Legionellae grow best in water at temperatures between 20 and 40 °C, particularly where there is an accumulation of organic and inorganic material. Thus the strategy is to keep the systems clean by regular maintenance, to keep cold water at below 20 °C and hot water above 50 °C, to avoid the use of certain materials in the construction of water systems and, where appropriate, to use a programme of treatment with biocides and other chemicals.

Aerosols can be generated from many sources such as cooling towers, showers, taps, nebulisers and other domestic and industrial equipment. The use of effective drift eliminators in cooling towers can considerably reduce the release of aerosol. However in some instances, for example showers, there is little that can be done but to avoid their use. Where the population at risk is particularly susceptible (e.g. transplant patients), this approach is sometimes taken. Approved codes of practice and guidelines detailing all aspects of design, maintenance and running of water systems and cooling towers have been provided from a number of governmental and professional bodies and much excellent advice is now available (Health and Safety Commission, 2000).

INTRODUCTION

Coxiella burnetii is the causative agent of Q fever. Although traditionally classified as a rickettsial disease, *Coxiella* is a member of the family *Coxiellaceae* in the order Legionellales (<http://www.cme.msu.edu/bergeys/april2001-genus.pdf>). Although not often considered a significant public health threat, *C. burnetii* has received renewed attention as a potential bioterrorism agent due to its remarkable stability outside the host, its low infectious dose, and – perhaps most pertinent – its capability to be transmitted by the aerosol route.

DESCRIPTION OF THE ORGANISM

Definition

Coxiella burnetii is an obligate, intracellular Gram-negative bacterium ranging from 0.4 to 1 µm in length and 0.2 to 0.4 µm in width (Maurin and Raoult, 1999). Entry of *C. burnetii* into host cells is a passive process that results in the fusion of membrane-bound vesicles containing *C. burnetii* organisms with lysosomes (Baca and Paretsky, 1983; Baca, Klassen and Aragon, 1993; Heinzen *et al.*, 1996). *Coxiella burnetii* thrives within the acidic environment of phagolysosomes (Hackstadt and Williams, 1981, 1983; Zuerner and Thompson, 1983; Chen *et al.*, 1990). Like *Chlamydia*, *Coxiella* have a unique intracellular cycle consisting of two distinct morphological forms of the bacteria. First, small cell variants (SCVs) are 204–450 nm rods and have dense material in the periplasm. These forms are not metabolic but are highly infectious and resistant to many environmental conditions. The acidic environment of the phagolysosome appears to trigger the conversion of SCVs to LCVs (large cell variants; 2 µm in length), which are metabolically active and appear to form spores that develop to SCVs that are then released from the cell to restart the infectious cycle (McCaul, 1991). *Coxiella* are not flagellated.

Molecular Characterization

Although *C. burnetii* has been known historically as a member of the order Rickettsiales, partly based on its inability to grow in axenic medium, sequencing of the 16S rRNA gene (Stein *et al.*, 1993) has allowed for the reclassification of this organism into the gamma subdivision of Proteobacteria order Legionellales, family *Coxiellaceae*. On the basis of a combination of different molecular techniques, including DNA–DNA hybridization (Vodkin, Williams and Stephenson, 1986), restriction fragment length polymorphism (Hendrix, Samuel and Mallavia, 1991), and pulsed-field gel electrophoresis (Heinzen *et al.*,

1990), it has been demonstrated that considerable variation exists between the genomes of *C. burnetii* isolates. It does appear, however, that isolates tend to cluster depending on geographic location (Maurin and Raoult, 1999).

CLINICAL FEATURES, PATHOGENESIS, AND EPIDEMIOLOGY

Acute Q fever is characterized by two clinical presentations, atypical pneumonia and hepatitis. The primary mode of transmission is from inhalation of contaminated aerosols (Marrie, 1990). It is estimated that only between 1 and 10 bacteria are necessary to cause infection (Norlander, 2000). The specific route of transmission appears to correlate with the subsequent clinical presentation (Marrie *et al.*, 1996). For example, in Nova Scotia, Canada, Switzerland, and northern Spain, the primary manifestation of Q fever is pneumonia, presumably caused by inhalation of aerosols (Marrie *et al.*, 1988; Norlander, 2000). In contrast, in France and southern Spain, acute Q fever manifests as granulomatous hepatitis, which is assumed to result from the drinking of contaminated milk (Fishbein and Raoult, 1992). Acute Q fever is an acute febrile disease commonly associated with sudden onset of headache, chills, myalgia, arthralgia, photophobia, lymphadenopathy, conjunctivitis, nausea or vomiting, diarrhea and pharyngitis. Rash is rare and abnormal X-ray findings are present in 50% of cases. Although Q fever is rarely fatal (CFR approximately 1%), it may become a chronic illness that lasts longer than 6 months and has a higher rate of mortality (Sawyer, Fishbein and McDade, 1987). While chronic disease can afflict multiple organ systems, Q fever typically manifests itself as endocarditis and is often diagnosed among patients who have preexisting heart valve disease (Turck *et al.*, 1976; Ellis, Smith and Moffat, 1982).

Microscopically, the pathology of Q fever is similar to bacterial pneumonia and can be characterized by severe interalveolar and a patchy, focally necrotizing haemorrhagic pneumonia that involves the alveolar-lining cells (Perin, 1949). Necrotizing bronchitis and bronchiolitis may be present. *Coxiella burnetii* is found in histiocytes of the alveolar exudate. Histiocytic hyperplasia is found in mediastinal lymph nodes, spleen, and adrenals. Hepatocellular damage in acute Q fever consists of granulomatous changes in the lobules and occasional involvement of the portal areas (Srigley *et al.*, 1985). Granulomas consist of non-distinctive focal histiocytic and mixed inflammatory cell infiltrates with multinucleated giant cells.

Q fever is distributed worldwide and is often transmitted from infectious aerosols in animal tissues or products and occasionally from unpasteurized milk. The disease is only rarely reported in the United States. New Zealand is the only country where Q fever has not

been reported (Hilbink *et al.*, 1993). Naturally infected ticks may play a role in maintenance and transmission of *C. burnetii* among animal hosts, but probably play little or no role in transmission to humans (Eklund, Parker and Lackman, 1947). Occupational exposure to infected livestock, primarily cattle, sheep, and goats is a major risk factor. Abattoir workers, sheep shearers, and wool gatherers have the highest rates of infection and disease (Bernard *et al.*, 1982). Persons who have contact with sheep, particularly fetuses and birth products, have the greatest risk. There have been several reports of transmission of Q fever from pets to humans, likely due to human handling of litter, birth products, cats (Kosatsky, 1984), or dogs (Laughlin *et al.*, 1991; Buhariwalla, Cann and Marrie, 1996).

LABORATORY DIAGNOSIS

Q fever must be distinguished from several viral and bacterial illnesses, including meningococemia, measles, enteroviral exanthems, leptospirosis, typhoid fever, rubella, dengue fever, and Legionnaires' disease. Laboratory diagnosis of Q fever is routinely accomplished by serologic assays that detect anti-*C. burnetii* antibodies. Alternative procedures include isolation of *C. burnetii* from patient blood samples or tissue biopsies and techniques aimed at direct detection of organisms in these specimens. However, serologic methods are more widely used by clinical laboratories. Because antibody levels to *C. burnetii* are not detectable until 2–3 weeks following presentation of symptoms, serology cannot typically provide a diagnosis early enough to affect the outcome of disease. More recently, nested polymerase chain reactions (PCRs) have successfully identified *C. burnetii* in clinical and ectoparasite samples and PCR is now a readily utilized technique for rapid identification (Berri, Arricau-Bouvery and Rodolakis, 2003; Zhang *et al.*, 1998).

Serology

Indirect Fluorescent Antibody (IFA) Assays

IFA remains the gold standard for diagnosis of Q fever (Peacock *et al.*, 1983; Tissot-Dupont, Thirion and Raoult, 1994). IgG, IgM, and IgA antibodies can be measured against both *C. burnetii* phase I (obtained from spleens of infected mice) and phase II (obtained from *C. burnetii* grown in cell culture) antigens (Tissot-Dupont, Thirion and Raoult, 1994). Although seroconversion can be detected between 7 and 15 days after symptoms appear, 90% of patients will seroconvert by the third week. Diagnosis generally depends upon the demonstration of fourfold or greater increase in antibody titer between the acute- and convalescent-phase serum samples. Single serum specimens, however, can be used to make a diagnosis in many cases (Table 38.1). Although cross-reactivity has been described to occur between *C. burnetii* and *Legionella* or *Bartonella*, differential diagnosis can be made when antibody titers against both phase I and II antigens are obtained (Maurin and Raoult, 1999). IFA tests are reasonably sensitive; however, the subjectivity of endpoint determinations is an obvious disadvantage.

Table 38.1 Microimmunofluorescence cut-off values for Q fever diagnosis using a single serum specimen

Phase II antibody titer		Phase I antibody titer (IgG)	Interpretation
IgG	IgM		
≤100			Active Q fever improbable
≥200	≥50		Acute Q fever (100% predictive)
		≥1:800	Chronic Q fever (98% predictive)
		≥1:1600	Chronic Q fever (100% predictive)

Adapted from Maurin and Raoult (1999).

Complement Fixation

The CF assay for diagnosis of Q fever utilizes an extract of either phase I or phase II antigens of *C. burnetii* (Field, Hunt and Murphy, 1983; Herr *et al.*, 1985). By the fourth week after the onset of symptoms from Q fever, more than 90% of patients have antibodies that fix complement in the presence of phase II antigen (Elisberg and Bozeman, 1969). Antigenic phase variation must be considered for the interpretation of serologic results for Q fever. In acute, self-limited Q fever infections, antibodies to the phase II antigen appear first and dominate the humoral immune response. A CF titer ≥40 indicates acute Q fever (Guigno *et al.*, 1992). With chronic Q fever infections, however, phase I titers eventually equal or exceed phase II titers; thus a CF titer ≥200 indicates chronic Q fever (Peter *et al.*, 1992). The detection of antibodies that fix complement in the presence of phase I CF antigen has been useful in recognition of subacute Q fever endocarditis. The CF assay has the disadvantages that it is more time consuming than IFA, and seroconversion is detected almost 1 week later than IFA.

Other Serologic Techniques

Several other serologic methods have been described for diagnosis of Q fever including enzyme-linked immunosorbent assay (ELISA), microagglutination, dot blotting, western blotting, and radioimmunoassay (Maurin and Raoult, 1999). ELISA tests are purported to be more sensitive than IFA and CF (Peter *et al.*, 1988; Cowley *et al.*, 1992; Uhaa *et al.*, 1994; Field *et al.*, 2000, 2002), but they are not widely used in the clinical setting due to decreased specificity over some other assays, and because the length of setup time is not practical for small numbers of sera. Furthermore, the lack of standardization of homemade ELISA between laboratories may give rise to conflicting results. A new ELISA, available commercially to measure IgG and IgM, can be standardized between laboratories, and is more sensitive than IFA or CF (Field *et al.*, 2000, 2002). Samples positive by ELISA, however, should be confirmed using IFA for enhanced specificity. ELISA may be useful for large-scale serosurveys. Although microagglutination may be sensitive enough to detect antibodies soon after symptoms appear, a large amount of antigen is required for its use (Kazar *et al.*, 1981).

Bacterial Isolation and Culture

Many laboratory-acquired cases of Q fever have been reported; thus attempted isolation and culture of *C. burnetii* are only recommended for research laboratories that have personnel with experience in cultivating *Coxiellae* in addition to biosafety containment level-3 facilities. The guinea pig remains the animal of choice for *C. burnetii* isolation, although mice and embryonated eggs are also used (Perin and Bengston, 1942; Ormsbee, 1952; Williams, Thomas and Peacock, 1986). Clinical specimens from infected humans are injected intraperitoneally into guinea pigs (Maurin and Raoult, 1999). Infection is monitored by measuring body temperature, animals are killed 5–8 days later, then spleens are extracted for isolation of *C. burnetii*. Spleen extracts are inoculated into embryonated eggs to propagate the bacteria.

Coxiella burnetii can infect monocytes, macrophages, and a wide variety of cell lines (Baca and Paretsky, 1983; Norlander, 2000). Several different human specimens, including blood, cerebrospinal fluid, cardiac valve, liver biopsy, and birth products can be inoculated onto cell cultures, typically grown in shell vials, which are then centrifuged to increase bacterial adherence, and incubated at 37 °C with 5% CO₂ and for 5–7 days (Maurin and Raoult, 1999). Although *Coxiellae* have typical Gram-negative cell walls, they do not stain with the Gram procedure. Growth can be observed with staining using the Gimenez technique (Gimenez, 1964) or by indirect immunofluorescence using monoclonal or polyclonal anti-*C. burnetii* antibodies.

More recently, green fluorescent protein has served as a marker for detecting transformed pathogens inside of host eukaryotic cells (Lukacova *et al.*, 1999).

Direct Detection of Organisms

Immunofluorescence

Coxiella burnetii have been detected by immunofluorescence in tissue biopsies obtained from patients with Q fever endocarditis. Biopsy specimens can be analyzed fresh or after fixation in formalin and paraffin embedding. Detection of organisms can be carried out using immunohistochemistry (Brouqui, Dumler and Raoult, 1994), capture ELISA/ELIFA (Thiele, Karo and Krauss, 1992), or immunofluorescence/immunoelectron microscopy with monoclonal or polyclonal antibodies (McCaul and Williams, 1990; Thiele, Karo and Krauss, 1992).

Polymerase Chain Reaction

PCR detection of *C. burnetii* DNA has been reported from clinical specimens (Stein and Raoult, 1992). Current PCR primers are designed to amplify the genes encoding 16S rRNA, superoxide dismutase, and glutathione. The addition of nested primers have allowed for the successful amplification of these genes from clinical samples (Berri, Arricau-Bouvery and Rodolakis, 2003; Zhang *et al.*, 1998).

TREATMENT

Antibiotic therapy is, in general, of great benefit to patients infected with *C. burnetii* especially when initiated within the first three days of illness. Acute Q fever is typically treated successfully with doxycycline, or other quinolones (Hoover, Vodkin and Williams, 1992; Maurin and Raoult, 1999). Other antimicrobials, including erythromycin or chloramphenicol, may be useful (Clark and Lennette, 1952; D'Angelo and Hetherington, 1979). Chronic Q fever, on the other hand, requires combination therapy of both doxycycline and ciprofloxacin for long periods up to years to prevent episodic illness (Maurin and Raoult, 1999; Raoult, 1993).

PREVENTION

Q fever can be prevented by avoidance of contact with potentially infectious animal tissues and products. Occupationally exposed persons may reduce their risk of infection with *C. burnetii* by wearing respirators that prevent aerosol infections. Q fever vaccines for human use are killed, purified whole-cell preparations of phase I *C. burnetii* that contain lipopolysaccharide-protein complex antigens (Kazar and Rehacek, 1987; Williams *et al.*, 1993). A vaccine used in Australia is highly effective in preventing illness among abattoir workers (Marmion *et al.*, 1984). Individuals at high risk of acquiring Q fever should consider vaccination, however, emergence of Q fever has been noted in populations not typically considered at risk, notably individuals in urban areas exposed to pets during parturition.

Section Four

Spiral Bacteria

Leptospira spp.

P. N. Levett

Saskatchewan Health, Provincial Laboratory, Regina, Saskatchewan, Canada

INTRODUCTION

Leptospirosis is a zoonosis caused by infection with pathogenic strains of the genus *Leptospira*. The most severe manifestation of leptospirosis is the syndrome of multiorgan infections known as Weil's disease, first described by Adolf Weil in Heidelberg in 1886. Weil described an infectious disease with jaundice and nephritis. Earlier descriptions of diseases that were probably leptospirosis were reviewed recently (Faine *et al.*, 1999). The aetiology of leptospirosis was demonstrated independently in 1915 by Inada and Ido, who detected in the blood of Japanese miners with infectious jaundice both spirochaetes and specific antibodies, and by Uhlenhuth and Fromme, who detected spirochaetes in the blood of German soldiers afflicted by 'French disease' while in the trenches (Everard, 1996). The importance of occupation as a risk factor was recognized early. The role of the rat as a source of human infection was discovered in 1917, while the potential for leptospiral disease in dogs and in livestock was not recognized until the 1930s and 1940s.

CLASSIFICATION

Definition

Leptospire are tightly coiled spirochaetes, usually $0.1\ \mu\text{m} \times 6\text{--}20\ \mu\text{m}$, but occasional cultures may contain much longer cells. The cells have pointed ends, either or both of which are usually bent into a distinctive hook (Figure 39.1). Morphologically all leptospire are indistinguishable. They have Gram-negative cell walls and may be stained using carbol fuchsin counterstain (Faine *et al.*, 1999).

Leptospire are obligate aerobes with an optimum growth temperature of 28–30 °C. They grow in simple media enriched with vitamins (vitamins B₂ and B₁₂ are growth factors), long-chain fatty acids and ammonium salts (Johnson and Faine, 1984). Growth of leptospire is often slow on first isolation and cultures are retained for up to 13 weeks before being discarded, but pure subcultures in liquid media usually grow within 10–14 days.

The complete genome sequences of several strains of *Leptospira* have been determined and the data are leading to important discoveries regarding gene transfer between *Leptospira* serovars (Haake *et al.*, 2004; Nascimento *et al.*, 2004).

Species

Traditionally the genus was divided into two species, *Leptospira interrogans*, comprising all pathogenic strains, and *L. biflexa*, containing the saprophytic strains isolated from the environment

(Johnson and Faine, 1984). The phenotypic classification of leptospire has been replaced by a genotypic one, in which a total of 16 species of *Leptospira* are defined by DNA hybridization studies (Yasuda *et al.*, 1987; Ramadass *et al.*, 1992; Pérolat *et al.*, 1998; Brenner *et al.*, 1999). Pathogenic and non-pathogenic serovars occur within the same species (Table 39.1); in addition there are several examples of serovars which exhibit sufficient genetic diversity to be classified into different species. There is evidence of significant horizontal transfer between species (Haake *et al.*, 2004). The phenotypic characteristics previously used to differentiate *L. interrogans* sensu lato and *L. biflexa* sensu lato are no longer useful. At present neither serogroup nor serovar reliably predicts the species of *Leptospira*. DNA hybridization is available in relatively few research laboratories. Leptospiral species can be identified by 16S rRNA gene sequencing, but the serological classification of pathogenic leptospire remains the principal method of identifying isolates as pathogens.

Serovars

Leptospire are divided into numerous serovars by agglutination and cross-agglutinin adsorption (Johnson and Faine, 1984; Kmety and Dikken, 1993). Antigenically related serovars are grouped into serogroups. More than 60 serovars of *L. biflexa* sensu lato are recognized (Johnson and Faine, 1984), and within *L. interrogans* sensu lato over 230 serovars are organized into 23 serogroups (Kmety and

Figure 39.1 Leptospire viewed by darkfield microscopy (Public Health Image Library).

Table 39.1 Named species of *Leptospira* and distribution of serogroups

Species	Includes some serovars of serogroup
<i>L. alexanderi</i>	Manhao Hebdomadis ^a Javanica ^a Mini ^a
<i>L. biflexa</i> ^b	Semarang ^{a, c}
<i>L. borgpetersenii</i>	Javanica Ballum Hebdomadis ^a Sejroe ^a Tarassovi ^a Mini
<i>L. fainei</i>	Hurstbridge
<i>L. inadai</i> ^b	Lyme
<i>L. interrogans</i>	Icterohaemorrhagiae ^a Canicola Pomona ^a Australis ^a Autumnalis ^a Pyrogenes ^a Grippotyphosa ^a Djasiman Hebdomadis ^a Sejroe ^a Bataviae

<i>L. weilii</i>	Celledoni Icterohaemorrhagiae ^a Sarmin
<i>L. wolbachii</i> ^b	Codice ^c

^a Serovars of these serogroups are found within two or more genospecies.

^b *L. biflexa*, *L. inadai* and *L. wolbachii* are species which consist currently of non-pathogenic strains only. *L. meyeri* consists of both pathogenic strains and non-pathogenic strains.

^c These serogroups comprise non-pathogenic leptospires.

Dikken, 1993). Further serovars have been isolated but have yet to be validly published.

EPIDEMIOLOGY

Geographical Distribution

Leptospirosis is considered to be one of the most widespread zoonoses (World Health Organization, 1999). Human infection is acquired by direct or indirect contact with infected animal tissues or urine. The incidence of leptospirosis is much higher in warm-climate countries than in temperate regions. This is due largely to longer survival of

leptospires in damp soil with high humidity at ambient temperatures of 25–30 °C, and at a slightly alkaline pH. However, in most warm-climate countries opportunities for exposure to infected animals, whether domesticated or wild, are greater and other avocational activities further magnify the risk of exposure. In tropical regions there are more potential reservoir animals and almost invariably there are more serovars isolated from animals and humans. Conversely, in temperate regions in developed countries there are relatively few reservoir animals and thus less diversity among serovars.

Routes of Transmission

Leptospires usually enter the body through the mucous membranes of the upper respiratory tract or the conjunctivae, or through abraded skin, following exposure to contaminated water, infected urine or animal tissues. Water-borne transmission has been documented; numerous point-source outbreaks have been reported (Levett, 2001). Ingestion of water or immersion in water is commonly identified as a risk factor, suggesting that the oral mucosae and the conjunctivae are readily penetrated by leptospires.

Life Cycle

Animals, including man, can be divided into maintenance hosts or accidental hosts. A maintenance host is a species in which infection is endemic, usually transferred from animal to animal by direct contact. Often such infections occur while young animals are still in the nest. Other animals, such as humans, may become infected by indirect contact with the maintenance host. The most important maintenance hosts are rodents and other small mammals, which serve as reservoirs of infection for domestic animals, dogs and humans. The extent to which infection is transmitted depends upon many factors, which include climate, population densities and the degree of contact between maintenance and accidental hosts. Some serovars are host adapted; for example, the brown rat (*Rattus norvegicus*) is the ubiquitous carrier of serovar Icterohaemorrhagiae. Domestic animals may also be maintenance hosts; dairy cattle may harbour serovar Hardjo, while pigs may carry serovars Pomona, Tarassovi or Bratislava. Distinct variations in maintenance hosts and their associated serovars occur throughout the world and it is necessary to understand the local epidemiology in order to control the disease in humans.

Occupational and Recreational Exposure

Occupation remains a significant risk factor for humans, although protective measures have reduced the incidence of occupational disease in many countries. Direct contact with infected animals accounts for most infections in farmers, veterinarians, abattoir workers and meat inspectors, while indirect contact is important for sewer workers, miners, soldiers, septic tank cleaners, fish farmers, rice-field workers and sugar-cane cutters. In developed countries there has been a change in epidemiology of leptospirosis in recent years, with a shift away from occupational exposures and towards recreational exposures. Increasingly the disease occurs in tourists who have taken part in adventure tourism activities in tropical regions, which have often involved exposure to fresh water (Haake *et al.*, 2002).

CLINICAL FEATURES

The spectrum of symptoms caused by leptospiral infection is extremely broad; the classical syndrome of Weil's disease represents

only the most severe presentation. Formerly it was considered that distinct clinical syndromes were associated with specific serovars. However, this association has been disproven. In humans, severe leptospirosis is frequently, but not invariably, caused by serovars of the Icterohaemorrhagiae serogroup. The specific serovars involved depend largely on the geographical location and the ecology of local maintenance hosts.

The clinical presentation of leptospirosis is biphasic (Figure 39.2), the acute, or septicaemic, phase lasting about a week, and being followed by the immune phase, characterized by antibody production and excretion of leptospires in the urine (Turner, 1967). Most of the

complications of leptospirosis are associated with localization of leptospires within the tissues during the immune phase, and thus occur during the second week of the illness. In severe disease the two phases may not be apparent.

The great majority of infections are either subclinical or of very mild severity and will probably not be brought to medical attention. A smaller proportion of infections, but the overwhelming majority of the recognized cases, will present with a febrile illness of sudden onset, the symptoms of which include chills, headache, myalgia, abdominal pain, conjunctival suffusion and less often a skin rash (Table 39.2). This anicteric syndrome usually lasts for about a week, and its resolution coincides with the

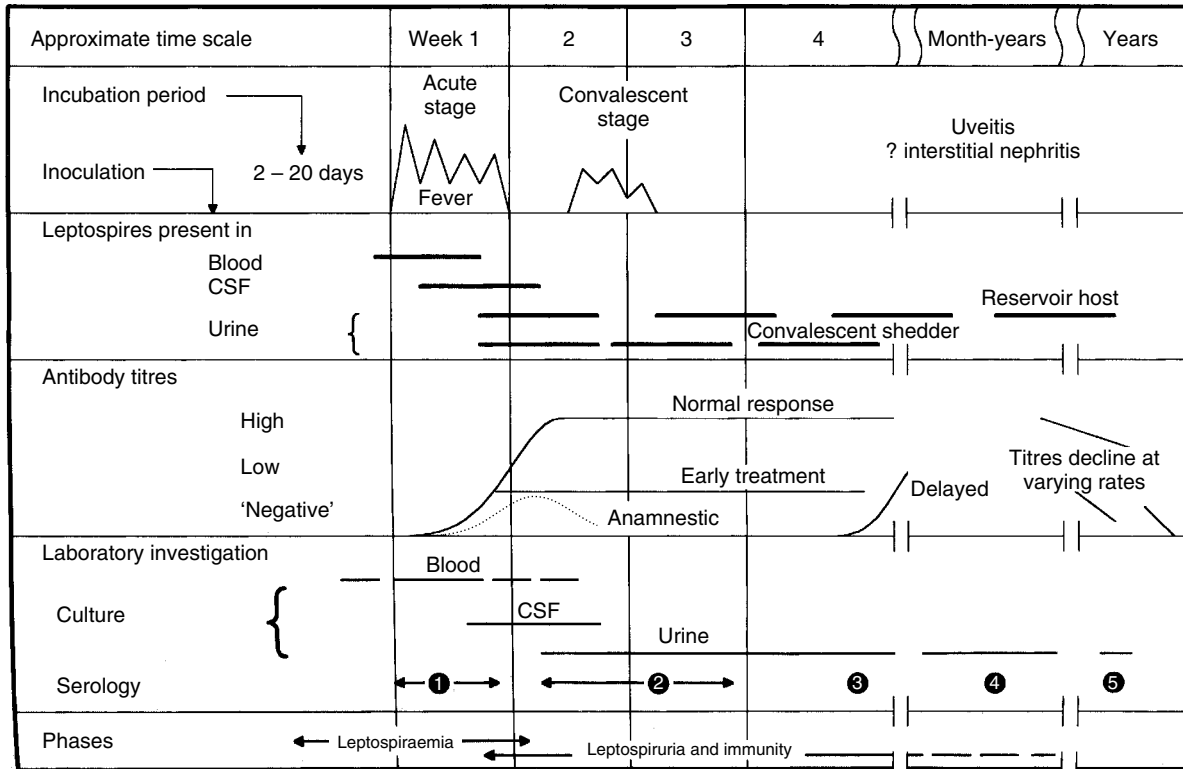

Figure 39.2 Biphasic nature of clinical leptospirosis and relevant investigations. Redrawn by permission of the BMJ Publishing Group from Turner, L. H., *BMJ* 1969; i: 231-235.

Table 39.2 Symptoms on admission in 88 patients with severe leptospirosis (Edwards *et al.*, 1990) and 150 anicteric patients (Berman *et al.*, 1973)

Symptom	Prevalence in leptospirosis (%)	
	Severe	Anicteric
Jaundice	95	1.5
Fever	85	97
Anorexia	85	—
Headache	76	98
Conjunctival suffusion	54	42
Vomiting	50	33
Myalgia	49	79
Abdominal pain	43	28
Nausea	37	41
Dehydration	37	—
Cough	32	20
Hepatomegaly	27	15
Lymphadenopathy	21	21
Diarrhoea	14	29
Rash	2	7

appearance of antibodies. The fever may be biphasic and may recur after a remission of 3 to 4 days. The headache is often intense, with retroorbital pain and photophobia. Aseptic meningitis may be found in $\leq 25\%$ of all leptospirosis cases and may account for a significant minority of all causes of aseptic meningitis. Mortality is almost nil in anicteric leptospirosis.

The differential diagnosis includes common viral infections, such as influenza, and in the tropics, dengue, in addition to the bacterial causes of PUO, such as typhoid and brucellosis. A comprehensive list of other conditions that may be mimicked by leptospirosis would include malaria, viral hepatitis, rickettsiosis, mononucleosis and HIV seroconversion (Turner, 1967; Levett, 2001).

Icteric leptospirosis is a much more severe disease, in which the clinical course is often very rapidly progressive. Severe cases often present late in the course of the disease, and this contributes to the high mortality rate, which ranges between 5 and 15%. Between 5 and 10% of all patients with leptospirosis have the icteric form of the disease (Heath, Alexander and Galton, 1965). The jaundice occurring in leptospirosis is not associated with hepatocellular necrosis and liver function returns to normal after recovery. Serum bilirubin levels may be high and may take several weeks to fall to within normal limits. There are moderate rises in transaminase levels and minor elevation of the alkaline phosphatase level usually occurs.

The complications of severe leptospirosis emphasize the multi-systemic nature of the disease. Leptospirosis is a common cause of acute renal failure (ARF), which occurs in 16–40% of cases (Ramachandran *et al.*, 1976; Winearls *et al.*, 1984; Edwards *et al.*, 1990). Thrombocytopenia (platelet count $< 100 \times 10^9/l$) occurs in $\geq 50\%$ of cases and is a significant predictor for the development of ARF (Edwards, Nicholson and Everard, 1982). However, thrombocytopenia in leptospirosis is transient and does not result from disseminated intravascular coagulation (Edwards *et al.*, 1986). Adult respiratory distress syndrome (Ramachandran and Perera, 1977) is another common complication. Pulmonary haemorrhage has become more commonly recognized in recent years (Im *et al.*, 1986; Zaki, Shieh, and the Epidemic Working Group, 1996; Yersin *et al.*, 2000; Carvalho and Bethlem, 2002). Serum amylase levels are often raised significantly, but pancreatitis is not a common finding (Edwards and Everard, 1991).

Fatality in severe leptospirosis often follows cardiac arrest, resulting from the development of interstitial myocarditis, pericarditis and cardiac arrhythmias (Ramachandran, 1975; Lee *et al.*, 1986). These complications occur in $\leq 50\%$ of patients (Areán, 1957; de Brito *et al.*, 1987) and are more common in older patients.

Anterior uveitis, usually bilateral, occurs after recovery from the acute illness in a minority of cases (Rathinam *et al.*, 1997). Uveitis may present weeks, months or occasionally years after the acute stage. The incidence of ocular complications is variable, but this probably reflects the long time-scale over which they may occur (Mancel *et al.*, 1999). In the United States the incidence was estimated at 3% (Heath, Alexander and Galton, 1965). Rare complications include cerebrovascular accidents, rhabdomyolysis and Guillain-Barré syndrome (Levett, 2001). Leptospirosis during pregnancy has been shown to cause fetal infection and death, but only a handful of cases have been reported (Levett, 2001).

LABORATORY DIAGNOSIS

Leptospiral diagnosis depends heavily upon serological detection of specific antibodies, and effective serological assays have been developed in recent years. A definitive identification of the infecting

serovar is possible only if an isolate is obtained from blood, urine, CSF or other specimen during the acute illness. The selection of appropriate specimens is dependent on the stage of the disease, and therefore an adequate history is essential, with particular attention to the duration of symptoms.

Microscopy

Blood, urine, CSF and other specimens may be examined directly by darkground microscopy. However, both the sensitivity and specificity of microscopy may be unacceptably low (Vijayachari *et al.*, 2001), since many artefacts may be mistaken for leptospire.

Histopathology

Spirochaetes can be demonstrated by silver staining, using stains such as the modified Wartin-Starry. This approach is not specific for leptospire. A more recent approach is the use of immunohistochemical staining using pooled antisera against a combination of serovars (Zaki, Shieh, and the Epidemic Working Group, 1996). Using this approach the morphology of the spirochaetes in tissue sections can be seen readily (Plate 12).

Culture

Leptospire grow in simple media, to which either serum or albumin and Tween have been added (Faine *et al.*, 1999). Numerous media containing serum have been described, including those of Fletcher, Korthof, Stuart and Ellinghausen (Turner, 1970). Pooled rabbit serum, rich in vitamin B₁₂, is usually employed. The most widely used medium for isolation of human leptospire is EMJH (Ellinghausen and McCullough, 1965; Johnson and Harris, 1967). This is a serum-free medium, containing Tween 80 and bovine serum albumin fraction V. Growth of contaminants can be inhibited by the addition of 5-fluorouracil (Johnson and Rogers, 1964).

During the first (leptospiraemic) phase of the disease, cultures of blood in EMJH are made at the patient's bedside, by injecting one drop of blood into the bottle. Urine is an appropriate specimen for culture from the start of the second week of illness (Figure 39.2). Survival of leptospire in human urine is limited, and hence urine samples should be processed as soon as possible by neutralization and centrifugation at 1500 g for 30 min, after which the pellet is resuspended in phosphate-buffered saline and inoculated into semisolid medium containing 5-fluorouracil. Specimens that may be contaminated, such as urine, or contaminated cultures, may be filtered using a 0.22 μm filter before inoculation. Cultures are incubated at 28–30 °C. Low-power ($\times 100$ –200) darkground microscopy is used to examine cultures weekly for up to 13 weeks before cultures are discarded. After obtaining pure subcultures, isolates are identified using a combination of molecular and serologic methods. Since some serovars are distributed within several species, identification of the species by 16S rRNA gene sequencing is valuable. Serovar identification can be performed by cross-agglutinin absorption testing, available in only a few reference laboratories (Dikken and Kmety, 1978), by agglutination with a panel of monoclonal antibodies (Terpstra, 1992), or by molecular typing. Although identification of isolates is not helpful for patient management, it is essential for understanding of the epidemiology in a region and the design of appropriate public health interventions.

Molecular Typing

Pulsed-field gel electrophoresis (PFGE) has become the standard molecular method for identification of serovars (Herrmann *et al.*, 1992). Earlier approaches using restriction endonuclease digestion of genomic DNA led to extremely complex patterns, which were difficult to interpret. Numerous PCR-based methods have been applied to epidemiological characterization of isolates from different sources. Of particular significance is the potential for some methods (such as PCR-REA and LSSP-PCR) which retain the use of specific primers, to be applied directly to DNA derived from clinical material, without the necessity of first isolating leptospire in culture.

Serology

Serology provides the means of diagnosis in most cases of leptospirosis. However, antibodies do not appear in the blood until late in the first week of the disease (Figure 39.2) and the diagnosis is thus often retrospective.

Microscopic Agglutination Test

The reference method for serological diagnosis of leptospirosis is the microscopic agglutination test (MAT), performed on paired sera, usually taken a minimum of 3 days apart. Patients' sera are mixed with live antigen suspensions of leptospiral serovars. The range of antigens used should include all serogroups and all locally common serovars. After incubation the serum/antigen mixtures are examined by darkfield microscopy for agglutination and the titres are determined.

Interpretation of the MAT is complicated by the high degree of cross-reaction that occurs between different serogroups, especially in acute-phase samples. This is to some extent predictable, thus patients often have similar titres to all serovars of an individual serogroup, but 'paradoxical' reactions, in which the highest titres are detected to a serogroup unrelated to the infecting one, are also common (Figure 39.3).

Acute infection is suggested by a single titre of ≥ 800 and confirmed by a fourfold or greater rise in titre between paired sera. Titres following acute infection may be extremely high ($\geq 25\,600$) and may take months, or even years, to fall to low levels (Cumberland *et al.*, 2001). Often, it becomes possible to distinguish a predominant serogroup only months after infection, as cross-reacting titres decline at different rates. It is important, therefore, to examine several sera taken at monthly intervals after the acute disease, in order to determine the presumptive infecting serogroup (Levett, 2003). Some patients are found to have serological evidence of previous infection with a different leptospiral serovar. In these cases, serological diagnosis is complicated further by the 'anamnesic response', in which the first rise in antibody titre is usually directed against the infecting serovar from the previous exposure.

The MAT is a complex test to control, perform and interpret. An international proficiency testing scheme has been developed and has produced a positive effect on MAT testing in many countries (Chappel *et al.*, 2004).

Other Serological Tests

Because of the complexity of the MAT, rapid screening tests for leptospiral antibodies have been developed as an aid to presumptive

diagnosis. Such tests are genus specific and the methods used have included complement fixation, slide agglutination, counter immunoelectrophoresis, indirect haemagglutination, microcapsule agglutination, latex agglutination, lateral flow and ELISA in a variety of formats (Levett, 2001). Many methods have been described but relatively few have found widespread use in diagnostic laboratories.

Several methods for the use of ELISA have been described (Adler *et al.*, 1980; Terpstra, Ligthart and Schoone, 1985), using different serovars or combinations of serovars as antigens. The IgM antibodies produced in leptospirosis are broadly cross-reactive, but titres vary slightly depending upon the antigen used in the assay and the infecting serovar. In acute infection, IgM antibodies reach very high titres (≥ 1280 is quite common). Lower titres may be non-specific and a second specimen is required to detect a rise in titre. A high IgM titre also indicates the necessity for a convalescent specimen to be taken 10–14 days after the acute sample. In either case a fourfold or greater rise in titre of IgM is considered diagnostic. Several IgM-ELISA assays are available commercially. IgM-dipstick assays and a latex agglutination assay have been evaluated (Smits *et al.*, 1999, 2001; Levett *et al.*, 2001) and have the advantage of requiring only very basic laboratory equipment.

Molecular Methods of Diagnosis

Several primer sets have been described for use in PCR, but few have been evaluated using either human (Merien, Baranton and Pérolat, 1995; Brown *et al.*, 1995) or veterinary (Wagenaar *et al.*, 2000; Harkin, Roshto and Sullivan, 2003) clinical samples. PCR has been found useful in confirming a diagnosis of leptospirosis, particularly in severe disease, when patients may die before sero-conversion occurs (Brown *et al.*, 2003). Blood, urine, CSF, aqueous humor, dialysate fluid and postmortem tissues have all been used as sources of leptospiral DNA (Merien *et al.*, 1993; Brown *et al.*, 1995). Real-time quantitative assays (Smythe *et al.*, 2002; Levett *et al.*, 2005; Merien *et al.*, 2005) appear to offer an increase in sensitivity over earlier methods.

MANAGEMENT

Treatment of leptospirosis is dependent upon the severity and duration of symptoms at the time of presentation. Patients with mild, flu-like symptoms require only symptomatic treatment, but should be cautioned to seek further medical help if they become jaundiced. Patients who present with more severe anicteric leptospirosis will require hospital admission and close observation. If the headache is particularly severe a lumbar puncture usually produces a dramatic improvement.

The management of icteric leptospirosis requires admission of the patient to the ICU initially. Patients with pre-renal azotaemia can be rehydrated for the first 2–3 days while their renal function is observed, but patients in ARF require dialysis as a matter of urgency (Nicholson *et al.*, 1989). This may be accomplished by peritoneal dialysis or by haemodialysis. Cardiac monitoring is also necessary during the first few days after admission.

The role of antibiotics in the management of leptospirosis is still contentious, despite numerous reports of their use. A major difficulty in assessing the efficacy of antibiotic treatment results from the late presentation of many patients with severe disease, after the leptospire have localized in the tissues. Few well-designed and controlled studies have been reported (Guidugli, Castro and Atallah, 2003).

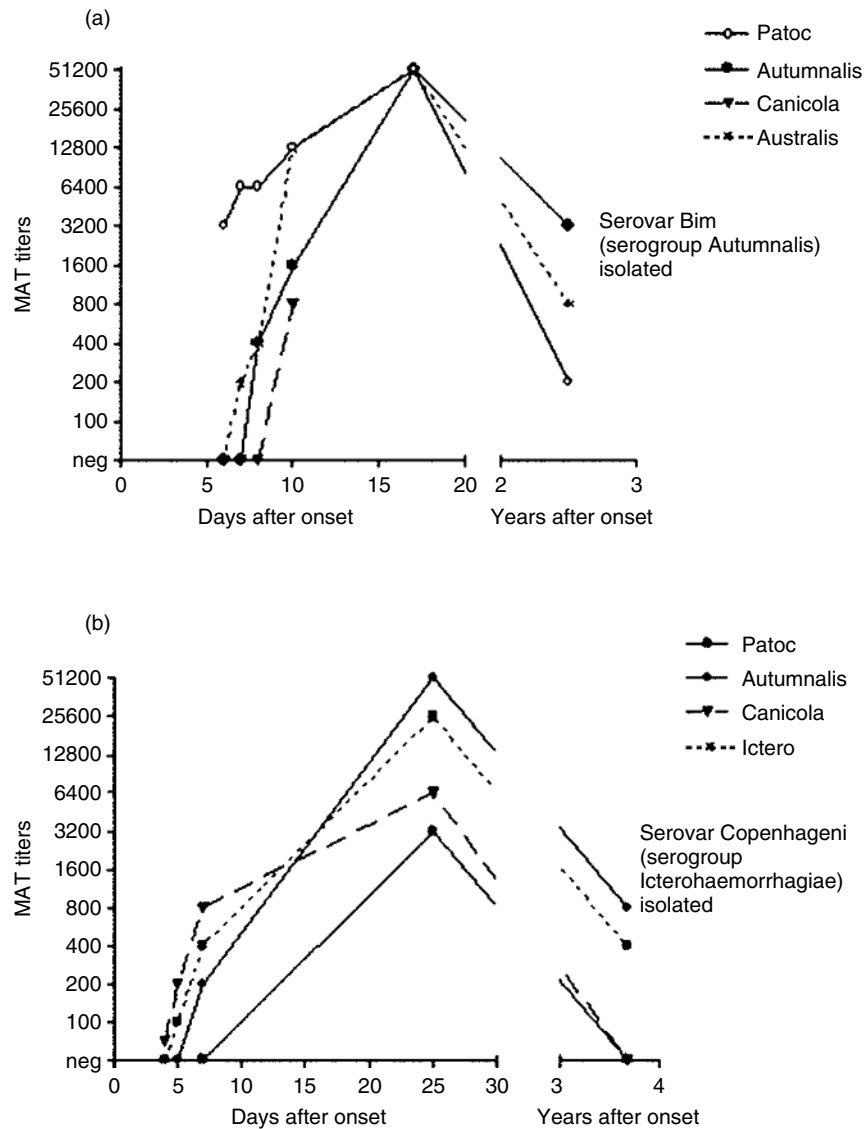

Figure 39.3 Paradoxical immune response to acute infection with serovar Bim, in which the presumptive serogroup (Autumnalis) was identified during follow-up (a) and with serovar Copenhageni, in which serogroup Icterohaemorrhagiae was never identified as the predominant serogroup (b). Reproduced by permission of ASM Press, from Levett, P. N., *Clinical Microbiology Reviews*, 2001; 14: 296–326.

Doxycycline (100 mg bds for 7 days) was shown to reduce the duration and severity of illness in anicteric leptospirosis by an average of 2 days (McClain *et al.*, 1984). Patients with severe disease were excluded from this study.

Three randomized trials of penicillin produced conflicting results. One study included 42 patients with severe leptospirosis, of whom 19 were jaundiced (Watt *et al.*, 1988). The mean duration of illness before admission was 9 days. No patients required dialysis and there were no deaths. IV penicillin was given at a dose of 6 MU/day for 7 days and was found to halve the duration of fever. A second study included 79 patients with icteric leptospirosis, of whom four died (Edwards *et al.*, 1988). Patients in the treatment group received IV penicillin at a dose of 8 MU/day for 5 days. The mean duration of illness prior to admission was 6 days. No difference was observed between treatment and control groups in outcome or duration of the illness. In the largest study, of 253 patients, the mean duration of

illness prior to admission was 6 days and 94% of the subjects were icteric (Costa *et al.*, 2003). The dose of penicillin was 6 MU/day for 7 days and there was no significant difference in mortality between treated and untreated groups in this study.

Recently, prospective open-label trials comparing penicillin with ceftriaxone (Panaphut *et al.*, 2003) or penicillin with cefotaxime or doxycycline (Suputtamongkol *et al.*, 2004) have shown these four antibiotics to be equally effective. Less than half of the subjects in these studies were jaundiced, and most patients had received some antibiotics before hospital admission.

A common finding in some of these studies has been the prevention of leptospirosis or a significant reduction in its duration (McClain *et al.*, 1984; Edwards *et al.*, 1988; Watt *et al.*, 1988). This finding alone is sufficient justification for antibiotic use, but any antibiotic treatment should be started as early as possible and should be regarded as an adjunct to other therapeutic approaches.

CONTROL

Control and prevention of leptospirosis in humans is inextricably linked with the control of animal reservoirs. The most efficient approaches to control in a given geographical location depend upon the local epidemiology. The epidemiology of leptospirosis may be altered markedly by changing agricultural and cultural practices. As an example, recent large outbreaks of leptospirosis have occurred in recreational athletes from several countries after competitive events in the USA and in Borneo (Morgan *et al.*, 2002; Sejvar *et al.*, 2003), associated with prolonged exposure to fresh water. The necessity for continued surveillance of human and veterinary leptospirosis should be emphasized.

The use of protective clothing has markedly reduced the incidence of leptospirosis associated with many occupations. Chemoprophylaxis with doxycycline (200 mg once weekly) is effective if the risk exposure is predicted beforehand (Takafuji *et al.*, 1984).

Immunization of animals may be practised in regions where livestock animals are important reservoirs, both for economic reasons and to prevent infection of humans. Current vaccines are killed suspensions of whole cells grown in protein-free medium. Usually two doses are given, followed by annual booster injections. Cattle are often immunized against serovars Hardjo and Pomona, while pigs may be immunized against Pomona, Tarassovi, Bratislava, Grippotyphosa and Icterohaemorrhagiae, depending upon the geographical region. Canine vaccines usually include Icterohaemorrhagiae and Canicola, but in North America serovars Grippotyphosa and Pomona are included. Vaccines are used in human populations at high risk of acquiring leptospirosis. A trivalent vaccine is used in Cuba, containing serovars Icterohaemorrhagiae, Pomona and Canicola (Martínez Sánchez *et al.*, 1998). Widespread use of vaccines has been restricted to China, Japan and some other SE Asian countries and has been effective in controlling epidemics, particularly in rice-field workers.

Immunity to leptospirosis was long thought to result solely from the humoral response to lipopolysaccharide (Adler and Faine, 1977). Vaccination with killed bacterins induces low titres of antibody and requires the administration of booster doses at frequent intervals. Immunity generated by such vaccines is relatively serovar specific. In animals, immunization protects against disease but rarely prevents infection and renal colonization and thus does not effectively prevent immunized animals from becoming carriers. Immunized dogs have served as reservoirs for human infection (Feigin *et al.*, 1973; Everard *et al.*, 1987).

More recent evidence suggests that cell-mediated immunity is also important, both in humans and animals (Naiman *et al.*, 2001; Klimpel, Matthias and Vinetz, 2003). A monovalent bovine Hardjo vaccine induced a T-helper 1 immune response (Naiman *et al.*, 2002) and protected against both renal colonization and urinary shedding (Bolin and Alt, 2001).

Helicobacter spp. and Related Organisms

Peter J. Jenks

Department of Microbiology, Plymouth Hospitals, Derriford Hospital, Plymouth, UK

INTRODUCTION

Helicobacter pylori is a Gram-negative, microaerobic, spiral bacterium that colonizes the stomachs of approximately half the world's population (Dunn, Cohen and Blaser, 1997). The bacterium is uniquely adapted for survival within the gastric mucosa, and colonization usually persists for years or even decades. Infection with *H. pylori* is associated with chronic gastritis and peptic ulceration, and the bacterium is also considered a risk factor for developing gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma (Blaser, 1990; Parsonnet *et al.*, 1991; Parsonnet *et al.*, 1994). The recognition of an etiologic link between *H. pylori* and severe gastroduodenal disease has revolutionized the management of these conditions and provided a potential strategy for the prevention of gastric cancer. Evidence is beginning to emerge of a link between other *Helicobacter* species and human disease conditions.

THE GENUS *HELICOBACTER*

The existence of gastric spiral bacteria was first noted over 100 years ago, well before the recognition of any association with gastric disease, and there are early reports of such organisms in the stomachs of dogs, cats and humans (Salomon, 1896; Lim, 1920). The simultaneous occurrence of bacteria and peptic ulceration was also described well before the isolation of *H. pylori* (Rosenow and Sandford, 1915), and in 1975 a relationship was reported between the migration of polymorphonuclear leukocytes through the gastric mucosa and the presence of spiral bacteria in the gastric epithelium (Steer, 1975). In 1983, Robin Warren and Barry Marshall reported that curved bacteria were often present in gastric biopsy specimens submitted for histological examination (Marshall, 1983; Warren, 1983), and this group went on to isolate and fulfil Koch's postulates for this '*pyloric Campylobacter*' (Marshall *et al.*, 1985). Further analysis, particularly of cellular fatty acids, menaquinones, morphology and biochemical capabilities, suggested that this organism was not a *Campylobacter*, and in 1989 it was placed in a phylogenetically distinct genus, *Helicobacter*, with *H. pylori* as the type species (Goodwin *et al.*, 1989). Analysis of the 16S rRNA sequence relationships of members of this genus reveals two large groups of *Helicobacter* species (Table 40.1). The first group contains *H. pylori*, *Helicobacter heilmannii* and other *Helicobacter* species that colonize gastric mucosa, and the second more diverse group contains the enteric, biliary and blood-associated *Helicobacter* species (reviewed in Solnick and Schauer, 2001).

Table 40.1 *Helicobacter* species and their hosts

<i>Helicobacter</i> species	Natural host(s)
Gastric	
' <i>Candidatus Helicobacter bovis</i> '	Cattle
' <i>Candidatus Helicobacter suis</i> '	Pig
<i>Helicobacter acinonychis</i>	Cheetah
<i>Helicobacter bizzozeronii</i>	Dog
<i>Helicobacter cetorum</i>	Dolphin, whale
<i>Helicobacter felis</i>	Cat, dog
<i>Helicobacter heilmannii</i>	Human, nonhuman primate
<i>Helicobacter mustelae</i>	Ferret
<i>Helicobacter nemestrinae</i>	Pigtailed macaque
<i>Helicobacter pylori</i>	Human, rhesus macaque
<i>Helicobacter salomonis</i>	Dog
' <i>Helicobacter suncus</i> '	House musk shrew
Enterohepatic	
<i>Helicobacter aurati</i>	Hamster
<i>Helicobacter bilis</i>	Mouse, dog, human
' <i>Helicobacter canadensis</i> '	Human
<i>Helicobacter canis</i>	Dog, human
<i>Helicobacter cholecystus</i>	Hamster
<i>Helicobacter cinaedi</i>	Human, hamster
<i>Helicobacter</i> sp. cotton-top	Cotton-top tamarin
<i>Helicobacter fennelliae</i>	Human
' <i>Helicobacter ganmani</i> '	Mouse
<i>Helicobacter hepaticus</i>	Mouse
' <i>Helicobacter mainz</i> '	Human
<i>Helicobacter marmotae</i>	Woodchuck, cat
' <i>Helicobacter mesocricetorum</i> '	Hamster
<i>Helicobacter muridarum</i>	Mouse, rat
<i>Helicobacter pametensis</i>	Tern, pig
<i>Helicobacter pullorum</i>	Chicken, human
' <i>Helicobacter rappini</i> '	Sheep, human
<i>Helicobacter</i> sp. flexispira	Pig, sheep, dog, human
<i>Helicobacter rodentium</i>	Mouse
<i>Helicobacter trogontum</i>	Rat
' <i>Helicobacter typhlonius</i> '	Mouse
<i>Helicobacter westmeadii</i>	Human
<i>Helicobacter winghamensis</i>	Human

EPIDEMIOLOGY

Helicobacter pylori is the most common persistent bacterial infection of humans, infecting between 70 and 90% of the population of developing countries and 25–50% of the population of developed countries

(Dunn, Cohen and Blaser, 1997). Most infections are acquired before the age of 10 years, with males and females infected at approximately the same rates, and there is an inverse relationship between the incidence of infection and socioeconomic status. The only natural reservoir of *H. pylori* is the human stomach, and although it is possible to experimentally infect other animal species, there is no evidence that these act as important sources of transmission of the bacterium. The fastidious nutritional requirements of *H. pylori* mean that it is unable to grow or survive for prolonged periods outside the human host. Definite proof of the exact mode of transmission of *H. pylori* is lacking, but person-to-person transmission via gastric–oral and/or faecal–oral route is considered the most likely means by which the organism is spread. Intrafamilial transmission seems particularly important, with the mother playing a key role in transmitting the agent to the child. The organism can be cultivated from vomitus and, occasionally, from saliva and faeces, indicating that the organism is potentially transmissible during episodes of gastrointestinal illness, particularly with vomiting (Parsonnet, Shmueli and Haggerty, 1999). It is possible that transmission occurs more frequently in the acute phase of the infection when the organism may be excreted in higher numbers. Detection of *H. pylori* in dental plaque is most likely to reflect regurgitation of the bacterium into the mouth, and there is little evidence for long-term survival of the bacterium within this ecological niche. Iatrogenic transmission of *H. pylori* via contaminated endoscopes has been largely eliminated by the rigorous implementation of disinfection procedures.

HELICOBACTER SPECIES AND HUMAN DISEASE

All patients infected with *H. pylori* develop chronic superficial gastritis, a condition that is asymptomatic in most cases (Blaser, 1990). In a proportion of patients infection is complicated by severe gastroduodenal disease, and *H. pylori* is now recognized to cause approximately 90% of duodenal and 70% of gastric ulcers (Figure 40.1). Epidemiological evidence of a link with adenocarcinoma (both intestinal and diffuse histological types) of the distal stomach and gastric MALT lymphoma has resulted in the classification of the organism as a group I carcinogen (IARC Working Group on the Evaluation of Carcinogenic Risks to Humans, 1994). In the developing world infection is also linked with chronic diarrhoea, malnutrition and poor growth, as well as predisposing to enteric infections, including typhoid fever and cholera (Frenck and Clemens, 2003). Numerous studies have attempted to identify an association between infection with *H. pylori* and extradigestive diseases, particularly atherosclerosis and autoimmune disorders. Interpretation of such studies is often

Figure 40.1 Representation of gastroduodenal diseases associated with *H. pylori* infection. MALT, mucosa-associated lymphoid tissue.

difficult owing to the presence of multiple confounding factors, and it remains unclear whether such associations are causal or occasional. Enterohepatic *Helicobacter* species of clinical interest include *Helicobacter cinaedi*, *Helicobacter fennelliae*, '*Helicobacter mainz*' and '*Helicobacter westmeadii*', which are particularly associated with gastroenteritis and bacteraemia in human immunodeficiency virus (HIV)-positive homosexual males. The recent isolation of various *Helicobacter* species from bile and gallbladder tissue of patients with conditions ranging from chronic cholecystitis and primary sclerosing cholangitis to gallbladder and primary hepatic cancer suggests a possible role of these micro-organisms in certain hepatobiliary disorders (reviewed in Leong and Sung, 2002). Again, many of these studies have been small and lacked well-matched controls, but it is plausible that some *Helicobacter* species are able to survive in this niche and cause human disease.

MICROBIOLOGY OF *H. PYLORI*

Helicobacter pylori is a spiral, Gram-negative bacterium that is motile by means of four to eight sheathed flagella (Figure 40.2). The bacterium is an obligate microaerobe, requiring 5–7% O₂ and 5–10% CO₂, and grows optimally in a humid atmosphere at 37 °C on a variety of basal media supplemented with 5–10% horse or sheep blood. *Helicobacter pylori* will also grow in liquid media such as brain–heart infusion (BHI), brucella or Isosensitest broths supplemented with 5–10% fetal calf serum or 1–2% cyclodextrin. A selective supplement containing vancomycin, trimethoprim, cefsulodin (or polymyxin B) and amphotericin B is frequently added to media used for the isolation of *H. pylori* from clinical specimens and is useful for reducing contamination by other organisms. Sterile saline is a suitable medium for the transport of gastric biopsy specimens. More complex media, such as Stuart's medium or supplemented BHI, may improve recovery rates where prolonged transportation times are unavoidable. Although growth is frequently visible after 3–5 days, primary isolation may require incubation for up to 10 days.

After prolonged culture on solid or liquid medium, the normal helical bacillary morphology of the bacterium changes to predominantly coccoid forms, and it has been postulated that these represent a dormant stage important for survival in a hostile environment. However, numerous studies have failed to convincingly demonstrate that coccoid forms can either regenerate into spiral cells or are

Figure 40.2 Electron micrograph of *H. pylori* showing spiral morphology and sheathed unipolar flagella.

themselves infectious agents. Furthermore, most evidence suggests that the conversion of *H. pylori* from bacillary to the coccoid form is a passive process and that the coccoid form is the morphological manifestation of cell death (Kusters *et al.*, 1997).

Helicobacter pylori possesses urease, oxidase and catalase enzyme activities but is unable to hydrolyse hippurate or reduce nitrate (Goodwin and Armstrong, 1990). The organism is resistant to nalidixic acid (30 µg) and sensitive to cephalothin (30 µg). *Helicobacter pylori* is able to metabolize a variety of substrates via a specialized series of pathways that are different from those found in other bacteria, and detailed description of the biochemical and metabolic pathways of *H. pylori* can be found in excellent reviews of these subjects (Kelly, 1998; Doig *et al.*, 1999; Marais *et al.*, 1999). The presence of incomplete citric acid and other biosynthetic pathways is likely to explain the complex nutritional requirements of *H. pylori*, and its microaerophilic nature is probably due to the involvement of oxygen-sensitive enzymes in central metabolic pathways. The ability of *H. pylori* to use molecular hydrogen, present as a by-product of fermentation by normal colonic flora, as an energy-yielding substrate has been recently shown to facilitate survival within the stomach (Olson and Maier, 2002).

In response to the sequestration and storage of available iron by the host, *H. pylori* has evolved many mechanisms for scavenging iron molecules from host-borne sources including three heme-binding outer membrane proteins (Worst, Otto and Graaf, 1995) and a 70-kDa lactoferrin-binding protein (Dhaenens, Szczebara and Husson, 1997). Gene homologues of uptake systems for ferrous iron (*feo*), ferric iron (*ceu*) and iron-citrate complexes (*fec*) have also been identified in the complete genome sequences of *H. pylori* strain 26695 (Tomb *et al.*, 1997; Alm *et al.*, 1999). Once iron enters the bacterium, the ferritin Pfr binds non-heme iron and forms iron-containing paracrystalline inclusion bodies that allow storage and protects against iron toxicity (Frazier *et al.*, 1993; Bereswill *et al.*, 1998).

GENOME, GENOMICS AND GENETIC DIVERSITY

The size of the circular *H. pylori* chromosome varies from 1.6 to 1.73 Mb, with a G + C composition of between 34.1 and 37.5 mol%. The genomes of two strains of *H. pylori*, 26695 and J99, have been sequenced and have provided new insights into the unique lifestyle and pathogenesis of this bacterium (Tomb *et al.*, 1997; Alm *et al.*, 1999). Like other bacteria that have evolved to colonize a relatively restricted environmental niche, *H. pylori* has a small genome containing a minimal set of metabolic genes. Features that may be particularly relevant to understanding the biology of *H. pylori* include the absence of several key regulatory proteins and biosynthetic enzymes and the presence of a unique combination of virulence factors and multiple DNA-restriction and -modification enzymes. Comparison of the two completed genomes has revealed that around 7% of genes are specific to each strain, with almost half of these genes being clustered in a single hypervariable region, known as the plasticity zone. While the function of 58% of gene products is either known or may be predicted by sequence homology, 18.5% gene products have orthologues of unknown function in other species and 23.5% of proteins are *H. pylori* specific (Alm *et al.*, 1999). Although a recent comparative analysis of the *H. pylori* genomes has reduced the number of hypothetical proteins further (Boneca *et al.*, 2003), one of the major challenges facing researchers is to assign function to and characterize these currently unclassified genes, many of which are likely to be novel determinants important in survival and colonization of the stomach. One approach to this problem has been to use the complete genome sequence to perform *in silico* structural and functional predictions using methods such as fold assignments for genome proteins (Pawlowski *et al.*, 1999) and protein-protein interaction screens (Rain *et al.*, 2001). Signature-tagged mutagenesis, which utilizes negative selection to identify genes that may be important for

pathogenesis, has also provided information on previously unknown colonization factors of *H. pylori*, including a collagenase (Kavermann *et al.*, 2003). Global analysis of gene expression using whole-genome microarray-based technology (reviewed in Thompson and de Reuse, 2002) and comparative proteome analysis (Jungblut *et al.*, 2000) are also providing important clues to the function of genes with unknown function. The goal of characterizing these genes would be the selection of candidates suitable for the rational development of new therapeutic agents that may provide alternatives to antibiotic-based therapies in the future.

Because *H. pylori* is naturally competent for transformation, it is able to acquire new genetic material by horizontal transfer (Nedenskov-Sorensen, Bukholm and Bovre, 1990). *Helicobacter pylori* exhibits a panmictic (free recombinational) population structure that results from frequent genetic recombination during mixed colonization by unrelated strains (Suerbaum *et al.*, 1998). Gene transfer between *H. pylori* strains is common and can generate novel subtypes that exhibit changes in important virulence markers, such as the *cag* pathogenicity island (Kersulyte, Chalkauskas and Berg, 1999). The persistent accumulation of *de novo* mutations also contributes to *H. pylori* genetic variation and evolution (Wang, Humayun and Taylor, 1999), and this process appears to be facilitated by the absence of certain DNA repair systems, such as components of the mismatch repair (MMR) system (Labigne and Jenks, 2001). The ability to generate such an extraordinary degree of genetic diversity has been shown to facilitate adaptation of *H. pylori* to environmental challenges within the stomach and contribute to the longevity of infection (Loughlin *et al.*, 2003). Approximately 40% of *H. pylori* strains contain plasmids varying in size from 1.5 to 23.3 kb. Although virulence factors have not been identified on plasmids, these mobile genetic elements appear to participate in recombinational exchange with the chromosome, so contributing to the extensive genetic heterogeneity characteristic of *H. pylori* (De Ungria *et al.*, 1999).

GENE REGULATION

Despite advances in our knowledge of the factors that are essential for colonization and the induction of mucosal damage, little is known of the molecular mechanisms that regulate the coordinated expression of genes responsible for these functions. Sequence analysis of the genome sequences has revealed a low abundance of regulatory networks when compared with other Gram-negative bacteria (Tomb *et al.*, 1997; Alm *et al.*, 1999). *Helicobacter pylori* possesses only three sigma factors RpoD (σ^{80}), RpoN (σ^{54}) and FliA (σ^{28}) and lacks homologues of the stress-response sigma factors, RpoS (σ^{38}) and RpoH (σ^{32}). There are relatively few two-component regulatory systems, with only four histidine kinases with their cognate response regulators as well as two orphan response regulators (Beier and Frank, 2000). Of the handful of other transcriptional regulators, HspR represses the expression of the major chaperones of *H. pylori* (Spohn and Scarlato, 1999), the ferric uptake regulator (Fur) functions in the regulation of iron homeostasis (Delany *et al.*, 2001) as well as acid resistance and the regulation of the amidase and formamidase enzymes, and NikR largely mediates the nickel-responsive induction of urease (van Vliet *et al.*, 2002).

The paucity of regulatory systems may reflect the fact that *H. pylori* survives in the relatively restricted niche of the human gastric mucosa, with an apparent lack of competition from other micro-organisms. However, the human stomach is far from a stable habitat, experiencing considerable fluctuations in nutrient availability, reactive oxygen species, pH and temperature, and a certain degree of adaptability would be expected to allow successful and persistent colonization. Furthermore, it is clear that *H. pylori* is able to sense and respond to diverse environmental stimuli despite the absence of classical global regulators.

PATHOGENESIS

Colonization of the Gastric Mucosa

Motility

Motility in *H. pylori* is conferred by four to eight unipolar flagella which allow it to remain highly motile in the viscous environment of the mucus layer overlying the gastric mucosa. The bacterium requires flagellum-dependent motility to survive and multiply in this environmental niche as well as to penetrate the mucus layer to reach the surface of the epithelial cells. The flagellar filaments are composed of polymers of a major (FlaA) and a minor flagellin (FlaB), and the expression of both subunits is necessary for full motility and colonization (Eaton *et al.*, 1996). Each flagellar filament is connected to the basal body via a flagellar hook, and the flagella are enclosed in a membranous sheath which is thought to shield the inner filament and protect it from acid-induced damage (Geis *et al.*, 1993). Export and assembly of flagellar proteins in *H. pylori* is mediated by a highly conserved family of proteins which are implicated in the export of flagellar proteins and other virulence factors in many bacterial species. In contrast, the regulation of flagellar gene expression in *H. pylori* differs from that in model organisms such as *Escherichia coli* and can be ordered into three hierarchical classes that respond to many stimuli including growth phase and changes in environmental conditions (Colland *et al.*, 2001; Josenhans *et al.*, 2002; Thompson *et al.*, 2003).

Mechanisms of Acid Tolerance

Acid resistance is central to the pathogenesis of *H. pylori*, and a series of complex physiological adaptations accompany changes in environmental pH (McGowan *et al.*, 2003; Merrell *et al.*, 2003). The urease enzyme, which catalyses the hydrolysis of urea to carbon dioxide and ammonium, provides *H. pylori* with its most important defence against gastric acidity. *Helicobacter pylori* urease accounts for up to 6% of total cellular proteins of the organism, and the generation of ammonia by ureolysis creates a neutral microenvironment around the bacterium that protects it from the acid pH of the stomach (Goodwin, Armstrong and Marshall, 1986). The relatively high affinity constant (K_m) of *H. pylori* for urea, coupled with its high rate of activity, means that the enzyme remains catalytically efficient despite the low intragastric concentration of urea (Dunn *et al.*, 1990). The urease apoenzyme of *H. pylori* is composed of a hexapolymeric structure consisting of the two structural subunits, UreA (26 kDa) and UreB (61 kDa) in a 1:1 molar ratio, to which are bound two nickel ions per monomer (Dunn *et al.*, 1990). As well as encoding the two structural subunits, the urease gene complex also encodes an acid-gated urea channel (UreI) and the accessory assembly proteins (UreE–H). The latter interact with the apoenzyme and incorporate nickel ions into the urease complex, ensuring that the enzyme remains catalytically active under conditions of low pH (Labigne, Cussac and Courcoux, 1991). Because nickel is an essential cofactor of urease activity, *H. pylori* has evolved many systems for the incorporation and storage of nickel ions within the bacterial cell, and the expression and activity of *H. pylori* urease are upregulated by increased availability of this cofactor through the regulatory protein NikR (van Vliet *et al.*, 2002). Urease is necessary for colonization of the gastric mucosa, and its essential role appears to extend beyond that of simple acid protection (Eaton and Krakowka, 1994). Other physiologically important functions of urease include the provision of a nitrogen source via production of ammonia, chemotactic motility and the promotion of nutrient release from the gastric mucosa through the induction of epithelial cell inflammation and apoptosis. Other systems also contribute to ammonia production in *H. pylori*, including an aliphatic amidase (Skouloubris, Labigne and DeReuse, 1997) and an arginase, which synthesizes urea from L-arginine,

providing an intracellular pool of substrate for the urease enzyme (McGee *et al.*, 1999).

The product of another member of the urease gene cluster, UreI, is an integral cytoplasmic membrane protein that is essential for survival of the *H. pylori* in an acid environment (Skouloubris *et al.*, 1998). UreI functions as a proton-gated transmembrane channel that regulates the passage of urea across the inner membrane into the cytoplasm (Weeks *et al.*, 2000). The UreI protein forms a membrane complex with the urease enzyme catalytic subunits (UreA/B), which facilitates rapid delivery and hydrolysis of urea to ammonia (Volland *et al.*, 2003). In acid conditions, the urea channel opens and, because of increased substrate delivery, cytoplasmic urease activity increases to produce more ammonia. Delivery of ammonia to the periplasmic space neutralizes the immediate environment of the bacterium and maintains the proton motive force across the inner cytoplasmic membrane due to the formation of ammonium ions. As the pH rises, UreI-mediated urea transport is switched off, resulting in the lowering of cytoplasmic urease activity, thereby preventing lethal alkalization of the cytoplasm owing to excess production of ammonia.

Adhesion

The ability to bind to epithelial surfaces is important for many bacterial pathogens that colonize mucosal surfaces. Once they escape the gastric fluid and penetrate the gastric mucus, most *H. pylori* remain within the mucus layer, but a certain proportion (~2%) are found in intimate contact with the surface of the underlying epithelial cells (Hessey *et al.*, 1990). Interaction of *H. pylori* with mucosal cells can be associated with the formation of adherence pedestals reminiscent of enteropathogenic *E. coli* (Dytoc *et al.*, 1993), and *H. pylori* adherence to gastric epithelial cells may result in several cellular events, including modulation of cell signalling cascades, rearrangement of the host cytoskeleton and cytokine release (Segal *et al.*, 1999).

Many specific adhesins and cognate host-cell receptors have been implicated in the association of *H. pylori* with the surface of gastric epithelial cells. The best-characterized adhesins of *H. pylori* are members of a superfamily of about 30 genes encoding putative *Helicobacter* outer membrane proteins (Hops). The blood group antigen-binding adhesin (BabA2) belongs to this superfamily of outer membrane proteins and binds to the fucosylated Lewis^b blood group antigen (Ilver *et al.*, 1998). Two other Hops, encoded by the *alpAB* (adherence-associated lipoprotein) gene locus, also mediate specific adherence of *H. pylori* to human gastric tissue, probably via a different receptor (Odenbreit *et al.*, 1999). High levels of sialylated glycoconjugates are associated with *H. pylori* infection, and the formation of sialyl-Lewis^x glycosphingolipids in the gastric epithelium is induced by *H. pylori* infection (Mahdavi *et al.*, 2002). By mediating binding to sialyl-Lewis^x antigens via the sialic acid-binding adhesin (SabA), *H. pylori* is able to exploit inflammation-activated domains of sialylated epithelium and complement baseline adhesion to other host receptors (Mahdavi *et al.*, 2002). This spectrum of adhesin–receptor interactions contributes to the chronicity of *H. pylori* infection and represents an adaptation to human genetic diversity and the host defences (Mahdavi *et al.*, 2002).

Resistance to Oxidative Stress

Helicobacter pylori has adapted to survive in an environment which is bathed in oxygen-derived free radicals generated from the bacterium's own metabolism and the inflammatory defences of the host. The ability of *H. pylori* to neutralize reactive oxygen species confers resistance against phagocytic killing (Ramarao, Gary-Owen and

Meyer, 2000) and is essential for long-term survival in the murine gastric mucosa (Harris *et al.*, 2003). *Helicobacter pylori* produces many detoxifying enzymes that protect against the effects of reactive oxygen species, including catalase, superoxide dismutase and alkyl hydroperoxide reductase. These antioxidant enzyme-encoding genes are upregulated in response to oxidative stress conditions, despite the fact that *H. pylori* lacks both the RpoS sigma factor and the oxidatively activated transcriptional regulators OxyR and SoxRS (Jenks, unpublished data). The *H. pylori* neutrophil-activating protein (NapA) was originally described as a promoter of neutrophil adhesion to endothelial cells (Yoshida *et al.*, 1993) and has significant homology to bacterioferritins and the *E. coli* DNA-binding protein from starved cells Dps (Evans *et al.*, 1995). The latter is a non-specific DNA-binding protein that is induced by stress conditions and protects DNA from oxidative damage by sequestering iron that may otherwise generate free radicals through the Fenton reaction. Evidence that NapA has a similar DNA-protective role in *H. pylori* is provided by the observation that *napA* mutants are more susceptible to oxidative stress and display increased oxidant-induced genomic DNA damage (Jenks, unpublished data). The fact that NapA is also able to induce inflammatory reactions and tissue damage suggests that it has evolved additional functions that contribute to the pathological process.

Induction of Pathological Changes

Despite being non-invasive, *H. pylori* is capable of inducing severe pathological changes in the gastric mucosa of the host. The generation of mucosal lesions by *H. pylori* is a result of a complex series of interactions between bacterial factors that cause direct or indirect tissue damage and the host response that is determined by genetic and environmental factors. Strains expressing high levels of vacuolating cytotoxin (VacA), the *cag* pathogenicity island and a functional BabA2 correlate with more severe disease (Covacci *et al.*, 1999). While the presence of these and other markers signals an increased predisposition to the development of severe pathology, many factors, particularly geographic variation in the genotype of dominant circulating strains, limit their value as indicators of pathogenic strains. Caution is therefore required in applying these disease associations in different human populations.

Vacuolating Cytotoxin

Helicobacter pylori secretes a VacA that induces the formation of vacuoles in the cytoplasm of eukaryotic cells (Figure 40.3) (Leunk *et al.*, 1988). Although the *vacA* gene is present in almost all strains of

H. pylori, isolates differ in vacuolating activity because of variability in the coding region of the signal sequence and the middle region of the *vacA* gene. Certain alleles of the signal sequence correlate with higher expression of active toxin, are associated with the greater gastric inflammation and are more commonly isolated from individuals with peptic ulcer disease (Atherton *et al.*, 1995). Mosaicism of the middle region determines targeting and internalization of the toxin but does not affect activity once the toxin enters the host-cell cytoplasm (Pagliaccia *et al.*, 1998). The precursor form of VacA has a molecular weight of 140 kDa and undergoes amino- and carboxy-terminal processing to yield a mature secreted toxin of approximately 87 kDa. Mature VacA contains amino- and carboxyl-terminal domains (p37 and p58, respectively), both of which are essential for toxin activity (Ye, Willhite and Blanke, 1999). Release of VacA from *H. pylori* occurs both by a specific secretion pathway and by budding of outer membrane vesicles, with the latter mechanism representing a potential alternative pathway for the delivery of other bacterial components to the gastric mucosa (Fiocca *et al.*, 1999). Once secreted, VacA monomers oligomerize into inactive rosettes comprising of 12 or 14 subunits (Cover *et al.*, 1994). Acidification enhances cytotoxic activity and results in the disruption of VacA oligomers into monomeric components that insert into lipid membranes to form hexameric, anion-conductive channels. These channels increase paracellular epithelial permeability to low-molecular-weight molecules, and this selective permeabilization may increase the supply of essential nutrients, including urea, therefore favouring growth *in vivo* (Papini *et al.*, 1998; Tombola *et al.*, 2001). VacA channels are actively endocytosed and result in the formation of vacuoles which are a hybrid between the lysosomal and late endosomal compartments of eukaryotic cells (Papini *et al.*, 1994). In a separate pathway distinct from vacuole formation, VacA is also capable of binding to receptor-type protein tyrosine phosphatase (Ptpz) which mediates multiple intracellular signalling pathways that regulate membrane trafficking, cytoskeletal rearrangements and cellular adhesion (Yahiro *et al.*, 1999). Alterations in the activity of Ptpz, and hence the rate of dephosphorylation of host-cell target proteins, may result in epithelial cell detachment from the underlying basement membrane, exposing the lamina propria to the damaging effects of gastric acid and leading to ulcer formation (Fujikawa *et al.*, 2003; Peek, 2003). Interaction of VacA with Ptpz may also interfere with signal transduction pathways known to be essential for cell proliferation and ulcer healing (Peek, 2003).

VacA has many other biological effects including alteration of tight-junction permeability and induction of gastric epithelial cell apoptosis. The toxin inhibits antigen presentation and processing within the gastric mucosa (Molinari *et al.*, 1998) and may also prevent phagosome maturation (Zheng and Jones, 2003), effects that would contribute to the evasion of the host immune response. Oral administration of mice with VacA leads to mucosal degeneration and epithelial cell injury (Telford *et al.*, 1994), and co-culture experiments have indicated that the toxin is important during the early stages of infection of the host (Salama *et al.*, 2001).

Cytotoxin-Associated Gene A and the *cag* Pathogenicity Island

Cytotoxin-associated gene A (CagA) was first described as an immunodominant antigen with a molecular mass of 120 kDa (Crabtree *et al.*, 1991) and was subsequently found to be expressed by most VacA-producing *H. pylori* strains (Covacci *et al.*, 1993). More recently, the multigenic locus upstream of *cagA* was found to have the typical features of a pathogenicity island (PAI) that has been acquired by *H. pylori* relatively recently in its evolution (Censini *et al.*, 1996). The *cag* PAI encodes a type IV secretion system, a syringe-like structure that serves to inject effector molecules into the host cell, allowing the bacterium to modulate certain aspects of the host cell's metabolism, including cytoskeletal rearrangements, host-cell morphological

Figure 40.3 Vacuolating cytotoxin-induced vacuolation of rabbit kidney epithelial (RK13) cells observed at $\times 50$ magnification. (A) Epithelial cells after the addition of liquid broth alone (negative control). (B) Epithelial cells after the addition of liquid broth culture supernatants of a VacA-producing strain of *H. pylori*, with examples of vacuolation indicated by arrows. These images were kindly provided by Darren Letley.

changes and expression of proto-oncogenes. Microscopic studies have recently confirmed the presence of sheathed, central hollow needle-shaped organelle at the surface of *H. pylori* (Rohde *et al.*, 2003) (Figure 40.4). A functional type IV secretion system translocates CagA directly into gastric epithelial cells (Segal *et al.*, 1999; Asahi *et al.*, 2000; Odenbreit *et al.*, 2000; Stein, Rappuoli and Covacci, 2000) where it localizes on the inner surface of the plasma membrane and is tyrosine phosphorylated by the Src family of protein tyrosine kinases (Selbach *et al.*, 2002; Stein *et al.*, 2002). CagA tyrosine phosphorylation sites (EPIYA motifs) are located in the C-terminal half of CagA, and the number of motifs determines the phosphorylation level of individual CagA molecules. Phosphorylated CagA then binds the Src homology 2-containing tyrosine phosphatase, SHP-2, and stimulates its phosphatase activity, resulting in the dephosphorylation of various host-cell proteins (Puls, Fischer and Haas, 2002). SHP-2 phosphatase plays an important role in the regulation of intracellular signal transduction, stimulating mitogenic signalling and mediating the adhesion, migration and division of cells through actin reorganization (reviewed in Hatakeyama, 2003). By stimulating SHP-2, CagA may deregulate cell growth and induce proliferation of gastric epithelial cells, ultimately leading to malignant transformation (Hatakeyama, 2003). Polymorphism in the number of CagA tyrosine phosphorylation sites may determine the biological activity of CagA and the associated risk of gastric carcinoma, since proteins with more EPIYA motifs undergo greater tyrosine phosphorylation, exhibit increased SHP-2 binding and induce greater phenotypic changes on host cells (Higashi *et al.*, 2002).

A further important function of the *cag* PAI is the induction of proinflammatory chemokines such as interleukin-8 (IL-8), Rantes and epithelial neutrophil-activating peptide 78 ENA-78, from gastric epithelial cells via the stress kinase pathway (Naumann *et al.*, 1999). Chemokine induction occurs independently of CagA translocation, and distinct genes of the *cag* PAI are essential for these two processes (Fischer *et al.*, 2001). The host cellular responses that lead to the activation of immunomodulatory chemokines may result from direct activation of the stress kinase pathway by the type IV system itself (Foryst-Ludwig and Naumann, 2000) or by type IV apparatus-mediated translocation of other bacterial effector molecules, such as peptidoglycan, into the host cell (Viala *et al.*, 2003). The significance of the potential for interplay between *cag* PAI-mediated activation of gastric epithelial cell kinases and blockade of related cell signalling pathways by VacA is currently unknown. However, it appears that different bacterial factors modify the intensity of the host inflammatory immune response, therefore contributing to the persistence of *H. pylori* and the degree of induced mucosal damage.

Figure 40.4 Structure of the *H. pylori* *cag* type IV secretion system. (A) Surface filamentous structures of *H. pylori* are induced after contact with gastric epithelial (AGS) cells. (B) Immunogold labelling of surface-exposed needle-shaped organelle at the surface of the bacterium. The asterisk indicates the central, hollow structure. These images were kindly provided by Manfred Rohde and Rainer Haas.

Lipopolysaccharide

Helicobacter pylori lipopolysaccharide (LPS) contains various modifications that allow the bacterium to moderate the degree of inflammation induced and which may contribute to its persistence in the gastric mucosa and disease causation. The LPS of *H. pylori* has lower biological activity and immunogenicity than the LPS of Enterobacteriaceae (Muotiala *et al.*, 1992). The glycoprotein moiety of *H. pylori* LPS O-side chains contains antigenic domains identical to the mono- and di-fucosylated Lewis^x and Lewis^y and also H-type 1 blood group antigens that are also expressed at the surface of gastric parietal cells, in mucin and by the gastric H⁺K⁺-ATPase. Most strains of *H. pylori* produce either Lewis^x or Lewis^y, but certain strains express both these carbohydrate antigens (Monteiro *et al.*, 1998). Antigenic mimicry between *H. pylori* LPS and human gastric epithelial cell surface glycoforms may result in immune tolerance against *H. pylori* antigens via downregulation of the T helper (Th) type 1 response. In chronic infection, immune cross-reactivity may ultimately result in the induction of autoantibodies that recognize mucosal epitopes and contribute to the development of chronic active gastritis (Negrini *et al.*, 1991; Appelmelk *et al.*, 1996). Lewis antigen expression is not a stable trait, and LPS displays a high frequency of phase variation which is mediated by length alteration of homopolymeric tracts by slipped-strand mispairing (Appelmelk *et al.*, 1998). This increased heterogeneity of *H. pylori* is another factor in allowing adaptation to microenvironmental changes and evasion of the immune response.

Other biological properties attributed to *H. pylori* LPS include the inhibition of glycosylation and sulphation of gastric mucus, which may impede its protective function and increase the vulnerability of the epithelial surface to gastric acidity (Moran, 1996). The LPS of certain *H. pylori* strains has also been shown to induce secretion of pepsinogen, and the increased proteolytic activity of pepsin may be implicated in *H. pylori*-induced mucosal damage (Young *et al.*, 1992).

DIAGNOSIS OF *H. PYLORI*

Diagnosis of *H. pylori* infection may be established by many invasive and non-invasive techniques. Culture of the organism from multiple endoscopic gastric mucosal biopsies taken from the antrum and corpus is the most specific method and offers the distinct advantage of allowing further investigations, such as susceptibility testing and typing, to be performed. Definitive identification of the organism relies on the typical 'seagull' morphology of the Gram film and positive oxidase, catalase and rapid urease tests. Histological examination of at least two biopsies is as sensitive as culture for the detection of *H. pylori* and is also relatively specific. Stains for the recognition of the organism include Warthin–Starry, Giemsa and Creosyl violet, and sensitivity can be improved by the use of immunostaining with an anti-*H. pylori* antibody. The biopsy urease test detects the presence of urease activity in gastric biopsies by using a broth that contains urea and a pH indicator. This test is frequently performed in the endoscopy suite and is rapid, sensitive and cheap. The polymerase chain reaction (PCR) has been used for the detection of *H. pylori* in various samples but has not been widely adopted for routine diagnostic use.

Non-invasive methods include the urea breath test, which is semi-quantitative and is frequently used to check eradication after treatment. The urea breath test is based on the release of carbon dioxide from urea by the highly active urease enzyme. Urea labelled with either radioactive ¹⁴C or non-radioactive ¹³C is given as a test meal, and the labelled carbon dioxide is exhaled and detected by scintillation counting or mass spectroscopy. Laboratory testing for serum IgG by enzyme-linked immunoadsorbent assay is frequently used for screening for *H. pylori* infection. Other non-invasive tests include the detection of antibody in saliva, which is less sensitive than serum testing, and *H. pylori* faecal antigen detection by enzyme immunoassay

(EIA), which is easy to perform and may be particularly useful in the screening of children.

Susceptibility Testing

Until recently, methods of susceptibility testing of *H. pylori* suffered from a lack of consistency and conflicting results were frequently found when different techniques were compared. This combined with cost implications and the convenience of non-culture-based diagnostic tests means that laboratory susceptibility testing is rarely performed before empirical therapy is commenced. The recent trend towards standardization of testing is designed to improve agreement in reporting and should mean that culture and susceptibility testing of *H. pylori* can be performed in most hospital laboratories. Agar dilution is generally regarded as the gold standard method of susceptibility testing for *H. pylori* and is highly reproducible, but laborious and time-consuming (National Committee for Clinical Laboratory Standards, 1999). The epsilometer (E-test) is frequently used since it is easier to perform and has good reproducibility (Cederbrant, Kahlmeter and Ljungh, 1993). Disk diffusion has been shown to be reliable in *H. pylori* when test methods are well controlled and, as with the E-test, allows visualization of resistant subpopulations within the zone of inhibition. When performed appropriately, there is a good correlation with all methods for the testing of clarithromycin, tetracycline and amoxicillin, and disk testing would appear an adequate choice for these agents. Testing for metronidazole susceptibility is more difficult since the distribution of MICs is continuous, resistant subpopulations are frequently present and results are more easily affected by test conditions. Although the E-test is usually recommended, even this method may overestimate resistance (Mégraud *et al.*, 1999), and more than one testing method may be appropriate, particularly for strains close to the breakpoint. Continued refinement of protocols and participation in quality control schemes is important for improving the reproducibility of testing and will allow the implementation of community surveillance, both to monitor the prevalence of resistant strains and to guide empirical treatment based on local resistance patterns. Basing individual therapy on pretreatment laboratory susceptibility data significantly improves the eradication rate (Toracchio *et al.*, 2000). As the proportion of patients colonized with resistant strains continues to rise, routine susceptibility testing would allow a more rational approach to antibiotic selection, extending the useful life of these agents for the treatment of not only *H. pylori* but other infections as well.

A rapid and useful alternative to conventional susceptibility testing is to use molecular methods to detect resistance markers, permitting resistance testing without the need for culture. Because resistance to metronidazole is associated with multiple changes within *rdxA* and possibly other reductase-encoding genes, it has not been possible to develop simple molecular assays capable of detecting nitroimidazole resistance in *H. pylori*. Although many genotype-based methods, usually based on PCR, have been developed to identify the limited number of point mutations that cause macrolide resistance, these are yet to be widely adopted by routine diagnostic microbiology laboratories.

TREATMENT OF *H. PYLORI*

Eradication of *H. pylori* from the gastric and duodenal mucosa of infected patients is the most important goal in the management of peptic ulcer disease and other *H. pylori*-associated conditions (Jenks, 2002). Although the bacterium appears susceptible to many antibiotics *in vitro*, relatively few are effective in clinical practice. This is partly because certain antibiotics are unable to achieve therapeutic concentration in the gastric mucosa, and the slow rate of growth and metabolism of the organism also contribute to this relative

in vivo resistance. *Helicobacter pylori* is therefore difficult to eradicate, and effective treatment requires multidrug regimens, consisting of two antibiotics (usually selected from clarithromycin, metronidazole, amoxicillin and tetracycline), combined with acid suppressants and/or bismuth compounds (Malfertheiner *et al.*, 2002). Although several controlled clinical trials have shown that current first-line regimens are effective in most patients, a significant proportion fail therapy in clinical trials and success rates are frequently as low as 70% in everyday clinical practice. Several factors adversely affect treatment outcome, including advanced age, smoking, high pretreatment intra-gastric bacterial load, bacterial genotype, poor patient compliance due to the high incidence of side effects associated with multidrug regimens and host genetic polymorphisms of the cytochrome P450 isoenzymes that are specifically involved in the metabolism of proton-pump inhibitors. However, as happens for many infectious diseases, resistance to the antibiotic component of the regimen is the most important cause of treatment failure, and increased use of antibiotics has resulted in a significant rise in both the prevalence of resistance and multi-resistant strains. Although resistance to amoxicillin and tetracycline remains relatively rare, 10–50% of clinical strains isolated in western Europe are resistant to metronidazole and up to 20% are resistant to clarithromycin (Mégraud, 1998). Resistance to either the macrolide or amoxicillin component of a regimen correlates closely with reduced therapeutic efficacy. Although there have been conflicting reports concerning the clinical impact of imidazole resistance in *H. pylori*, recent meta-analyses have demonstrated that resistance to this class of antibiotics is also an important predictor of treatment failure (Houben *et al.*, 1999; Van der Wouden *et al.*, 1999). How to respond to the worldwide increase in the prevalence of antibiotic resistance is the most important challenge facing the clinical management of patients with *H. pylori* infection. The solution will involve safeguarding the already limited number of treatment options as well as identifying novel molecular targets with potential for therapeutic intervention.

Resistance to Antimicrobial Agents

The antimicrobial toxicity of metronidazole is dependent on reduction of its nitro moiety to the nitro anion radical and other DNA-damaging compounds, including nitroso and hydroxylamine derivatives. In the vast majority of *H. pylori* strains, resistance to metronidazole is associated with mutational inactivation of the *rdxA* gene, which encodes an oxygen-insensitive NADPH nitroreductase involved in the reductive activation of metronidazole (Goodwin *et al.*, 1998; Jenks, Ferrero and Labigne, 1999). Other reductase-encoding genes, including *frxA* (which encodes NADPH flavin oxidoreductase) and *fdxB* (which encodes ferredoxin-like protein), are occasionally associated with resistance to metronidazole (Jeong *et al.*, 2000; Kwon *et al.*, 2000). Although resistance has been reported to be associated with inactivation of *frxA* alone, the most important role of these genes is to mediate the transition to high-level resistance once inactivation of the *rdxA* gene has occurred (Jeong *et al.*, 2000).

Most clarithromycin-resistant *H. pylori* strains emerge after spontaneous mutation of the 23S rRNA gene and selection of mutants after exposure to the drug (Versalovic *et al.*, 1996). Stable amoxicillin resistance in *H. pylori* is not mediated through β -lactamase production but results from point mutations within the *penicillin-binding protein (PBP) 1A* gene (Gerrits *et al.*, 2002). Nonstable amoxicillin resistance, which is also associated with a marked reduction in treatment efficacy, is probably due to a decreased expression of the penicillin-binding protein PBP 4 (Dore, Graham and Sepulveda, 1999). The small number of tetracycline-resistant *H. pylori* strains that have been studied contain a mutation within the 16S rRNA gene that alters the affinity of the ribosome for the antibiotic (Trieber and Taylor, 2002). Although an initial analysis of membrane-associated systems suggested that active efflux does not play a role in the intrinsic resistance of *H. pylori* (Bina *et al.*, 2000), recent studies have suggested that

altered membrane permeability contributes to resistance to both β -lactams and tetracycline (Dailidienė *et al.*, 2002; Kwon *et al.*, 2003).

PREVENTION AND ERADICATION OF *H. PYLORI* BY VACCINES

Currently recommended *H. pylori* eradication therapies are relatively expensive, and the impact of antibiotic resistance is likely to further reduce the efficacy of currently available regimens. Although novel antimicrobial agents may facilitate treatment in the future, only a vaccine will have a global impact on the prevalence of *H. pylori* infection and, hence, on *H. pylori*-associated morbidity and mortality (Suerbaum and Josenhans, 1999). Evaluation of the cost-effectiveness of vaccination against *H. pylori* in developed countries found that it had the potential to deliver the highest health benefit of all vaccines tested and could significantly reduce health care expenditure (Rupnow *et al.*, 1999). Although the implementation of public health measures might prove more effective in developing countries (Rupnow *et al.*, 1999), the introduction of a vaccine in those regions with the highest disease burden would represent a major advance in the management of *H. pylori* infection.

Helicobacter pylori has developed a spectrum of strategies to resist host defence mechanisms and establish persistent gastric infection. By modulating cytokine production, *H. pylori* is able to bias Th cell differentiation, resulting in an ineffective immune response that contributes to both persistence and gastric disease processes (reviewed in Zevering, Jacob and Meyer, 1999). Although the mechanisms of immune subversion are unclear, it is known that protection can occur in a strictly Th1-dependent fashion and that the immunosuppressive cytokine IL-10 downregulates protective host responses and facilitates persistent colonization (Figure 40.5). It is attractive to envisage an immune-based strategy that would programme the natural tendency of *H. pylori* to subvert the host response and establish a persistent infection, to one that elicits a protective response resulting in eradication.

Experiments using animal models of infection and a variety of *H. pylori* antigens have demonstrated the feasibility of developing both prophylactic and therapeutic vaccines against *H. pylori* infection. These have included the urease holoenzyme and its subunits, the HspB (GroEL) and HspA (GroES) heat shock proteins, purified VacA cytotoxin, CagA, NapA and catalase (reviewed in Suerbaum and Josenhans, 1999). The observation that these antigens may serve as effective vaccines against *H. pylori*, despite being located within the cytoplasm, appears to be explained by their adsorption onto the cell surface during bacterial lysis (Phadnis *et al.*, 1996). Unfortunately, in

human clinical trials, these antigens either have not been successful in preventing infection or have failed to induce sterilizing immunity (reviewed in Prinz, Hafsi and Volland, 2003). Homology searches of the complete genome sequence of *H. pylori* and the application of techniques that allow genome-wide screening for immunogenic proteins may facilitate the identification of novel antigens for inclusion in prophylactic and/or therapeutic subunit vaccines against *H. pylori*. Ultimately, improved results are dependent on an improved understanding of the host immune response to infection as well as the use of multiple protective antigens, modification of the route and mode of administration and development of less toxic and more potent adjuvants.

Campylobacter and *Arcobacter* spp.

Diane E. Taylor¹ and Monika Keelan²

¹Department of Medical Microbiology and Immunology; and ²Department of Laboratory Medicine & Pathology, Division of Medical Laboratory Science, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

The epsilon subdivision of Proteobacteria includes the family Campylobacteraceae, which is comprised of genera *Campylobacter*, *Arcobacter* and, more recently, genus *Sulfurospirillum*, as well as the generically misclassified *Bacteroides ureolyticus* (Vandamme, 2000). The complex taxonomy of Gram-negative spiral-shaped bacteria is continuously evolving with new information acquired from phylogenetic studies (Dekeyser *et al.*, 1972; Butzler *et al.*, 1973; Skirrow, 1977; Vandamme and De Ley, 1991; Trust *et al.*, 1994; Ursing, Lior and Owen, 1994; On, 1996; Vandamme *et al.*, 1997). Genus *Sulfurospirillum* are free-living *Campylobacter*-like organisms that reduce sulfur and are isolated from mud, and *Bacteroides ureolyticus* are non-motile rods that resemble *Campylobacter* that have been isolated from soft-tissue ulcers, periodontal disease and urethritis (Vandamme, 2000). These newer additions to the Campylobacteraceae family are not discussed in detail in this chapter.

Taxonomic issues resolved through studies that exploit DNA–rRNA hybridization, DNA–DNA hybridization and 16S rRNA sequencing concluded that the genus *Helicobacter* is too unrelated to *Campylobacter* and *Arcobacter* to group them together (Romaniuk *et al.*, 1987; Vandamme *et al.*, 1991). Identification methods for Campylobacteria have been extensively reviewed (On, 1996). Quantitative DNA–DNA hybridization demonstrated that the proposed species *C. hyoilei* actually represents additional strains of *C. coli*; therefore its usage is to be discouraged in favour of *C. coli* (Vandamme *et al.*, 1997; Vandamme and On, 2001). Phenotypic characteristics also provide support for differentiation of bacterial species (Thompson *et al.*, 1988; Vandamme *et al.*, 1991, 1992b), although identification of Campylobacteraceae is problematic due to the relative biochemical inactivity and fastidious growth requirements (On, 1996, 2001). *Campylobacter sputorum* is emended to include three biovars, *sputorum*, *fecalis* and *paraureolyticus*, with previously defined biovar *bubulus* now considered to be biovar *sputorum* (On, Atabay and Corry, 1999; Vandamme and On, 2001). Extensive 16S rRNA gene sequence diversity in *C. hyointestinalis* confirms the taxonomic position of the two different subspecies previously described – *C. hyointestinalis* subsp. *hyointestinalis* and *C. hyointestinalis* subsp. *lawsonii* (On and Holmes, 1995; Harrington and On, 1999). Two new *Campylobacter* spp. isolated from humans have also been characterized: *C. lanienae* sp. nov. and *C. hominus* sp. nov. (Logan *et al.*, 2000; Lawson *et al.*, 2001).

Values of less than 97.0% 16S rRNA similarity between two organisms suggest they represent distinct species (Stackebrandt and Goebel, 1994). As an alternative to 16S rRNA gene sequencing, the *recA* gene and restriction fragment length polymorphism (RFLP) analysis of the 23S rRNA gene may possibly resolve conflicts in highly divergent 16S rRNA genes of certain species (On, 2000).

DNA–DNA hybridization is generally accepted to be superior to 16S rRNA phylogenetic analysis for establishing relationships between closely related taxa (Stackebrandt and Goebel, 1994). A bacterial species is defined as a group of strains (including the type strain) sharing 70% or greater DNA–DNA relatedness with 5C or less ΔT_m (Wayne *et al.*, 1987). Amplified fragment length polymorphisms (AFLP) analysis is a high-resolution, whole-genome fingerprinting method that is able to concurrently identify taxonomic and epidemiological relationships among *Campylobacter* species (On and Harrington, 2000). A polyphasic taxonomic approach that examines the overall phenotypic, ecologic and genotypic consistencies is considered to be essential for the accurate classification and identification of bacteria within *Proteobacteria* (Stackebrandt and Goebel, 1994; Vandamme *et al.*, 1996; Harrington and On, 1999).

The species of genera *Campylobacter* and *Arcobacter* are remarkably diverse in their natural habitats and ability to produce disease. Habitats include the human oral cavity, human and/or animal intestinal tracts, the genital tracts of cattle and the sediments in salt marshes. Diseases include diarrhoea, bacteremia, septic abortion, infertility and possibly diseases of the oral cavity. The procedures for isolation and culture vary considerably with the species with respect to temperature, atmospheric conditions and media composition. Unfortunately, the phenotypic characteristics of Campylobacteria do not reflect their diversity, making it difficult to readily differentiate the genera and species. These identification and classification problems remain a challenge for the clinical laboratory.

PROPERTIES OF THE FAMILY CAMPYLOBACTERACEAE

Detection and identification of *Campylobacter* and *Arcobacter* species is a challenging task due to cross-species similarities in phenotype and general biochemical unreactivity. Most species are curved, S-shaped or spiral Gram-negative rods. Four species (*C. showae*, *C. rectus*, *C. gracilis* and *C. hominus* sp. nov.) produce only straight rods. Campylobacteria may stain poorly with Gram counterstains other than carbol or basic fuchsin. The cells vary in length from 0.5 to 5 μm and in width from 0.2 to 0.8 μm . With the exception of *C. gracilis* and *C. hominus* sp. nov. which are non-motile, most of the species have a darting type of motility produced by the action of unsheathed flagella. There may be a single polar flagellum or bipolar flagella in all species except *C. showae*, which has a cluster of two to five flagella at one end. Spores are not produced but spherical coccid forms have been observed in some species in older cultures or under unfavourable growth conditions. A characteristic common to all Campylobacteraceae is their ability to grow under microaerobic conditions, although some also grow

under aerobic or anaerobic conditions. Growth is optimal between 30 and 37 °C. None of the species ferment or oxidize carbohydrates and all species utilize organic amino acids or tricarboxylic acid intermediates as sources of carbon. The DNA base ratio ranges between 27 and 47%. All species of the family except *A. nitrofigilis* are either commensal or pathogens of humans or animals. *Arcobacter nitrofigilis* is unique in the family in its ability to fix nitrogen and in its association with the roots of halophytic plants. A list of the species is provided in Table 41.1.

The Genus *Campylobacter*

Although the bacteria of the genus *Campylobacter* are the most common bacterial cause of enteritis worldwide, they are largely unfamiliar to the general public although their importance to human health is as great, or greater, than the well-known *Salmonella*, *Shigella* and verotoxin-producing *Escherichia coli*. *Campylobacter* first identified with human illness were referred to 'related vibrios' to distinguish them from species of *Vibrio*, e.g. *Vibrio cholerae* (King, 1957, 1962). A convincing association of these organisms with human diarrhoea was demonstrated a decade later (Dekeyser *et al.*, 1972; Butzler *et al.*, 1973). Their significance to human health, however, was not established until a medium was designed for routine isolation of the organisms (Skirrow, 1977).

Table 41.1 Classification of Campylobacteraceae

Genus <i>Campylobacter</i>
Group 1. Thermophilic enteropathogenic species
<i>C. jejuni</i> subsp. <i>jejuni</i>
<i>C. jejuni</i> subsp. <i>doylei</i>
<i>C. coli</i> ^a
<i>C. lari</i>
<i>C. upsaliensis</i>
<i>C. helveticus</i>
Group 2. Animal pathogens and commensals that may infect humans
<i>C. fetus</i> subsp. <i>fetus</i>
<i>C. fetus</i> subsp. <i>venerealis</i>
<i>C. hyointestinalis</i> subsp. <i>hyointestinalis</i>
<i>C. hyointestinalis</i> subsp. <i>lawsonii</i>
<i>C. sputorum</i> biovar <i>sputorum</i> ^b
<i>C. sputorum</i> biovar <i>faecalis</i>
<i>C. sputorum</i> biovar <i>paraureolyticus</i>
<i>C. mucosalis</i>
<i>C. lanienae</i> sp. nov.
Group 3. Species associated with periodontal disease
<i>C. concisus</i>
<i>C. curvus</i>
<i>C. rectus</i>
<i>C. showae</i>
<i>C. gracilis</i>
<i>C. hominus</i> sp. nov.
Genus <i>Arcobacter</i>
<i>A. nitrofigilis</i>
<i>A. cryaerophilus</i>
<i>A. butzleri</i>
<i>A. skirrowii</i>
Genus <i>Sulfurospirillum</i>
<i>S. arcachonense</i>
<i>S. arsenophilum</i>
<i>S. barnesii</i>
<i>S. deleyianum</i>
[<i>Bacteroides</i>] <i>ureolyticus</i>

The type species of genus *Campylobacter* and genus *Arcobacter* are *C. fetus* subsp. *fetus* and *A. nitrofigilis*.

^a *C. hyoilei* is synonymous with *C. coli*, but its name usage is discouraged.

^b *C. sputorum* biovar *sputorum* incorporates biovar *bubulus*.

Campylobacteraceae can be conveniently separated into three groups on the basis of phenotypic characteristics (Table 41.1). The first and most important group to human health consists of five thermophilic enteropathogenic species. In this group are *C. jejuni* with two subspecies, *C. coli*, *C. lari*, *C. upsaliensis* and *C. helveticus*. A second group includes four species well known to veterinary microbiologists because of their frequent occurrence as pathogens or commensals in farm livestock, although some species have been shown to be pathogenic for humans. Included are *C. fetus* with two subspecies, *C. hyointestinalis* with two subspecies, *C. sputorum* with three biovars and *C. mucosalis*. A third group, found in human periodontal disease, consists of *C. concisus*, *C. curvus*, *C. rectus*, *C. showae* and *C. gracilis*. Two new species, *C. lanienae* sp. nov. and *C. hominus* sp. nov., have been grouped according to their similarity with other *Campylobacter* species.

Genetics and Pathogenicity

Several molecular methods have been specifically designed for use with *Campylobacter*. DNA has been successfully introduced into *C. jejuni* subsp. *jejuni* by natural transformation, electrotransformation or conjugation (Taylor, 1992a). However, not all strains appeared to be competent and plasmid DNA transformed with low frequency regardless of the technique, although conjugation is fairly efficient. Many chromosomal genes have been stably expressed in *E. coli*, including amino acid biosynthesis genes, ribosomal RNA genes and transfer RNA genes. One of the genes (*flbA*) involved in flagellar biogenesis in *C. jejuni* subsp. *jejuni* was cloned, although expression in *E. coli* was not detected (Miller, Pesci and Pickett, 1993). All of these genes are general housekeeping genes and appear to be highly conserved across species boundaries. Several shuttle vector series are available for *Campylobacter* genes and may be used for cloning, expression systems, sequence analysis and for site-specific mutagenesis (Taylor, 1992a; Yao *et al.*, 1993). These vectors were not functional for genes from *C. hyointestinalis* and hence a separate vector has been developed (Waterman, Hackett and Manning, 1993).

Since *C. jejuni* subsp. *jejuni* genome has been sequenced (Parkhill *et al.*, 2000), it has become possible to decipher some of the functions of the bacteria by examining the content and expression of the genome (Dorrell *et al.*, 2001). At least 21% of genes in the NCTC11168 appear to be dispensable as they are absent or highly divergent. A total of 1300 *C. jejuni* core genes present are associated with metabolic, biosynthetic, cellular and regulatory processes, as well as many virulence determinants. All of these genes are general housekeeping genes and appear to be highly conserved across species boundaries. Most recently, comparative genome analysis of 18 *C. jejuni* from different sources using whole-genome DNA microarrays has revealed that 16.3% of the genes present in the sequenced strain, NCTC11168, were either absent or highly variable in sequence (Pearson *et al.*, 2003). Seven clusters of variable sequences comprising 50% of the variable gene pool were found, suggesting these clusters were lost or acquired as a group during evolution. These clusters differ from variable gene clusters in islands and pathogenicity islands because their G+C content is not different from the genome and not associated with mobile elements for DNA transfer. PR1 contains genes utilized in alternative electron transfer, which may play a role in oxygen-restricted environments. Three of the gene clusters (PR4, 5 and 6) are involved with the production of surface structures (lipooligosaccharides, flagella and capsule) and may be important in the avoidance of innate and adaptive immune responses in the host. The remaining clusters contain proteins of the outer and periplasmic membranes which may play a role in *Campylobacter* adaptation to different ecological niches.

The factors determining the clinical outcome of infection with *C. jejuni* are likely dependent upon the infecting strain as well as on

the susceptibility of the host. Colonization of human intestine with *C. jejuni* results in the expression of several putative virulence factors, yet the mechanisms of pathogenesis are unclear (Van Vliet and Ketley, 2001). Colonization may be influenced by the expression of lipopolysaccharides (LPS) on the bacterial cell surface. A mutation in the *galE* gene involved in the synthesis of LPS reduced the ability of *C. jejuni* to adhere and invade INT 407 cells, suggesting that LPS is a virulence factor for *C. jejuni* infection, although the *C. jejuni* was still able to colonize chickens (Fry *et al.*, 2000). Flagella are an important determinant in virulence since colonization of intestinal tracts does not occur with non-motile mutants of *C. jejuni* (Wassenaar, Fry and van der Zeijst, 1995). Internalization of *C. jejuni* into mammalian cells requires the secretion of invasion proteins (Konkel *et al.*, 1999). *Campylobacter jejuni* also produces cytolethal distending toxin which interferes with the cell cycle (Whitehouse *et al.*, 1998). Porins may affect the ability of *Campylobacter* to survive transmission from animals to humans (Bacon, Johnson and Rodgers, 1999; Dedieu, Pages and Bolla, 2002). The presence of plasmids in *C. jejuni* may play an important role in the pathogenesis associated with infection. A transmissible plasmid encodes resistance to tetracycline via the Tet(O) determinant in *C. jejuni* (Taylor *et al.*, 1981; Connell *et al.*, 2003). Another plasmid, pVir, isolated from *C. jejuni* 81–176 (Bacon *et al.*, 2000, 2002), encodes proteins with homology to components of a type IV secretion system (including *virB11*) associated with virulence in other bacterial pathogens (Christie, 2001). Two recent reports also cite the presence of *virB11* in human and animal isolates of *C. jejuni* (Bang *et al.*, 2003; Datta, Niwa and Itoh, 2003). The pVir plasmid enhances the ability of *C. jejuni* 81–176 to adhere and invade intestinal epithelial cells in culture (Bacon *et al.*, 2002). Continued study on the prevalence of putative virulence genes will provide insight into the adaptability of *Campylobacter* species and their association with the development of disease (Bang *et al.*, 2003; Datta, Niwa and Itoh, 2003).

Flagellar Genes and Phase Variation

Several attempts have been made to clone toxin genes as well as membrane proteins from *C. jejuni* subsp. *jejuni*, but none of these efforts has resulted in stable, entire clones (Calva *et al.*, 1989; Taylor, 1992a). The flagella biosynthesize genes that have been cloned from *C. jejuni* subsp. *jejuni*; however, no expression of gene products in *E. coli* has ever been detected. Both *C. jejuni* subsp. *jejuni* and *C. coli* produce two flagellin genes, *flaA* and *flaB*, which have strong sequence homology but differ in their regulatory mechanisms (Guerry *et al.*, 1992; Taylor, 1992a). Although both protein products are present in the flagella, mutations in the *flaA* gene induce the synthesis of truncated flagella, which results in only partial motility, whereas *flaB* mutations do not alter the length of the flagella or the motility of the cell. Recombination of the flagellin gene locus and horizontal gene transfer have been demonstrated and may provide a mechanism by which the bacteria evades the immune response or adapts to its environment (Wassenaar, Fry and van der Zeijst, 1995). Phase variation in *Campylobacter* spp. occurs relatively frequently *in vitro* and the transition from aflagellate to flagellate has also been observed *in vivo* by passage through the rabbit intestine (Caldwell *et al.*, 1985). The genetic mechanism for this is unknown but may involve turning off or on of the expression of the *flaA* gene. *Campylobacter* spp. are also able to reversibly express flagella of different antigenic specificities and, at least in some cases, this corresponds to the production of multiple flagellins and to a DNA rearrangement (Guerry *et al.*, 1992). A recombination event within the hypervariable sequences in the internal region of the *fla* gene may account for this rearrangement, but the exact mechanism is unknown.

Surface Proteins

Virulence-related surface layer proteins (S proteins) from *C. fetus* have been cloned (*sapA* genes) and will express in *E. coli* (Blaser and Gotschlich, 1990). It was shown that wildtype and S mutants possessed several *sapA* homologues but that only the mutants lacked expression sequences (Tummuru and Blaser, 1993). Comparison of *sapA* sequences from a pair of variant strains suggested that antigenic variation had occurred as a result of site-specific recombination of unique coding regions. The occurrence of Guillain–Barré syndrome following infection with *C. jejuni* (in particular serotype 0:19) has provoked much interest. It has been found that lipopolysaccharides extracted from *C. jejuni* have core oligosaccharides with terminal structures resembling human gangliosides (Aspinall *et al.*, 1994). Genes involved in LPS biosynthesis have been cloned (Klena, Gray and Konkel, 1998; Wood *et al.*, 1999). Both O- and N-glycosylation pathways are present in *Campylobacter*, which will facilitate the study of glycoprotein synthesis and the role of these molecules in pathogenesis (Szymanski *et al.*, 2003). A functional N-glycosylation pathway has recently been transferred from *C. jejuni* to *E. coli* (Wacker *et al.*, 2003). Alterations in protein glycosylation in *C. jejuni* may affect the immunogenicity of the proteins (Young *et al.*, 2002). *Campylobacter hyolei* (*coli*) LOS have been expressed in *E. coli* (Korolik *et al.*, 1997). Phase variation of lipooligosaccharide may also affect invasiveness of *C. jejuni* through alterations in the biosynthesis of the ganglioside GM1-like LOS structure (Linton *et al.*, 2000; Gilbert *et al.*, 2002; Guerry *et al.*, 2002).

Difficulties that have been experienced during the cloning of *Campylobacter* genes are numerous and have included both the failure to express the gene in *E. coli* and the instability of the genes in this host. The possible reasons for this may include differences in methylation between species, differences in promoter sequences used, the high A–T content of *Campylobacter* DNA and/or the lack of accessory proteins that might enable expression. As well, *C. hyointestinalis* was shown to have a restriction barrier against DNA from other *Campylobacter* spp. (Waterman, Hackett and Manning, 1993).

Campylobacter jejuni is a highly plastic organism as demonstrated by the number of hypervariable regions in the genome (Pearson *et al.*, 2003). These regions may be involved in the colonization of *C. jejuni* in animals and in lateral gene transfer among strains, which may have implications regarding the epidemiology of *C. jejuni* human infections. Increased understanding of the host–pathogen interaction is mediated by the identification of a unique protein glycosylation system and plasmid-encoded components of a type IV secretion system (Linton *et al.*, 2000).

Thermophilic Enteropathogenic Campylobacteria: Clinical Significance, Occurrence and Epidemiology

Thermophilic enteropathogenic species, with few exceptions, are isolated from the intestinal tracts of humans and/or animals at 42–43 °C. *Campylobacter jejuni* subsp. *jejuni* is recognized as the most important cause of *Campylobacter* enteritis (campylobacteriosis) in humans occurring in 89–93% of the cases. *Campylobacter coli* is most closely related to *C. jejuni* and is the cause of 7–10% of the human cases, while *C. lari* is the cause of only 0.1–0.2% (Healing, Greenwood and Pearson, 1992). The frequency of infections in the human population due to these three species is difficult to estimate precisely, but incidences ranging from 6 to 7 per 100 000 to 87 per 100 000 have been reported in the USA and the UK (Skirrow and Blaser, 1992). Most infections are due to sporadic cases: exposure to raw meat, a pet with diarrhoea and drinking untreated water, family outbreaks and larger community outbreaks arising from contaminated food, water or unpasteurized milk (Adak *et al.*, 1995; Sopwith *et al.*, 2003). It has also been implicated in travellers' diarrhoea. In developing countries it is the paediatric population in which the largest number of cases

occur. Incidences as high as 40 000 per 100 000 have been reported and most of these occur in children 2 years old or younger. The adult population in the underdeveloped world is much less affected, presumably owing to the development of immunity during childhood exposure. Isolates of these three thermophilic species are rarely recovered from healthy humans in developed countries, but they can be obtained almost as frequently from healthy children as from children with diarrhoea in underdeveloped countries (Taylor, 1992b).

The campylobacteriosis produced in humans by these three thermophilic species varies from a mild short-term diarrhoea of 2 days to a severe form that may last a week or longer. The diarrhoea is watery and may contain blood. Vomiting only occurs in a small percentage of cases. The diarrhoea may be accompanied by severe pain, leading to suspicions of acute appendicitis, cholecystitis or peritonitis. Complications are infrequent but include septicaemia, reactive arthritis, Guillain-Barré syndrome, erythema nodosum and meningitis.

C. jejuni subsp. *jejuni*

In addition to its role as a major cause of human enteritis, *C. jejuni* subsp. *jejuni* also causes diarrhoea in cattle and has been isolated from dogs, cats and non-human primates with diarrhoea. This species has also been implicated as the cause of mastitis in cattle and abortion in sheep. In chickens, turkeys, pigeons, crows and gulls and other wild birds, *C. jejuni* subsp. *jejuni* constitutes part of normal intestinal flora. Other sources of isolates include hamsters, flies and mushrooms. Since there are such a large number of potential contributors to the contamination of natural waters, it is not surprising that large outbreaks have been traced to unchlorinated water supplies. Unpasteurized milk has also been implicated in a number of milk-borne outbreaks. However, the majority of the human cases can be traced to poultry, particularly to the consumption of chickens that have been incompletely cooked or to cookware, utensils and cutting boards that have been contaminated during the preparation of the chicken. These cases are, for the most part, sporadic but they constitute the majority of the human cases. Transmission of *C. jejuni* subsp. *jejuni* from cats and dogs has been reported to be the cause of sporadic cases, usually limited to a small number of associated individuals often in the same family (Tauxe, 1992). Occasionally complications of *C. jejuni* infection result in the development

of more severe neurological and autoimmune illnesses such as Guillain-Barré, Miller-Fisher and Reiter's syndromes (Nachamkin, Allos and Ho, 1998).

Differentiation of *C. jejuni* subsp. *jejuni* from *C. coli* is commonly achieved with the hippurate hydrolysis test, in which *C. coli* is negative. Difficulty arises when some *C. jejuni* strains are also unable to hydrolyse hippurate (Totten *et al.*, 1987). Additional tests such as growth on a minimal media are useful (Table 41.2).

Epidemiological investigations have confirmed that campylobacteriosis is a zoonotic disease. The use of both phenotyping and genotyping methods is required to achieve greater discrimination among subtype isolates of *C. jejuni* from humans and animals (Wassenaar and Newell, 2000). Tracing infections to animal sources has been accomplished mostly through the use of serotyping systems used mainly by reference laboratories (Penner, 1988). One system distinguishes strains on the basis of differences in specificities in thermostable antigens that are known to be lipopolysaccharide (Penner system) and the other employs differences in thermolabile antigens to distinguish between strains (Lior system). Serotyping of heat-stable antigens is widely accepted as a basis for reference typing of strains (Frost *et al.*, 1998). Although serotyping is a widely used method that may be useful in certain epidemiological studies, up to 20% of human and veterinary strains may be non-typable (Nielsen, Engberg and Mogens, 1997). Serotyping has been reported to be useful when used in combination with genotypic methods such as pulsed-field gel electrophoresis (PFGE) or flagellar typing by PCR-RFLP-*fla* (Birkenhead *et al.*, 1993). Genotyping methods have the advantage to be able to type strains that cannot be typed using phenotypic methods because genotyping methods measure stable chromosomal differences. In contrast phenotyping methods measure characteristics (i.e. antigens) that may not be stably expressed. PCR-RFLP-*fla* typing is a simple, inexpensive method that has been successfully applied to animals and humans (Newell *et al.*, 2000). In the past, PFGE was reported to have superior discriminatory potential, compared to other molecular typing methods for *C. jejuni*, although some strains may not be typable due to the inability of commonly used enzymes to digest the DNA (Newell *et al.*, 2000). Random amplification of polymorphic DNA (RAPD) typing is less sensitive to genetic instability than *fla* typing, but is not very reproducible with complex banding patterns (Madden, Moran and Scates, 1996). Flagellar gene sequencing may also be used to

Table 41.2 Characteristics for differentiating thermophilic enteropathogenic species of *Campylobacter*

Phenotypic characteristics	<i>C. jejuni</i>		<i>C. coli</i>	<i>C. lari</i>	<i>C. upsaliensis</i>	<i>C. helveticus</i>

Test reactions: +, present in >90% of strains examined; -, present in <11% of strains examined; v, variable strain-dependent reactions. Sources of data include Goossens and Butzler (1992), Stanley *et al.* (1992), Steele and Owen (1988), Tenover and Fennell (1992), On and Holmes (1995), On (1996) and Vandamme (2000).

^a At least 80% of strains examined have this characteristic.

^b Susceptibility to 30 µg disk of antibiotic: S, susceptible; R, resistant; v, variable strain dependent.

discriminate isolates of *C. jejuni* (Meinersmann *et al.*, 1997; Petersen and On, 2000). RAPD with PCR-RFLP-*iam* (invasion-associated marker) typing is a recent method by which invasive strains may be differentiated from non-invasive strains (Carvalho *et al.*, 2001). RFLP and PFGE have been successfully used to identify nosocomial transmission of *C. jejuni* (Llovo *et al.*, 2003). Other techniques to distinguish strains include plasmid profile determinations, phage typing, analysis of proteins from outer membranes, multilocus enzyme electrophoresis and ribotyping. Multilocus sequence typing (MLST) has recently been proposed to be a useful strategy for diverse bacterial populations that have a weakly clonal population structure such as *Campylobacter* (Dingle *et al.*, 2001, 2002). MLST is based on the sequence typing of seven housekeeping genes, which evolve slowly due to the stabilizing selection for the conservation of metabolic function. A set of reference isolates for examining clonal complexes of *C. jejuni* have been established (Wareing *et al.*, 2003). Whole-genome typing performed on digests of the *Campylobacter* genome using microarrays (Kim *et al.*, 2002) examines the entire genome, not just the housekeeping genes, and therefore is likely to be more discriminatory and more relevant than other typing strategies. Whole-genome typing by amplified fragment length polymorphism (AFLP) fingerprinting is reported to provide a similar level of discrimination as PFGE, although more recent reports suggest that AFLP is a superior method that facilitates concurrent species identification and relationships among *Campylobacter* strains (On and Harrington, 2000). Future studies must directly compare genotyping, PCR-RFLP and AFLP with standard methods of serotyping and PFGE currently used in reference public health laboratories.

The molecular techniques are generally too complex for routine use and future research needs to be directed towards simplification.

C. jejuni subsp. *doylei*

The subspecies *C. jejuni* subsp. *doylei*, has been proposed for groups of bacteria isolated from faecal samples of paediatric patients with diarrhoea in Australia and South Africa and from gastric biopsies of adults in West Germany and the UK (Steele and Owen, 1988). These bacteria, previously referred to as atypical *C. jejuni* or as GCL0-2, grow optimally at 35–37 °C and poorly or not at all at 42 °C. They do not reduce nitrate to nitrite and approximately 20% do not produce catalase. The isolates are susceptible to cephalothin and generally also to nalidixic acid. Because of their preference for a growth temperature of 35–37 °C and their susceptibility to cephalothin, they are not likely to be isolated with procedures used routinely for *C. jejuni* subsp. *jejuni* and other thermophiles. The bacteria produce non-haemolytic, pinpoint colonies after incubation for 5 to 6 days at 37 °C. In this respect and in their inability to reduce nitrate or grow at 42 °C, they resemble *Helicobacter fennelliae* (formerly *C. fennelliae*), with which they may be confused. Unlike *C. jejuni* subsp. *doylei*, however, the colonies of *H. fennelliae* have a distinct bleach-like odour and a tendency to swarm (Tenover and Fennell, 1992). The pathogenesis mechanism of *C. jejuni* subsp. *doylei* isolates has not yet been demonstrated.

C. coli

Campylobacter coli is a significant cause of human enteritis but its incidence is much lower than that of *C. jejuni* subsp. *jejuni*. This may be due to under-reporting arising from the inhibition of some *C. coli* strains by the antibiotics in the isolation media (Tenover and Fennell, 1992). Incidence varies from one area to the next as shown by the higher proportion of human enteritis cases in developing countries caused by *C. coli* (Skirrow and Blaser, 1992). *Campylobacter coli* is well known as the species that is most frequently found in healthy pigs, but it also occurs in the intestines of cattle, sheep and chickens. Many strains of *C. coli* can be serotyped on the basis of

their thermostable and thermolabile antigens. Although most strains of *C. coli* are susceptible to nalidixic acid, recent reports have drawn attention to the development of resistance to this antibiotic. In such cases they may be misclassified as *C. lari*, which are characteristically resistant to nalidixic acid. Molecular methods are often required to differentiate *C. coli* from *C. jejuni*, since some *C. jejuni*, like *C. coli*, are hippurate negative (Totten *et al.*, 1987).

C. lari

Organisms of this species were first isolated from seagulls and referred to as nalidixic acid-resistant thermophilic *Campylobacter* (NARTC). Susceptibility to nalidixic acid is dependent upon the strain. They have also been obtained from other species of birds, and from dogs, monkeys and sheep (Tenover and Fennell, 1992). *Campylobacter lari* is also a cause of human enteritis but such cases are rare relative to *C. jejuni* subsp. *jejuni*. Some strains of *C. lari* are capable of producing urease, a characteristic not shared by any other species of the genus. The ability to grow anaerobically in 0.1% trimethylamine-*N*-oxide hydrochloride is a key distinguishing feature, as well as an inability to hydrolyse indole acetate permits its differentiation from other species of the thermophilic enteropathogenic group of the genus.

C. upsaliensis

In studies to investigate transmission of *Campylobacter* from dogs to humans, a number of strains were isolated from dogs that differed from the typical thermophilic enteropathogenic species by testing negative or weakly positive for catalase production. They were known as the catalase-negative or weak (CNW) group of strains before it was recognized that they were representatives of a new species. This species, named *C. upsaliensis*, consists of strains that are generally more susceptible to antibiotics and have a wider diversity in their susceptibilities than do the other members of the thermophilic group. For effective isolation, the filtration technique and media without antibiotics are recommended. Adoption of these measures has permitted the isolation of *C. upsaliensis* from patients with gastroenteritis and bacteremia, providing a convincing line of evidence that they are causes of diarrhoea in humans (Goossens and Butzler, 1992). *Campylobacter upsaliensis* has been isolated from a patient with diarrhoea (Taylor, Hiratsuka and Mueller, 1989), and also from the faeces of asymptomatic and diarrhoeic cats and dogs (Sandstedt and Ursing, 1991).

Isolates of *C. upsaliensis* are readily differentiated from other thermophilic species by a negative or weak reaction for catalase, and by their inability to hydrolyse hippurate or grow anaerobically in 0.1% trimethylamine-*N*-oxide hydrochloride. *Campylobacter upsaliensis* isolates are usually susceptible to both cephalothin and nalidixic acid. They most closely resemble *C. helveticus* strains, from which they can be differentiated by their positive reactions for reduction of selenite and growth on potato starch.

C. helveticus

The most recently defined species of the thermophilic enteropathogenic group is *C. helveticus*. It was discovered during studies on the detection of *C. upsaliensis* in cats and dogs with gastroenteritis (Stanley *et al.*, 1992). The species reflects the phenotypic characteristics of *C. upsaliensis* but has a homology level of only 35% in DNA–DNA hybridizations and less homology with other species of the thermophilic group. Its differentiation from *C. upsaliensis* is based on its inability to reduce selenite or grow on potato starch. It is differentiated from the other thermophilic species by its lack of catalase production. On blood agar, *C. helveticus* produces smooth, flat

colonies with a characteristic blue-green hue and a watery spreading appearance.

Approximately half of the Campylobacters isolated from cats belong to *C. helveticus* and the species is present in both healthy cats and in cats with gastroenteritis, but only 2% of the Campylobacters isolated from dogs belong to this species.

Laboratory Diagnosis

Procedures for Isolating Campylobacteria

Bacteria of the genus *Campylobacter* have a characteristic morphology and a darting type of motility that permits their identification by direct examination of broth suspensions of faeces. However, *C. jejuni* subsp. *jejuni* cannot be distinguished from *C. coli* by this procedure and the test is considerably less sensitive than isolation by culture.

A method used in early studies utilized the supernatant from a saline suspension of faeces which is drawn up in a syringe and then forced through a 0.65 µm filter. The filtered fluid, which contains the filter-passing Campylobacteria, is inoculated on a solid isolation medium (Dekeyser *et al.*, 1972). It has been replaced by direct plating on a selective isolation medium, the first of which was described in 1977 (Skirrow, 1977). The Skirrow medium consists of a blood agar base in which is incorporated lysed horse blood, vancomycin, trimethoprim and polymyxin B. Blood contains catalase, peroxidase and superoxide dismutase which are believed to remove toxic oxygen derivatives that inhibit Campylobacteria, while the three antibiotics inhibit the growth of other enteric bacteria. The Skirrow medium is immensely successful in isolating *C. jejuni* subsp. *jejuni* but some faecal flora are not inhibited and some species of *Campylobacter* are inhibited. It is best to avoid cephalothin in media as it may inhibit some Campylobacters. Semisolid motility agar is blood free (Goossens and Butzler, 1991) and, like Skirrow media, is effective at isolating Campylobacteria at 42 °C, but neither is effective at 37 °C (Endtz *et al.*, 1991). This has prompted investigations of other media formulations to overcome these problems. Different cephalosporins have been examined for their inhibition of faecal bacteria, and amphotericin B and cycloheximide have been used to inhibit yeasts. Activated charcoal has been used as a replacement for blood in blood-free media (charcoal-selective media) (Karmali *et al.*, 1986). Such media are generally less expensive and have an advantage in areas of the world where regular supplies of sterile horse or sheep blood are not readily available. One blood-free selective medium developed to replace blood with charcoal is referred to as modified charcoal cefoperazone deoxycholate agar (CCDA medium) (Hutchinson and Bolton, 1984). It also contains ferrous sulfate and sodium pyruvate to enhance aerotolerance and growth of the bacteria.

A simpler method of filtering faecal suspensions requires six to eight drops of faecal suspension to be applied to a membrane filter (0.4 or 0.65 µm pore size) placed on a solid base medium with blood. The filter is removed and discarded 30 min after the application of the suspension. Only about 10% of the Campylobacteria in the sample pass through the filter to produce colonies, thereby limiting detectability of these organisms in faeces to those samples with more than 10⁵ cfu per gram (Goossens and Butzler, 1992). Some authors advocate that both inoculation on a selective medium and filtration on a non-selective medium be performed to enhance recovery of the thermophilic species. A charcoal-based media with cefoperazone, amphotericin and teichoplanin has been used for the primary isolation of *C. upsaliensis* (Aspinall *et al.*, 1996). Considering that some Campylobacters are susceptible to the antibiotics in media, they should be avoided to prevent favouring fast-growing isolates, or altering the true distribution of different Campylobacters present in the specimen (Sillely, 2003).

To isolate *Campylobacter* spp. from water, milk or food, pre-enrichment steps are recommended. Enrichment is usually unnecessary

for fresh stool samples but should be considered for samples that have been stored or maintained in transport media. A number of enrichment media have been described and tested, but agreement is lacking on the choice of an enrichment medium. Those that have been examined include Campy-thio broth, alkaline peptone water, Doyle and Roman enrichment broth, Lovett's enrichment broth and the Preston semi-solid enrichment medium. It should be noted that these media have been tested primarily for improving isolation of *C. jejuni* (Goossens and Butzler, 1992; Tenover and Fennell, 1992), but may in fact be artificially be selecting for this species (Sillely, 2003).

Since Campylobacteria are microaerophilic it is essential that they be cultured in an atmosphere with reduced oxygen concentration. The recommended gaseous mixture is 5% oxygen, 10% carbon dioxide and 85% nitrogen for most *Campylobacter* species. The most convenient method of achieving such an atmosphere is with commercially available gas-generating envelopes that are activated in the anaerobic jars. Hydrogen has been shown to enhance growth of some species and to be essential for microaerobic growth of *C. mucosalis*, *C. hyointestinalis* subsp. *lawsonii*, *C. concisus*, *C. curvus*, *C. rectus*, *C. showae*, *C. gracilis* and *C. hominus* sp. nov. (Goossens and Butzler, 1992; Vandamme, 2000). These hydrogen-requiring species need 6% oxygen, 6% carbon dioxide, 3% hydrogen and 85% nitrogen. Gas-generating envelopes that produce an atmosphere of approximately 10% hydrogen, 10% carbon dioxide and 80% nitrogen are available but it should be noted that the hydrogen may be hazardous (Tenover and Fennell, 1992). A commercially available supplement consisting of equal concentrations of ferrous sulfate, sodium metabisulfite and sodium pyruvate may be incorporated in the isolation medium to enhance aerotolerance and growth. The use of this supplement is recommended by many workers and is particularly important in laboratories that use the burning candle to reduce the concentration of oxygen.

If more than a 2-h delay will elapse prior to culturing the specimens, they are best placed in Cary-Blair transport media (Wang *et al.*, 1983). Specimens should be inoculated to two selective plates, one with blood and one without, and incubated at 42 °C under microaerobic conditions since most Campylobacteria will grow, apart from *C. fetus*. However, *Campylobacter* and *Arcobacter* species grow well at 37 °C on selective media, such as CCDA. Culture should be made at both 37 and 42 °C or repeated at 37 °C, if negative at 42 °C (Nachamkin, 1995). Since blood culture isolation is difficult, if curved Gram-negative rods are present, it is best to subculture to non-selective media at 37 °C under microaerobic conditions. Plates should be incubated for 72 h before they may be considered negative.

Identification

Accurate identification of *Campylobacter* species is necessary to collect useful surveillance data for subsequent risk assessment studies and development of effective interventions to prevent the spread of Campylobacteria. Unfortunately, the biochemical inertness of Campylobacteria prevents effective discrimination of the species by phenotypic methods, such as tolerance to different temperatures and to agents that inhibit growth. However, tests for oxidase, catalase, hippuricase, urease, indoxyl acetate hydrolysis, nitrate and nitrite reductases, hydrogen sulfide production, susceptibility to nalidixic acid and cephalothin and growth at 15, 25 and 42 °C are the most reliable for species differentiation. Tests for tolerance to 1% glycine, 3.5% sodium chloride and 0.1% trimethylamine *N*-oxide are less reproducible.

The experienced worker may be aided by slight differences in colony morphology on isolation media. Colonies produced by *C. jejuni* subsp. *jejuni* are grey, moist, flat and spreading after 42 h of incubation at 42 °C. They are often found to spread along the lines of inoculation. *Campylobacter coli* colonies tend to be creamy-grey, moist and more discrete than those of *C. jejuni* subsp. *jejuni*. Colonies

of *C. lari* are generally grey and discrete but more variable, resembling either *C. jejuni* subsp. *jejuni* or *C. coli* colonies.

Any colonies isolated from selective media under microaerobic conditions that are oxidase positive, Gram-negative curved, S-shaped or spiral rods 0.2–0.9 mm wide and 0.5–5 mm long may be reported as *Campylobacter* species (Nachamkin, Engberg and Aarestrup, 2000). The ability of many *C. jejuni* to hydrolyse hippurate allows its differentiation from *C. coli*, which lacks this ability. Speciation becomes more difficult for *C. jejuni* strains that are unable to hydrolyse hippurate (Totten *et al.*, 1987). A list of reactions by which the thermophilic species may be differentiated are summarized in Table 41.2.

Computerized schemes utilizing probability matrices for phenotypic characteristics (On and Holmes, 1995; On, 1996) in combination with other methods, including molecular methods, have been developed to improve the identification of species within the Campylobacteraceae family. These methods encompass a variety of techniques including enzymology (Elharrif and Megraud, 1986), serology (Hebert *et al.*, 1983), cellular fatty-acid profiles (Goodwin *et al.*, 1989), electrophoretic patterns (Costas *et al.*, 1987), ribotyping (Fitzgerald, Owen and Stanely, 1996; Smith *et al.*, 1998), DNA–DNA hybridization (Romaniuk and Trust, 1989; Stucki *et al.*, 1995), PCR–DNA fingerprinting (Giesendorf *et al.*, 1994; van Doorn *et al.*, 1997; Vandamme *et al.*, 1997), PCR–RFLP analysis (Cardarelli-Leite *et al.*, 1996; Marshall *et al.*, 1999) PCR–ELISA (Sails *et al.*, 2001; Kulkarni *et al.*, 2002), PFGE (Yan, Chang and Taylor, 1991; Ribot *et al.*, 2001; Wu *et al.*, 2002; Llovo *et al.*, 2003) and AFLP (On and Harrington, 2000; Duim *et al.*, 2001; Moreno *et al.*, 2002; Schouls *et al.*, 2003).

No single PCR method is yet able to identify all the species of *Campylobacter*, so it will likely be more effective to use a polyphasic approach (On, 1996; On and Jordan, 2003). PCR protocols are based on a variety of genes such as 16S rRNA, 23S rRNA, *ceuE*, *flaA*, *mapA* and *glyA* (Oyofe *et al.*, 1992; Eyers *et al.*, 1993; Gonzalez *et al.*, 1997; Al Rashid *et al.*, 2000), or some utilize random primers (On and Jordan, 2003). While several oligo probes and PCR methods are able to identify several *Campylobacter* species, only the combined PCR–oligo hybridization strategy using species-specific oligo probes based on the highly conserved *glyA* gene demonstrated sufficient sensitivity and specificity to distinguish between *C. jejuni*, *C. coli*, *C. lari*, *C. upsaliensis* and *A. butzleri* (Al Rashid *et al.*, 2000). A real-time PCR–biprobe assay is reported to accurately identify *C. jejuni/C. coli*, *C. lari*, *C. upsaliensis*, *C. hyointestinalis*, *C. fetus* as well as *C. helveticus* and *C. lanienae* from isolates and faecal DNA (Logan *et al.*, 2001). A standardized PCR-based detection assay, using a single select primer pair, has been developed and may be useful in large-scale screening programs for the most common food-borne *Campylobacter* species: *C. jejuni*, *C. coli* and *C. lari* (Lübeck *et al.* 2003a,b). Oligo-nucleotide microarrays have recently been developed that can differentiate *C. jejuni*, *C. coli*, *C. lari* and *C. upsaliensis* based on PCR amplification of specific regions in five target genes followed by microarray analysis of amplified DNA (*fur*, *glyA*, *cdtABC*, *ceuB-C* and *fliY*), with confirmation by *hipO* or *ask* PCR (Volokhov *et al.*, 2003).

Antibiotic Susceptibility

The US Food and Drug Administration analysed data from an international multicenter study of seven laboratory sites and recommended to the National Committee for Clinical Laboratory Standards (NCCLS) subcommittees on antimicrobial susceptibility testing (AST) and veterinary antimicrobial susceptibility testing that the AST method for *Campylobacter* be agar dilution (McDermott and Walker, 2003). NCCLS document M31-A2 containing the testing method and the tentative quality-control ranges and document M7-A6 with M100-S13 supplemental tables were made available in January 2003. The study was validated using isolates of *C. jejuni* subsp. *jejuni*,

C. jejuni subsp. *doylei*, *C. coli*, *C. fetus* and *C. lari*. The quality-control organism is *C. jejuni* isolate ATCC 33560. Tentative quality-control ranges have been proposed for five antibiotics: ciprofloxacin, doxycycline, gentamicin, meropenem and tetracycline. Minimal inhibitory concentrations (MICs) obtained by traditional agar dilution susceptibility testing on Mueller–Hinton media supplemented with 5% horse or sheep blood incubated at 35 °C for 24–48 h under microaerobic conditions have been reported to generally correlate well with the E-test method (Engberg *et al.*, 2001), although MICs at low or high concentrations do not correlate that well. The relationship between MICs and clinical outcome for *Campylobacter* has not yet been established.

Originally, Campylobacters were universally resistant to penicillins, cephalosporins (except broad spectrum), trimethoprim, sulfamethoxazole, rifampicin and vancomycin and susceptible to erythromycin, fluoroquinolones, tetracyclines, aminoglycosides and clindamycin (Nachamkin, Engberg and Aarestrup, 2000). Since 1989, antimicrobial resistance to the latter group of drugs has been rising at different rates throughout the world (Nachamkin, Engberg and Aarestrup, 2000).

The mechanisms of antibiotic resistance in *Campylobacter* have been reviewed recently (Trieber and Taylor, 2000). In a Canadian study, tetracycline resistance more than doubled over a 10-year period to a level of 55% (Gaudreau and Gilbert, 1998). Tetracycline resistance in *Campylobacter* is mediated by Tet(O), a ribosomal protection protein that inhibits tetracycline interaction with the ribosome (Connell *et al.*, 2003). The tetracycline-resistance gene (*tetO*) appears to be closely related to the *tetM* gene found in *Streptococcus* sp. (Taylor, 1984, 1992a), and both protein products function as GTPase proteins (Grewel, Manarathu and Taylor, 1993). In the absence of Tet(O) tetracycline interrupts protein synthesis by binding the ribosome and inhibiting the ribosomal elongation rate, producing short chains (Trieber and Taylor, 2000). Mutations in the *miaA* gene product and mutations in the ribosomal protein S12 (encoded by *rpsL*) alter translation accuracy which in turn affects Tet(O)-mediated tetracycline resistance (Taylor *et al.*, 1998). Antibiotic resistance genes, usually carried on plasmids, have been cloned and will express in *E. coli*. High levels of tetracycline resistance are usually associated with the Tet(O) determinant on a self-transmissible plasmid, but it may also be found on the chromosome, although it is unknown whether this is mediated by a transposon or through host-cell recombination (Taylor *et al.*, 1981; Taylor and Courvalin, 1988; Trieber and Taylor, 2000).

Chloramphenicol resistance in *Campylobacter* spp. occurs rarely and is mediated either through mutation of the 23S rRNA or the chloramphenicol-resistance determinant (*cat*) that is closely related to genes specifying a chloramphenicol transferase in *Clostridium* spp. (Taylor, 1984, 1992a; Spahn and Prescott, 1996).

The level of resistance to β -lactam antibiotics varies with antibiotic. Resistance to penicillin and cephalosporins is common, less common with ampicillin, rarely seen with amoxicillin and not at all with imipenem (Trieber and Taylor, 2000). For this reason, imipenem is used only to treat the most severe systemic infections and the other β -lactam antibiotics avoided. Resistance to β -lactams occurs by modification of a porin to reduce antibiotic uptake, alterations of penicillin-binding protein or production of β -lactamase. The addition of clavulanate, a β -lactamase inhibitor, to β -lactam antibiotics results in total susceptibility *in vitro* (Tajada *et al.*, 1996).

Trimethoprim resistance is intrinsic to Campylobacters due to the presence of either *dfr1* and *dfr9*, genes encoding dihydrofolate reductase (Taylor, 1992b). As a result, trimethoprim is often used in selective media for Campylobacters.

Aminoglycoside resistance occurs by modification of the antibiotic by one of three enzymes: aminoglycoside phosphotransferases (APH), aminoglycoside adenylyltransferases (AAD) and acetyltransferases. Kanamycin resistance is due to the production of APH, which is encoded by three different genes: *aphA-1*, which is chromosomally mediated and found among the Enterobacteriaceae; *aphA-3*, which is

found in Gram-positive cocci; and *aphA-7*, which is thought to be indigenous to *Campylobacter* (Taylor, 1992a). Streptomycin and spectinomycin resistance occurs with AAD, encoded by *aadA* and *aadE* genes (Björk, 1995). Streptothricin resistance in *C. coli* arises from antibiotic modification by acetyltransferase encoded by *sat4* (Jacob *et al.*, 1994). Aminoglycoside resistance may also arise from chromosomal mutations of ribosomal proteins and rRNA. Although spontaneous chromosomal streptomycin resistance in *C. coli* could be transformed to another *C. coli* by natural transformation, the nature of the mutation has not yet been characterized (Wang and Taylor, 1990; Trieber and Taylor, 2000).

Macrolide resistance in *Campylobacter* is very low and thought to be chromosomally mediated (Taylor, 1992b). Macrolides (erythromycin, azithromycin and clarithromycin) are protein synthesis inhibitors that reversibly bind the ribosome to a site that may include 23S rRNA and proteins (Spahn and Prescott, 1996). Erythromycin-resistance determinants have been identified in *C. rectus* as rRNA methylases (ErmB, GrmC, GrmQ and GrmFS) which methylate an adenine in the 23S rRNA and prevent binding of erythromycin (Roe, Weinberg and Roberts, 1995). In contrast, in *C. jejuni* and *C. coli*, the mechanism of erythromycin resistance is likely due to mutations at the 23S rRNA genes which result in decreased ability of erythromycin to bind the ribosomes (Trieber and Taylor, 1999).

Campylobacter spp. are generally highly susceptible to fluoroquinolones (ciprofloxacin, ofloxacin and norfloxacin), antibiotics derived from nalidixic acid and target type II topoisomerases, DNA gyrase and topoisomerase IV (Drlica and Zhao, 1997). Fluoroquinolones form a complex with the gyrase and the DNA to inhibit DNA replication and transcription and do not actually bind directly to the gyrase or the DNA (Willmott and Maxwell, 1993). Resistance to fluoroquinolones in *C. jejuni* arises from a chromosomal mutation genes encoding either gyrase, *gyrA* (Thr-86 to Ile, Asp-90 to Ala and Ala-70 to Thr) and/or topoisomerase IV, *parC* (Arg-139). Both human and veterinary use of fluoroquinolones may result in resistance in *Campylobacter* (Wang, Huang, Taylor, 1993; Piddock, 1995). The incidence of resistance to fluoroquinolones in *C. jejuni* and *C. coli* is on the rise, reaching levels as high as 88% in Spain (Trieber and Taylor, 2000). Resistance to nalidixic acid in *C. jejuni* and *C. coli* usually results in cross-resistance to fluoroquinolones but is not true for *C. fetus* which is intrinsically resistant to nalidixic acid (Taylor, Ng and Lior, 1985). A multidrug-resistance efflux pump has been characterized in *C. jejuni* and is a three-gene operon encoded on the chromosome as *CmeA*, *CmeB* and *CmeC* (Lin, Michel and Zhang, 2002; Pumbwe and Piddock, 2002).

Treatment

Most commonly, *Campylobacter* infections manifest as an acute diarrhoeal disease. General treatment for *Campylobacter* infections is supportive and symptomatic, with antibiotics being reserved for those with prolonged serious symptoms (abdominal pain, diarrhoea and blood in the stool), such as observed in immunocompromised persons, and in pregnancy in which the fetus may be affected (Allos and Blaser, 1995). Erythromycin is the drug of choice to treat *C. jejuni* infections in humans. Up to 68.4% of *C. coli* isolates may be resistant to erythromycin (Nachamkin, Engberg and Aarestrup, 2000). Alternatively, ciprofloxacin, gentamicin and tetracycline may be used to treat *Campylobacter* enteritis (Lucey *et al.*, 2000; Wilson *et al.*, 2000). Antimicrobial agents used for the treatment of infection in chickens and cattle are not currently monitored in the industry, making it difficult to assess levels of antimicrobial use. Increasing resistance to quinolones has been reported and may be associated with multidrug resistance on farms producing poultry and beef (Engberg *et al.*, 2001). Recent studies of human and animal *C. jejuni* isolates reported increasing resistance to ciprofloxacin, tetracycline and erythromycin in isolates collected in 2001 as compared with several

years previously (Gaudreau and Gilbert, 2003; Lubber *et al.*, 2003). Multidrug resistance is associated with an efflux pump (Lin *et al.*, 2003). Ciprofloxacin is used to treat human infections, while enrofloxacin is used for veterinary use (Luo *et al.*, 2003). Ciprofloxacin-resistant mutants can be isolated from chickens after only 1 day of enrofloxacin treatment, and these isolates are also cross-resistant to enrofloxacin and nalidixic acid. Resistance was shown to be due to a mutation in *gyrA* and suggests that *Campylobacter* is hypermutable under the selective pressure of fluoroquinolones (Luo *et al.*, 2003).

Prevention

As infection with *Campylobacter* spp. is a zoonosis, control is largely directed against removing the source of infection. The consumption of unchlorinated water is a well-recognized source. Contamination of drinking water for poultry may be a significant source of intestinal colonization in poultry flocks, and control measures can lead to reduced carriage (Healing, Greenwood and Pearson, 1992). Strict hygiene and decontamination technologies are needed to assure the safety of meat (Moorhead and Dykes, 2002). Adequate cooking of poultry is probably the single most important control measure. Pasteurization of milk is also important, as is the protection of doorstep bottles of milk from pecking by birds (Healing, Greenwood and Pearson, 1992). Improved implementation of hazard analysis of critical control points and consumer food-safety education efforts are necessary to prevent transmission of food-borne pathogens such as *Campylobacter* (Zhao *et al.*, 2001).

ANIMAL PATHOGENS AND COMMENSAL CAMPYLOBACTERIA THAT MAY CAUSE OPPORTUNISTIC INFECTIONS IN HUMANS

The four species within this group (*C. fetus*, *C. hyointestinalis*, *C. sputorum* and *C. mucosalis*) are, with the exception of *C. sputorum* biovar *sputorum*, either pathogens or commensals of farm animals. Human infections are uncommon and those that have been reported are usually opportunistic in predisposed patients. There is considerable diversity among the species in their habitats, pathogenicity, atmospheric conditions for growth and biochemical reactions (Table 41.3), although genetic analysis has shown them to be a closely related group (Thompson *et al.*, 1988; Vandamme *et al.*, 1991).

Although *C. hyointestinalis*, *C. coli* and *C. mucosalis* are readily isolated from porcine intestines, they have not been shown to have a direct effect in the development of intestinal disease. Some reports suggest that porcine diseases may be caused by intracellular *Campylobacter*-like organisms that cannot be cultured (McOrist, Boict and Lawson, 1989; Gebhart *et al.*, 1991). However, it is interesting to note that *C. hyointestinalis* and *C. mucosalis* occur far more frequently in piglets with intestinal lesions than in healthy animals, but the basis for this observation is not clear.

The filtration technique optimizes recovery of these *Campylobacter* from stools and helps to ascertain their incidence in human infection along with antibiotic-free media, when incubated under microaerobic conditions at 35–37 °C. *Campylobacter*, which are smaller than most enteric bacteria, pass through the filters and produce colonies, while the larger enteric bacteria are excluded.

C. fetus

Bacteria now classified as *C. fetus* have been known since 1913, when they were believed to belong to the genus *Vibrio* (Tenover and Fennell, 1992). Currently, the species consists of two groups classified as *C. fetus* subsp. *fetus* and *C. fetus* subsp. *venerealis*. *Sma*I-based macrorestriction digests, or PCR, allow for differentiation of the two subspecies (Hum *et al.*, 1997). The assignment of the two groups to

the taxonomic status of subspecies is based more on convenience than on differences that can be demonstrated by either DNA hybridization or phenotypic characteristics that are used to identify and classify Campylobacteria. The subspecies are, however, quite distinct in their habitats and in the sites of the host where they produce infections. The major habitat of *C. fetus* subsp. *fetus* is the intestinal tract of cattle and sheep, and isolations of the organisms from healthy animals are not uncommon and may cause spontaneous abortion (Skirrow, 1994). The bacteria may be acquired from food or water that has been contaminated with bacteria from faeces, aborted fetuses or from vaginal discharges of infected animals. After colonization of the intestine, the organisms may spread via the bloodstream to the placenta, for which they have a high affinity, and multiply in the developing fetus, which is then generally aborted.

In contrast, the normal habitat of *C. fetus* subsp. *venerealis* is the genital tract of cattle and sheep.

Human infections caused by *C. fetus* subsp. *fetus* are rare and usually occur in immunocompromised or debilitated patients. Gastroenteritis, endocarditis and septicaemia have been reported with complications arising from septicaemia that include meningitis, endocarditis, infection of the fetus and abortion, pleuropericardial effusion, cellulitis as well as abscesses from most parts of the body (On, 1996; Ganeshram *et al.*, 2000; Peetermans *et al.*, 2000; Briedis *et al.*, 2002; Tremblay, Gaudreau and Lorange, 2003). Some of the intestinal isolates have been recovered at 42 °C, but most strains of the species cannot tolerate this temperature, preferring 35–37 °C, and are also susceptible to cephalothin, the most common selective agent for culture. Since many *C. fetus* subsp. *fetus* strains would not be isolated, accurate determination of the incidence of this subspecies in human diarrhoea is not available.

The involvement of *C. fetus* subsp. *venerealis* in human disease is even much less frequent than is *C. fetus* subsp. *fetus* (Garcia, Eaglesome and Rigby, 1983).

C. hyointestinalis

A group of bacteria isolated from pigs with proliferative ileitis (Gebhart *et al.*, 1983) was confirmed to be a separate species and was

named *C. hyointestinalis* (Gebhart *et al.*, 1985). This bacteria is comprised of two subspecies, *C. hyointestinalis* subsp. *hyointestinalis* and *C. hyointestinalis* subsp. *lawsonii*, isolated from primarily enteric sources and pig stomachs, respectively (On and Homes 1995). *Campylobacter hyointestinalis* has also been isolated from stomachs or intestines of hamsters, cattle and deer, as well as from human faeces (Gebhart *et al.*, 1985; Hill, Thomas and Mackenzie, 1987; Harrington and On, 1999). Isolates obtained from a homosexual male (Fennell *et al.*, 1986) first implicated the species as another aetiological agent of human diarrhoea. In subsequent studies, isolates from both male and female patients with diarrhoea have been reported (Edmonds *et al.*, 1987), but isolates have also been obtained from asymptomatic individuals (Salama, Garcia and Taylor, 1992; On and Harrington, 2001) and the suggestion has been raised that *C. hyointestinalis* may be an opportunistic enteropathogen in humans (Minet, Grosbois and Megraud, 1988).

Campylobacter hyointestinalis is most closely related to *C. fetus* subsp. *fetus* (Vandamme *et al.*, 1991) and possesses a similar colony morphology and other phenotypic characteristics (Table 41.2). *Campylobacter hyointestinalis* grows optimally at 35–37 °C, less well at 42 °C and not at all at 25 °C. All strains grow microaerobically in the presence of hydrogen, and only a few do not require hydrogen. The colonies are yellow and do not swarm on moist media or show haemolysis (Gebhart *et al.*, 1985). The species is differentiated from *C. fetus* by its production of hydrogen sulfide in triple sugar iron medium and by its growth in trimethylamine *N*-oxide hydrochloride under anaerobic conditions. The number of reports of isolations of *C. hyointestinalis* from humans has not increased substantially since the first report of a human isolate (Fennell *et al.*, 1986), and thus its frequency as a pathogen or commensal in the human population remains uncertain. A species-specific PCR test for *C. hyointestinalis* has been described for the detection, but not differentiation of both subspecies (Linton, Owen and Stanley, 1996). The existence of polymorphic sites may, however, compromise the specificity of the PCR test. Subspecies of *C. hyointestinalis* may be differentiated by *Sma*I-derived macrorestriction profiles (On and Vandamme, 1997). Recovery of *C. hyointestinalis* from clinical specimens is often unsuccessful because the bacteria do not grow optimally at 42–43 °C and they may be susceptible to selective antibiotics.

C. sputorum

The species consists of three biovars (biotypes): *C. sputorum* biovar *sputorum*, *C. sputorum* biovar *faecalis* and *C. sputorum* biovar *paraureolyticus* differentiated on the basis of their habitats and simple biochemical tests (catalase positive and urease negative) (catalase negative and urease negative) and (catalase negative and urease positive), respectively (On *et al.*, 1998; Vandamme and On, 2001). Although there are reports of an isolate of *C. sputorum* biovar *sputorum* from a human leg abscess and another isolate from the faeces of an infant with diarrhoea the organisms of this biovar are believed to be commensals because they can be isolated from the oral cavity, faeces of healthy humans and reproductive tract of cattle (Karmali and Skirrow, 1984). *Campylobacter sputorum* biovar *faecalis* was originally believed to represent a separate species and was first classified as *Vibrio fecalis*, but it was shown to constitute a separate biogroup within the species *C. sputorum* in DNA-relatedness studies (Roop *et al.*, 1985). Organisms of this biovar have been isolated from sheep faeces, bovine semen and the bovine vagina, but evidence for a pathogenic role has not been forthcoming. *Campylobacter sputorum* biovar *paraureolyticus* has been isolated from the faeces of cattle and also from humans with diarrhoea, yet no pathological role is understood.

The morphology of the bacterial cells of the three biovars is not as tightly coiled as are those of *C. jejuni* subsp. *jejuni* (Tenover and Fennell, 1992). Isolates of each of the biovars grow microaerophilically at 42 °C but prefer 37 °C, and do not grow at 25 °C. The colonies are small (1–2.5 mm in diameter), grey in colour and do not swarm on moist agar. Some show low levels of alpha-haemolysis. The isolates reduce nitrate and nitrite, produce hydrogen sulfide in triple sugar iron medium and are susceptible to cephalothin.

C. mucosalis

Campylobacter mucosalis (formerly classified as *C. sputorum* subsp. *mucosalis*) is of interest primarily to veterinarians (no human infections reported) because of its occurrence in the intestinal mucosa of pigs with intestinal adenomatosis, necrotic enteritis, regional ileitis and proliferative haemorrhagic enteropathy (Roop *et al.*, 1985).

Organisms of *C. mucosalis* are noted for their yellowish colour and ability to grow at temperatures from 25 to 42 °C. Hydrogen is necessary for microaerophilic growth, a requirement that permits differentiation from *C. fetus*, *C. hyointestinalis*, *C. sputorum* and species of the thermophilic enteropathogenic group. The four species associated with periodontal diseases in humans also require hydrogen for microaerophilic growth, but they can be differentiated from *C. mucosalis* on the basis of their inability to grow at 25 °C.

Campylobacter Species Associated with Periodontal Disease

Five species are included in this group: *C. concisus*, *C. curvus*, *C. rectus*, *C. showae* and *C. gracilis*. Two species, *C. concisus* and *C. rectus*, were described as a result of a taxonomic study on bacteria associated with periodontal disease (Tanner *et al.*, 1981). *Campylobacter curvus* was first assigned to the genus *Wolinella* with the specific name '*curva*' to reflect the shape of the cells. *Campylobacter rectus* was previously designated *Wolinella recta*, with its cells the shape of plump, straight rods. The surface of *C. rectus* is covered with an array of hexagonal, packed macromolecular subunits (Tanner *et al.*, 1981). By DNA–rRNA hybridization and immunotyping, both strains more closely relate to the genus *Campylobacter* than to the type species of the genus *Wolinella* (Vandamme *et al.*, 1991). With corrections in the spelling of the epithets, the two species were therefore transferred from *Wolinella* to the genus *Campylobacter* (Vandamme *et al.*, 1991). *Campylobacter gracilis* was originally classified as *Bacteroides gracilis*, due to its description as a non-motile, non-spore-forming anaerobic

Gram-negative rod with a formate- and fumarate-requiring metabolism (Tanner *et al.*, 1981). Later analysis and comparison of the cellular fatty acids, respiratory quinones and proteins of *B. gracilis* with campylobacters resulted in the reclassification and transfer of this species to genus *Campylobacter* (Vandamme *et al.*, 1995). *Campylobacter gracilis* is the only oxidase-negative *Campylobacter* species.

Both *C. gracilis* and *C. rectus* have been detected in endodontic infections (Gomes, Lilley and Drucker, 1996; Le Goff *et al.*, 1997; Sundqvist *et al.*, 1998; Siqueira *et al.*, 2000b, 2001b). The prevalence of campylobacters associated with primary endodontic infections has likely been underestimated due to the difficulty in traditional phenotype-based species identification. Molecular methods, such as nested PCR technology, have increased the sensitivity and specificity for species-specific detection of *C. gracilis* and *C. rectus* (Jordan *et al.*, 2001), at rates of 21.1 and 23.3% respectively, in endodontal infections (Siqueira and Rôças, 2003). *Campylobacter rectus* has also been associated with appendicitis, while *C. gracilis* is associated with serious deep-tissue infections.

Campylobacter concisus and *C. curvus* have been isolated from human gingival crevices and associated with gingivitis, periodontitis and periodontosis (Tanner *et al.*, 1981; Tanner, Listgarten and Ebersole, 1984) and also from blood, oesophagus, stomach and duodenum (Goossens and Butzler, 1992). Both species have been recovered from stool and blood samples of healthy children and adults and those with diarrhoea (Vandamme *et al.*, 1989; Lindblom *et al.*, 1995; Van Etterijck *et al.*, 1996).

DNA–DNA hybridization tests, 16S rRNA sequence data and biochemical reactions typical of *Campylobacter* supported the proposal for creating a new species, *C. showae*, for another group of strains isolated from infected root canals, dental plaque and human gingival crevices of apparently healthy adults (Etoh *et al.*, 1993). The species differs from others of the genus in having rod-shaped bacteria with two to five flagella at one end of the cell. It is differentiated from *C. concisus*, *C. rectus* and *C. curvus* in its ability to produce catalase. While *C. concisus* and *C. curvus* are true microaerophils, *C. rectus*, *C. gracilis* and *C. showae* grow optimally under anaerobic conditions (On, 1996). Additional characteristics for differentiating these species are summarized in Table 41.4.

Newly Characterized *Campylobacter* Species

Campylobacter lanienae sp. nov. was recently identified in the stools of healthy abattoir workers and pigs and found to be most closely related to *C. hyointestinalis* (Logan *et al.*, 2000; Sasaki *et al.*, 2003). Cells are Gram-negative slender, slightly spiral rods with curved ends and single bipolar unsheathed flagella. *Campylobacter lanienae* is microaerophilic and grows weakly under anaerobic conditions. Other characteristics are summarized in Table 41.3.

Campylobacter hominus sp. nov. was recently identified in faecal samples from humans with diarrhoea and also those without clinical illness using 16S rRNA sequences (Lawson *et al.*, 2001). Phylogenetically, *C. hominus* sp. nov. is related to *C. gracilis* and *C. sputorum*. Anaerobic conditions, hydrogen and FAA medium (containing vitamin K, haemin, cysteine hydrochloride and L-arginine) and 37 °C are required for culture of *C. hominus* sp. nov. Cells are Gram-negative, straight, non-motile, non-spore-forming rods. Flagella are absent, but irregular fimbriae-like structures are present (Table 41.4).

THE GENUS ARCOBACTER

The genus *Arcobacter* is classified with rRNA superfamily VI of the Proteobacteria and includes four species: *A. nitrofigilis* and *A. cryaerophilus* (formerly in the genus *Campylobacter*), *A. butzleri* and *A. skirrowii* (Vandamme *et al.*, 1991, 1992b). Although *Arcobacter* spp. resemble *Campylobacter*, differences in a number of phenotypic traits warrant their placement in a separate genus. The name

Test reactions: +, present in >90% of strains examined; –, present in <11% of strains examined; v, variable strain-dependent reactions. Sources of data include Etoh *et al.* (1993), Goossens and Butzler (1992), Tanner *et al.* (1981), Tanner, Listgarten and Ebersole (1984), On and Holmes (1995), On (1996) and Vandamme (2000).

^a 38–66% of strains examined have this characteristic.

^b Susceptibility to 30 µg disk of antibiotic: S, susceptible; R, resistant; v, variable strain dependent.

^c At least 80% of strains examined have this characteristic.

Arcobacter was selected to suggest a bow shape, but, like Campylobacteria, they are usually curved, S-shaped or helical cells. Arcobacteria are differentiated from Campylobacteria by two main phenotypic characteristics: the ability to grow at 25 °C and aerotolerance. Although aerotolerance is not usually observed on initial isolation, it does emerge upon subculture.

The four *Arcobacter* spp. grow over a diverse range of temperatures and atmospheric conditions, but all species are able to grow aerobically at 30 °C, anaerobically at 35–37 °C and microaerophilically, with or without hydrogen, at 25–30 °C. Optimal growth occurs under microaerobic conditions with oxygen concentrations of 3–10%. *Arcobacter nitrofigilis* and *A. craerophilus* are capable of growth at 15 °C or at lower temperatures, but only the occasional strain of *A. cryaerophilus* grows at 42 °C, in contrast to 67% of *A. butzleri* and 33% of *A. skirrowii* strains that grow at this temperature.

Tolerance tests have been used to characterize *Arcobacter* species, but these tests are generally unsatisfactory for species identification and classification because of the diversity of the reactions among the four species and among the strains of each species. Some of the tolerance tests advocated include tests for growth in sodium chloride (in concentrations ranging from 1.0 to 3.5%), growth in bile (1.0%), in triphenyltetrazolium chloride (0.04–0.1%), sodium selenite (0.1%), cadmium chloride (2.5 and 2.0 µm disks), glucose (8%), brilliant green (0.004–0.003%) and in glycine (1.0%). MacConkey agar is the only selective media that has value as a differentiating test because it separates *A. butzleri* strains, which grow on the medium, from *A. skirrowii* strains, which do not. Virtually all *Arcobacter* strains (92–100%) are susceptible to nalidixic acid, but there is much diversity among the species in susceptibility to cephalothin.

Useful phenotypic characteristics for the identification of *Arcobacter* spp. are summarized in Table 41.5. All *Arcobacter* strains produce oxidase, hydrolyse indoxyl acetate and catalase, although isolates of *A. butzleri* characteristically exhibit a weak catalase reaction. Virtually all strains of *A. nitrofigilis*, *A. butzleri* and *A. skirrowii* and 70% of the *A. cryaerophilus* strains have DNase activity. All strains are resistant to the pteridine vibriostatic agent O/129. *Arcobacter*

nitrofigilis strains are the least tolerant of the Arcobacteria to glycine, but are the most tolerant to NaCl, with some strains able to grow at a concentration of NaCl as high as 7.0% (McClung, Patriquin and Davis, 1983). The production of brown pigment from tryptophan is also unique to *A. nitrofigilis*, and the production of urease by strains belonging to other species of *Arcobacter* has not been reported (McClung, Patriquin and Davis, 1983). *Arcobacter nitrofigilis* is capable of nitrogen fixation and a test for nitrogenase is critical for a complete identification, but the test is not routinely provided in the clinical laboratory (Hardy *et al.*, 1968). Another criterion for differentiating the species of *Arcobacter* is colony appearance (Vandamme *et al.*, 1992b). On charcoal medium white colonies are produced by *A. nitrofigilis*, beige-to-yellow colonies by *A. cryaerophilus*, white-to-beige by *A. butzleri* and greyish colonies by *A. skirrowii*.

Correct identification of *Arcobacter* spp. is difficult with the use of conventional phenotypic characterization due to the limited number of species-specific characteristics and discrepancies between different workers (Table 41.5). More sophisticated techniques such as gas–liquid chromatography and molecular DNA methods are able to absolutely identify species with genus *Arcobacter*. Cellular fatty-acid profiles obtained by gas–liquid chromatography are unique to each *Arcobacter* spp. and are consistent with groupings produced from the results of DNA–rRNA and DNA–DNA hybridizations (Vandamme *et al.*, 1992b). The increased availability of DNA-based methods offer a more rapid and specific approach to detection and identification of *Arcobacter* spp. than conventional phenotypic-based methods. PCR-based methods using DNA probes may be used for routine identification of genus *Arcobacter* and specifically *A. butzleri* (Wesley *et al.*, 1995; Harmon and Wesley, 1996, 1997; Hurtado and Owen, 1997; Gonzalez *et al.*, 2000). *Arcobacter* species have been differentiated and identified using a PCR-based method with two distinct DNA amplifications at different annealing temperatures (Bastijns *et al.*, 1995). More recently, a multiplex PCR assay using five primers targeting the 16S and 23S rRNA genes has been developed for the rapid detection and identification of *A. butzleri*, *A. cryaerophilus* and *A. skirrowii* after 24 h

cultivation in *Arcobacter* broth supplemented with cefoperazone, amphotericin and teicoplanin (Houf *et al.*, 2000).

A high prevalence of *Arcobacter* has been reported in Danish pig abortions, with more than one species present including 40.7% *A. cryaerophilus*, 37% *A. skirrowii* and 22.2% unclassified (On *et al.*, 2002).

SPECIES OF THE GENUS ARCOBACTER

A. nitrofigilis

Arcobacter nitrofigilis is the type species of the genus (Vandamme *et al.*, 1991), but it comprises the most unique group in the genus. The bacteria are microaerophilic, nitrogen fixing and associated with the roots of a halophytic plant, *Spartina alterniflora*, which has as its habitat the sediments of salt marshes where the oxygen content is at reduced levels (McClung and Patriquin, 1980). It is not surprising, therefore, that in the laboratory it is capable of growth at low temperatures and in media with high concentrations of sodium chloride. The observation that cells suspended in distilled water undergo rapid lysis suggests that viability is dependent on the presence of salt. Bacteria of this species are thus unlikely to be isolated in clinical laboratories that set the temperature for isolation at 37 or 42 °C. There is no known significance with respect to disease production in humans or animals.

A. cryaerophilus

During investigations of spiral-shaped organisms from aborted bovine fetuses, an unusual group of strains was isolated on *Leptospira* medium under microaerobic conditions at 30 °C. On subculture, the bacteria were culturable under aerobic, anaerobic and microaerobic conditions (Ellis *et al.*, 1977). The requirement for the two-step isolation procedure and the ability to grow in air at low temperatures are unique attributes of the strains. They were first assigned to a newly created species in the genus *Campylobacter* with the epithet '*cryaerophila*' to reflect both their characteristic growth at low temperatures and their aerotolerance, although it was recognized that the group displayed considerable heterogeneity and that, as a group,

they were more distantly related to *Campylobacter* spp. than were the *Campylobacter* spp. to each other (Neill *et al.*, 1985). DNA-rRNA hybridization experiments showed that they clustered along with *C. nitrofigilis* in a separate group that did not include any of the other *Campylobacter* spp. (Vandamme *et al.*, 1991). The relationships were confirmed by DNA-DNA hybridization and were in agreement with the 16S rRNA homology groups determined by others (Thompson *et al.*, 1988). In accordance with these results, the species (accompanied by a correction of the spelling of the epithet) was transferred along with *C. nitrofigilis* to the newly described genus *Arcobacter* (Vandamme *et al.*, 1991).

Early collection of *A. cryaerophilus* isolates originated mostly from bovine, ovine and porcine fetal tissue and is associated with spontaneous abortions (On *et al.*, 2002). In a collection of *A. cryaerophilus* strains made at the Centers for Disease Control (CDC) in Atlanta Georgia, two isolates were from human blood cultures and one from the stool of a patient with severe gastroenteritis (Kiehlbauch *et al.*, 1991). Although no medical significance has been linked to these human isolates, it does suggest that with adoption by clinical laboratories of appropriate isolation techniques, the occurrence of *A. cryaerophilus* in human specimens could be shown to be much higher than is now suspected.

A. butzleri

Through a study of aerotolerant spiral-shaped bacteria at the CDC, a group of strains was discovered on the basis of DNA-DNA hybridizations to be distinct from bacteria now classified as *A. cryaerophilus*. A new species was proposed with the epithet '*butzleri*' and assigned to the genus *Campylobacter*, although the authors recognized that the new species would be placed in genus *Arcobacter* when the proposal for the new genus was accepted (Kiehlbauch *et al.*, 1991).

Arcobacter butzleri is the species most commonly associated with human infections (Pugina *et al.*, 1991; Taylor *et al.*, 1991; Vandamme *et al.*, 1992a; Lerner, Brumberger and Preac-Mursic, 1994). The first indication that *A. butzleri* strains were associated with human enteritis was through the report of a faecal isolate from a patient who experienced diarrhoea and abdominal pain. The isolate was identified as *C. cryaerophilus* (Tee *et al.*, 1988), but in subsequent investigations

at the CDC it was confirmed that it belonged to *A. butzleri* (Kiehlbauch *et al.*, 1991). Of the 63 other *A. butzleri* strains under investigation at the CDC, approximately 75% were also from human cases of diarrhoea (Kiehlbauch *et al.*, 1991). Evidence for a pathogenic role for *A. butzleri* mounted with the report of an outbreak of abdominal cramps without diarrhoea in a nursery and primary school in Italy (Vandamme *et al.*, 1992a). Fourteen isolates of *A. butzleri* from this outbreak were demonstrated to be epidemiologically linked through the application of PCR-mediated DNA fingerprinting (Vandamme *et al.*, 1993). *Arcobacter butzleri* is found not only in humans but also in a variety of animals. Among the CDC isolates, 10 were from non-human primates, three from porcine tissue samples, one from a bovine stomach and one from an ostrich yolk sac (Kiehlbauch *et al.*, 1991; Anderson *et al.*, 1993). Seven *A. butzleri* strains have also been recovered from infant monkeys (Russell *et al.*, 1992). *Arcobacter butzleri* has been isolated from food, such as poultry (Festy *et al.*, 1993) and ground pork (Collins, Wesley and Murano, 1994), as well as a variety of water sources, including ground water (Rice *et al.*, 1999), river water (Musmanno *et al.*, 1997), canal water (Dhamabutra, Kamol-Rathanakul and Pienthaweechai, 1992) and a drinking water reservoir (Jacob, Lior and Feuerpfel, 1993).

Authors with experience in investigating Arcobacteria, particularly *A. butzleri*, stress the importance of improving the isolation procedure. *Arcobacter butzleri* is not often isolated with media and cultural conditions appropriate for *C. jejuni* subsp. *jejuni*.

A. skirrowii

This species is the most recent addition to the genus *Arcobacter*. It was described for a group of aerotolerant strains that were initially believed to belong to *A. cryaerophilus* and have been isolated from animals (Vandamme *et al.*, 1992b, 1996).

Future research should address the seasonal nature to *Campylobacter* infections and the variety of environmental sources that may harbour this bacteria. It is not known why *Campylobacter* infections peak in late May–June each year, or why *Campylobacters* cannot multiply without a warm host, since other food-poisoning related bacteria do not need a host (Jones, 2001).

Treponemes

Andrew J. L. Turner

Manchester Medical Microbiology Partnership, Department of Clinical Virology, Manchester Royal Infirmary, Oxford Road, Manchester, UK

INTRODUCTION

Treponemes are spirochaetes, spiral bacteria, which cause four human diseases: syphilis and the endemic treponematoses. The treponematoses are distinguished on the basis of epidemiological characteristics and clinical manifestations. *Treponema pallidum* subspecies *pallidum* causes syphilis; *Treponema pallidum* subspecies *endemicum* causes endemic syphilis or bejel; *Treponema pallidum* subspecies *pertenue* causes yaws and *Treponema carateum* causes pinta (Table 42.1). Syphilis is transmitted sexually and can affect the foetus and central nervous system, whereas central nervous system involvement and congenital transmission do not occur in endemic treponemal infection.

Despite the continued efficacy of penicillin therapy and concerted public health programmes, the treponematoses remain important. WHO has estimated that 2.5 million people are affected by the endemic treponematoses (WHO, 1998) and that there were approximately 12 million new cases of infectious syphilis in adults worldwide in 1999 (WHO, 2001). Syphilis is endemic in many parts of Africa and Southeast Asia, and there have been major epidemics in the former Soviet Union and Eastern Europe recently. In contrast, rates of infectious syphilis in the United States in 2000 were the lowest since reporting began; this decline in syphilis rates following an epidemic in the late 1980s and the concentration of the syphilis in a relatively small number of areas were among the reasons that prompted the development of a national plan to eliminate syphilis from the United States (St Louis and Wasserheit, 1998). Nevertheless, there have been numerous outbreaks of syphilis since the late 1990s in the USA and in other countries. These outbreaks have often occurred among men who have sex with men and have been characterised by high rates of co-infection with HIV, highlighting concerns about interactions between syphilis and HIV infection.

Syphilis also remains topical because of the recent publication of the genome sequence of *T. pallidum* (Fraser *et al.*, 1998) and the impact

of the application of genomics and proteomics on the understanding of this hitherto enigmatic organism (Norris and Weinstock, 2000).

DESCRIPTION OF THE ORGANISM

The following sections concentrate on *T. pallidum*; the other treponemes are not discussed in detail.

Morphology

Treponema pallidum is spiral shaped, varying from 0.16 to 0.20 μm in diameter and 5–15 μm in length. Each organism typically has between 6 and 14 spiral turns and pointed ends, lacking the hook shape of some commensal human spirochaetes. As a result of its small size, it is difficult to see by conventional light microscopy; unstained organisms can be visualised by darkground microscopy and this can be used for diagnosis. Ultrastructurally, *T. pallidum* resembles Gram-negative bacteria, with a concentric arrangement of outer membrane, periplasmic space, peptidoglycan layer, inner (cytoplasmic) membrane and protoplasmic cylinder (Figure 42.1). However, the *T. pallidum* outer membrane differs from that of Gram-negative bacteria in that it lacks lipopolysaccharide (LPS); this has been confirmed by the lack of genes encoding LPS biosynthesis in the genome (Fraser *et al.*, 1998). It also has few transmembrane proteins; freeze-fracture studies have shown that the outer membrane of *T. pallidum* contains approximately 100-fold fewer transmembrane proteins than other spirochaetes and Gram-negative bacteria (Radolf, Norgard and Schulz, 1989). The cytoplasmic membrane appears to be more like that of Gram-negative bacteria and contains high concentrations of intramembranous particles which appear to include many of the abundant and highly immunogenic lipoproteins of *T. pallidum*, including Tpp 47, Tpp17, Tpp15 and possibly glycerophosphodiester phosphodiesterase,

Table 42.1 Characteristics of pathogenic Treponemes^a

Organism	Disease	Distribution	Pathogenicity in humans	Pathogenicity in animals
<i>Treponema pallidum</i> subsp. <i>pallidum</i>	Syphilis	Worldwide	Highly invasive; CNS and congenital infection	Rabbit, primate, guinea pig and hamster
<i>Treponema pallidum</i> subsp. <i>endemicum</i>	Bejel	North Africa, Near East and Southern Europe	Moderately invasive	Rabbit and hamster
<i>Treponema pallidum</i> subsp. <i>pertenue</i>	Yaws	Central Africa, South America and Indonesia	Moderately invasive	Rabbit and hamster
<i>Treponema carateum</i>	Pinta	Central and South America	Not invasive	Primate only

^aCompiled from Norris *et al.* (2001) and Antal *et al.* (2002).

Figure 42.1 *T. pallidum* ultrastructure. (A) Membrane architecture of *T. pallidum* subspecies *pallidum* as demonstrated by freeze-fracture electron microscopy. The figure shows the paucity of OM transmembrane proteins. (B) Proposed molecular architecture of *T. pallidum*. The OM is depicted as having rare transmembrane proteins, while major immunogens are lipoproteins (LP1 and LP2) anchored to the periplasmic leaflet of the OM. The bacterium is also shown with periplasmic endoflagellum (Ef) and peptidoglycan (pg)-cytoplasmic membrane (CM) complex. Adapted with permission from Cox DL *et al.* (1992) *Infection and Immunity* **60** (3), 1076–1083, as modified from *Microbes and Infection* Volume 4, Salazar JC *et al.*, page 1134, copyright (2002) with permission from Elsevier.

although this is controversial. It has been shown that Tpp47, the major 47 kDa lipoprotein of *T. pallidum*, is a penicillin-binding protein with carboxypeptidase activity (Weigel, Radolf and Norgard, 1994) and this suggests that the other lipoproteins associated with the cytoplasmic membrane may also be involved in peptidoglycan biosynthesis. A further difference from Gram-negative bacteria is that the endoflagella lie entirely within the periplasmic space. There are usually three endoflagella originating from each end of the organism; they run the length of the organism and overlap in the centre with those from the opposite end. They are responsible for motility, which is important in pathogenesis because of its role in tissue invasion and in dissemination; they are also important because they are highly antigenic, stimulating a strong early antibody response that persists throughout infection and is thus a potential target for serological tests.

Physiology and Cultivation

Although limited multiplication can be obtained by co-cultivation with rabbit epithelial cells (Fieldsteel, Cox and Moeckli, 1981), *T. pallidum* has not been continuously cultured *in vitro* and this has hindered understanding of the organism. Until recently, it was necessary to propagate the organism by intratesticular inoculation of rabbits for research. Most research has been done on the Nichols strain; modern isolates of *T. pallidum* appear to be closely related to this strain even though it has been maintained in rabbits since it was originally isolated from the cerebrospinal fluid (CSF) of a patient with neurosyphilis in 1912. *Treponema pallidum* is an obligate human parasite; analysis of the genome sequence has confirmed earlier data that indicated *T. pallidum* has minimal metabolic activity and biosynthetic ability. It does have an extensive set of transport proteins though, which would allow it to scavenge essential nutrients from its

human host (Norris and Weinstock, 2000). *Treponema pallidum* is microaerophilic; its sensitivity to oxygen appears to be due to its lack of superoxide dismutase, catalase and other oxygen radical scavengers. Again, this is confirmed by the genome sequence, which suggests no obvious mechanism for protecting against oxygen toxicity, other than NADH oxidase. It appears similar to lactic acid bacteria in its relationship with oxygen, which may provide further insights into *T. pallidum* (Norris, Cox and Weinstock, 2001). It has a relatively long generation time of 30–33 h, which may be partly responsible for the difficulty of *in vitro* culture and is also of therapeutic significance.

Phylogeny

The treponemes are classified in the genus *Treponema* within the Spirochaetaceae family of the order Spirochaetales; the order also includes the genera *Borrelia* and *Leptospira*. Spirochaetes are characterised by spiral morphology, motility and the periplasmic location of their flagella. The pathogenic treponemes are virtually indistinguishable in terms of DNA homology, morphology, protein content and physiology and until recently the only reliable criterion for differentiating them was their pattern of pathogenesis in humans and in experimentally infected animals (Table 42.1). On the basis of DNA homology and clinical observations, three of the human treponemal pathogens are now classified as subspecies of *Treponema pallidum*: *Treponema pallidum* subspecies *pallidum*, *Treponema pallidum* subspecies *endemicum* and *Treponema pallidum* subspecies *pertenue*; *Treponema carateum* is classified as a separate species. However, it was recently reported that it was possible to differentiate *Treponema pallidum* subspecies *pallidum* from subspecies *endemicum* and *pertenue* on the basis of differences in the flanking regions of the 15-kDa lipoprotein gene *tpp 15* (Tp0171) (Centurion-Lara *et al.*, 1998). Other differences have also been described, most notably in the *T. pallidum* repeat (*tpr*) genes.

Molecular Biology and Antigenicity

Developments in analytical techniques have enabled considerable advances in the understanding of *T. pallidum*. The application of methods including protein gel electrophoresis, monoclonal antibody technology and gene cloning enabled characterisation of the major antigens (Norris and the Treponema Pallidum Polypeptide Research Group, 1993). The recent sequencing of the *T. pallidum* genome (Fraser *et al.*, 1998) has allowed prediction of gene sequences and functions. This analysis can include assessment of missing functions, which is particularly relevant in *T. pallidum* given its limited metabolic capabilities.

The genome consists of a single circular chromosome of approximately 1000 kb pairs and no extrachromosomal elements; it is thus one of the smallest prokaryotic genomes containing 1041 open-reading frames (ORFs). Biological functions have been predicted for more than 50% of these ORFs; a further 17% match hypothetical proteins from other species; the remaining 28% did not have significant similarity to other known sequences, which is typical of most bacterial genomes that have been sequenced. The *T. pallidum* genome appears to lack transposable elements; furthermore there are few sequence differences between *T. pallidum* subspecies and strains, suggesting either that the variants evolved recently or that they are very stable in terms of DNA content (Norris and Weinstock, 2000). The fact that *T. pallidum* has so far not developed or acquired resistance to penicillin may be related to this apparent genetic stability.

The *T. pallidum* repeat (*tpr*) genes, which encode 12 *T. pallidum* repeat proteins, or Tpr proteins (TprA to TprL), do exhibit interstrain and intrastrain differences though. The *tpr* genes appear to be treponeme specific. The genome sequence suggests similarities to the *T. denticola* major sheath protein (Msp). The *T. denticola* Msp is

thought to be a surface-exposed protein which has porin activity and is involved in cell attachment, although this is controversial (Caimano *et al.*, 1999). Nevertheless, Centurion-Lara *et al.* (1999) reported that rabbits immunised with a recombinant fragment of one of the Tpr proteins, TprK, developed opsonic antibody and exhibited reduced lesion severity when challenged with *T. pallidum*, consistent with a surface localisation for TprK. These findings led them to suggest that variation in the expression of Tpr antigens may be important in the evasion of the immune response. Although this was challenged by Hazlett *et al.* (2001), the evidence of a protective effect of immunisation with TprK proteins has been confirmed (Morgan, Lukehart and Van Voorhis, 2002) and extended by demonstrating that protection correlates with the specificity of antibodies to the variable region of the TprK protein used as an immunogen (Morgan, Lukehart and Van Voorhis, 2003). Furthermore, the same group has reported increased diversity among TprK sequences upon passage, suggesting a possible mechanism for evasion of the host immune response, which could contribute to persistence and re-infection (LaFond *et al.*, 2003).

Recently, to circumvent the difficulties of obtaining *T. pallidum* DNA, a large insert bacterial artificial chromosome (BAC) library was constructed in *Escherichia coli* using the entire *T. pallidum* subspecies *pallidum* genome (Smajs *et al.*, 2002). The BAC library covered 97% of the total predicted *T. pallidum* ORFs. Twelve protein products were identified, seven of which corresponded to previously identified *T. pallidum* polypeptides, indicating that at least some *T. pallidum* genes are expressed in *E. coli* and that this approach can be used for functional studies. This BAC library was subsequently used to produce PCR products, encoding 96% of the total predicted *T. pallidum* ORFs, which were cloned into a variety of plasmids, permitting their rapid conversion into a series of other functional vectors (McKevitt *et al.*, 2003). In total, 85 of 248 predicted proteins were expressed in *E. coli*, 12 of which were recognised by rabbit anti-sera; seven of the 12 had previously been identified as *T. pallidum* antigens, the remaining five represent novel antigens. These two studies clearly illustrate the potential of functional genomics and proteomics for utilising the *T. pallidum* genome sequence data to identify antigenic proteins of potential significance in the development of diagnostic tests and, possibly, vaccines.

PATHOGENICITY

The pathogenesis of treponemal infection is poorly understood. In syphilis, infection is believed to occur following inoculation of *T. pallidum* through breaks in the skin or mucous membranes. An early inoculation study in human volunteers showed that as few as 10 organisms may lead to infection (Magnuson *et al.*, 1956). Local multiplication of the organism leads to the formation of a lesion, the chancre, at the site of inoculation, within days or weeks of exposure. Dissemination occurs during the primary stage, resulting in systemic infection: early animal studies demonstrated that the organisms appear in lymph nodes within minutes and disseminate widely within hours. *Treponema pallidum* is extremely invasive, rapidly attaching to mammalian cell surfaces and penetrating endothelial junctions and tissue layers (Thomas *et al.*, 1988; Riviere, Thomas and Cobb, 1989). Most of the pathology is apparently due to the host immune response (Sell and Norris, 1983). Invasiveness may also be important in establishing latent infection; *T. pallidum* may be able to penetrate to areas that are inaccessible to the immune response and hence avoid elimination. The immune response to *T. pallidum* has recently been reviewed in detail (Salazar, Hazlett and Radolf, 2002).

Treponema pallidum has limited toxigenic capabilities. The outer membrane lacks LPS and contains very few transmembrane proteins. This is thought to explain the poor antigenicity of the organism (Cox *et al.*, 1992) and has led to the hypothesis that the organism acts as a 'stealth' organism by minimising the number of surface-localised targets that can be recognised by the host immune system.

An analysis of the *T. pallidum* genome sequence for potential virulence factors by comparison of predicted coding sequences with sequences in databases (Weinstock *et al.*, 1998) identified 67 genes of potential pathogenic significance, including the *tpr* genes and genes encoding putative haemolysins, regulators, polysaccharide biosynthesis proteins and possible surface proteins; less than one-third of these genes had been identified previously, further emphasising the value of genome sequencing in identifying areas for future study. A comparative analysis of the predicted gene products of *T. pallidum* and *Borrelia burgdorferi* (Subrahmanian, Koonin and Aravind, 2000) identified proteins that had previously been undetected in these organisms, such as von Willibrand A factor (vWA) domain-containing proteins, which may be involved in pathogenesis; spirochaete vWA proteins are likely to be involved in adhesion and could be therapeutic targets.

EPIDEMIOLOGY

Syphilis is usually transmitted by the sexual route; vertical transmission also occurs, generally *in utero*. Other routes of transmission, such as blood transfusion and sharp injury, have been described but are uncommon now. The risk of sexual transmission has been estimated to be about 60% per partnership (Garnett *et al.*, 1997). The endemic treponematoses are transmitted by direct person to person contact and possibly, for bejel, via drinking vessels (Antal, Lukehart and Meheus, 2002).

The incidence of syphilis in most industrialised countries fell during the 1980s, following the advent of HIV/AIDS. However, there was an epidemic in the United States between the late 1980s and early 1990s. It mainly affected heterosexual black Americans and was associated with a dramatic increase in the use of crack cocaine, the exchange of sex for money and drugs, decreased effectiveness of STD prevention and control programmes, increasing poverty and urban decay (Nakashima *et al.*, 1996). The adult epidemic was paralleled by an increase in congenital syphilis, with more than 3000 cases annually around the time of the peak of the adult epidemic in 1990. With renewed public health efforts, the incidence of early syphilis declined and in 2000 it was the lowest since reporting began in 1941. However, it increased again in 2001 and 2002 but only in men; increases in rates of syphilis have been reported among men who have sex with men in several US cities and rates of other STDs have also increased in this group, reflecting a general increase in unsafe sexual behaviour concomitant with the availability of highly active anti-retroviral therapy (Katz *et al.*, 2002).

Similar increases have been reported elsewhere. In the United Kingdom, the incidence of infectious syphilis in men and women more than doubled between 1998 and 2000. This was partly due to several localised outbreaks, notably in Bristol, Manchester and London, involving homosexual men and heterosexual men and women; most infections were acquired in the United Kingdom. There were several common features to these outbreaks including high rates of partner change and of anonymous contacts; unprotected oral sex reported as the sole high-risk sexual practice; illicit drug use and HIV co-infection (Doherty *et al.*, 2002). The number of new diagnoses in the UK in 2002 was the highest since 1984 with a high proportion of cases among men who have sex with men and high rate of co-infection with HIV.

There were also dramatic increases in the incidence of syphilis in the former Soviet Union in the 1990s; in the Russian Federation, the notification rate increased 62-fold between 1988 and 1996, probably for a combination of reasons including poverty, unemployment, a decline in government-funded public health services and increased population movement with the opening of national borders (Tichonova *et al.*, 1997). Even though syphilis rates declined in the late 1990s, this was at least partly due to reduced case-finding and a shift from public sector provision to private healthcare services, which

are less likely to report cases (Reidner, Dehne and Gromyko, 2000). As in the earlier epidemic in the USA, the adult epidemic in the Russian Federation was accompanied by epidemic of congenital syphilis, which increased 26-fold between 1991 and 1999. Late presentation for antenatal care, or a complete lack of it, resulting in no treatment or inadequate treatment, contributed to the fact that more than 60% of infected mothers delivered an infant with congenital syphilis and to high rates of foetal or infant death (Tikhonova *et al.*, 2003).

Nevertheless, the treponematoses principally affect the developing world: WHO estimated that 4 million of a total of 12 million new cases of syphilis in adults in 1999 occurred in South and South-east Asia, with a further 4 million estimated to have occurred in sub-Saharan Africa and 3 million in Latin America and the Caribbean (WHO Department of HIV/AIDS and STDs, 2001). Likewise, the endemic treponematoses predominantly affect children under 15 years of age in the remote rural communities in the tropics, with bejel extending to the adjacent arid areas and some temperate zones. The burden of disease that they cause was substantially reduced by the global endemic treponematoses control programme conducted by WHO in the 1950s and 1960s, but the subsequent integration of the programme with local health services was ineffective, leading to a resurgence of endemic treponematoses in many areas. As a result, endemic foci remain in parts of Africa, Southeast Asia, the Pacific Islands and South America, with about 460 000 of the estimated 2 million current worldwide cases thought to be infectious (Antal, Lukehart and Meheus, 2002).

CLINICAL FEATURES

Syphilis

Syphilis is classified as acquired or congenital, with both being divided into early and late stages. Early acquired syphilis includes primary, secondary and early latent syphilis and late acquired syphilis includes late latent and tertiary syphilis.

Primary syphilis is characterised by an ulcer, or chancre, at the site of inoculation and regional lymphadenopathy. The incubation period is typically about 3 weeks but varies from 10 to 90 days. The chancre is classically in the anogenital region, single, painless and indurated, with a clean base that discharges serum. However, chancres may be atypical: they may be multiple, painful, purulent, destructive and extragenital.

Secondary syphilis usually develops 4–8 weeks after the primary lesion has healed, although this may vary from 2 weeks to 6 months. Up to one-third of patients still have a chancre. The lesions of secondary syphilis are generalised, affecting skin and mucous membranes. There is usually a rash, often affecting the palms and soles, condyloma lata (papular lesions which have coalesced in warm moist areas), mucocutaneous lesions, fever and generalised lymphadenopathy. Less common manifestations include anterior uveitis, meningitis, cranial nerve palsies, hepatitis, splenomegaly, periostitis and glomerulonephritis.

Primary and secondary syphilis resolve spontaneously and the infection then enters the latent stage, which is characterised by asymptomatic infection and positive serology. It is classified into early and late stages on the basis of the risk of recurrence; untreated, about 25% patients relapse and develop recurrent mucocutaneous lesions, which are infectious. About 90% recurrences occur during the first year, 94% occur within 2 years and the rest occur within 4 years of infection (Clark and Danbolt, 1955). Early latent syphilis is defined as the first 2 years following infection by WHO, as it is in the UK, whereas in the USA it is defined as the first year following infection.

After a variable period, usually many years, about one-third of untreated patients will develop tertiary syphilis, with about

15% developing gummatous (benign tertiary) syphilis, about 10% developing cardiovascular syphilis and the remaining 10% developing neurosyphilis. The latter two stages are sometimes classified as quaternary syphilis. Gummas are granulomatous lesions. They can occur in any organ but most commonly affect bone and skin; they can be locally destructive, so the term benign can be misleading. Cardiovascular syphilis usually affects large vessels, classically the ascending aorta when it may lead to aortic regurgitation, angina and aortic aneurysm. Neurosyphilis may either be asymptomatic, which is characterised by abnormal CSF findings but no associated neurological signs or symptoms, or symptomatic. In fact, central nervous system involvement can occur at any time following primary infection and is not confined to tertiary syphilis. It can present in many ways, which may overlap; in the pre-penicillin era, the most common manifestations were meningovascular and parenchymatous neurosyphilis. Parenchymatous neurosyphilis has become uncommon since the advent of antimicrobial therapy; it may present as tabes dorsalis, a syndrome due to dorsal column loss, or general paresis of the insane, a progressive dementia.

Syphilis and HIV Infection

It has been suggested that HIV alters the natural history and clinical presentation of syphilis. A greater risk of persistent chancres, more rapid progression to secondary syphilis, with ulcerative skin lesions as well as an increased risk of neurosyphilis have been described (Hutchinson *et al.*, 1994), but most patients with coincident HIV present with typical manifestations of syphilis.

Congenital Syphilis

Unlike the endemic treponematoses, syphilis can cause vertical infection; most infections are thought to occur *in utero*, although they may occasionally occur perinatally. The consequences include stillbirth, neonatal death or congenital infection, though some neonates escape infection. The outcome depends on the stage of maternal infection and the stage of pregnancy at which transmission occurs; it is worse if the mother has early syphilis but, in contrast to sexual transmission, vertical transmission can occur even with late latent infection. Transmission can largely be prevented by treatment before the 16th week of pregnancy (Fiumara, 1975). The clinical manifestations are divided into early congenital syphilis, occurring within the first 2 years of life, and late congenital syphilis which includes all aspects of the disease occurring after the second year of life. Early congenital syphilis may be symptomatic at birth, which is associated with a worse prognosis, or it may present later, usually within the first 5 weeks of life. Late congenital syphilis is often diagnosed incidentally, on the basis of positive serology, although it can lead to significant morbidity. The paediatric aspects of treponemal infection have been comprehensively reviewed recently (Parish, 2000).

The Endemic Treponematoses

The clinical manifestations of the endemic treponematoses are also divided into early and late stages; the early stage is considered to be infectious, or potentially infectious, and lasts up to 5 years from infection. The endemic treponematoses have a relapsing clinical course and prominent cutaneous manifestations. In pinta, this is the only clinical manifestation; in yaws and endemic syphilis, the mucous membranes and bones can also be affected. In contrast to syphilis, congenital disease and CNS involvement do not occur and late sequelae are usually limited to skin, bone cartilage and mucosal surfaces. Further details can be found in a recent review (Antal, Lukehart and Meheus, 2002).

Oral Treponemes

The oral treponemes, particularly *T. denticola*, are associated with periodontal disease. Difficulty in culturing oral treponemes and the complex nature of the oral microflora have hindered their study. However, the *T. denticola* genome has been sequenced recently (Seshadri *et al.*, 2004). It is considerably larger than that of *T. pallidum*; in part, this appears to be because of expansion of the genome and this may have pathogenic significance, although some of the additional genes are of unknown function. As with *T. pallidum*, this new information, together with the application of current molecular methods, for example quantitative PCR (Yoshida *et al.*, 2004), should lead to greater understanding of the pathogenic role of the oral treponemes.

LABORATORY DIAGNOSIS

The diagnosis of treponemal infection is based on a combination of clinical evaluation, direct detection of organisms and serological testing. Direct detection of treponemes, either by microscopy or PCR, is particularly important in early primary infection before antibody is detectable, but at all other stages of infection serology is still the mainstay of routine laboratory diagnosis. Detailed descriptions of the individual tests and their performance characteristics at different stages of infection can be found in several comprehensive reviews (Young, 1992; Larsen, Steiner and Rudolph, 1995; Wicher, Horowitz and Wicher, 1999).

Direct Detection of *T. pallidum*

Microscopy

Darkground microscopy is the traditional method for direct detection of *T. pallidum* in lesion exudates; it can provide rapid results, with identification of the organism by its characteristic morphology and motility; yet there are many limitations to the technique and it requires technical expertise which is no longer widespread. Immunofluorescence using fixed smears of lesion material, or tissue specimens, has several advantages and is of comparable sensitivity; neither technique differentiates between the pathogenic treponemes. Polyclonal antisera were originally used for immunofluorescence but, despite absorption with non-pathogenic treponemes, the results were non-specific. More recently described monoclonal antibodies are more specific but the reagents are not widely available.

PCR

PCR offers potential for direct detection of treponemes in lesion material, as well as other specimens which can present diagnostic difficulties, such as CSF. Several different assays have been described, using a variety of targets and test formats. The most commonly described target is the 47-kDa protein gene (*Tpp 47*); other approaches include reverse transcriptase PCR for 16S rRNA and multiplexing to allow detection of other causes of genital ulcers: *Haemophilus ducrei* and herpes simplex virus. Early reports suggested a lack of sensitivity; concerns have also been expressed about specificity, as the function of many of the target genes is unknown. This has stimulated efforts to develop novel *T. pallidum*-specific targets (Liu *et al.*, 2001). Although it has been a useful research technique, PCR has yet to find a role in clinical laboratories. However, a recent comparison of PCR with conventional diagnostic methods suggests that it may have a useful role (Palmer *et al.*, 2003); additional developments, such as real-time PCR, should enhance this potential.

Rabbit Infectivity Testing

The rabbit infectivity test (RIT) is still used as the 'gold standard' for evaluating methods such as PCR for detecting organisms in clinical specimens. The sensitivity of RIT approaches 100%, but it is too impractical a technique for routine use.

Serology

Treponemal antibody tests are classified into two groups: non-treponemal tests, which detect the so-called non-specific antibody, and treponemal tests which detect specific treponemal antibody. Non-treponemal tests include the Venereal Diseases Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. Treponemal tests include the *T. pallidum* haemagglutination test (TPHA), the *T. pallidum* particle agglutination test (TPPA), the fluorescent treponemal antibody-absorbed test (FTA-abs) and most treponemal antibody enzyme immunoassays (EIAs). The first detectable antibody response is treponemal IgM antibody, towards the end of the second week of infection; IgG antibody is detectable at about 4 weeks. Serology cannot distinguish between syphilis and the endemic treponematoses.

Serology has several applications: it is used for screening low-risk populations, for example routine screening in pregnancy or screening blood and organ/tissue donors; for screening high-risk populations, such as genitourinary medicine clinic attenders; for diagnostic testing of patients whose history of clinical features are consistent with syphilis and to assess the stage of infection and monitor the response to therapy. The approach varies: in the USA and some European countries non-treponemal tests are used for screening; some European countries screen with a TPHA alone whereas in the UK, a combination of a non-treponemal test and a treponemal test, typically either a VDRL or an RPR test in parallel with a TPHA test, has been used. Recently, however, treponemal antigen-based EIAs have become the most widely used screening test (Young, 2000). Guidance for UK laboratories on the use of serological tests (Egglestone and Turner, 2000) highlights the importance of confirming a reactive screening test result by additional testing, ideally using a methodologically independent test; for example, a TPHA would be suitable to confirm a reactive EIA screening test. The guidance also refers to the importance of testing a second specimen to confirm the results and the correct identification of the first specimen.

Non-Treponemal Tests

These are flocculation tests based on the use of cardiolipin, a phospholipid antigen. The VDRL is read microscopically; the RPR test is a modification of the VDRL test that can be read macroscopically and hence is more suitable to larger workloads. Both tests are cheap, simple and quick to perform. They detect IgG and IgM antibodies; antibody becomes detectable about 3–5 weeks after the acquisition of infection. Sensitivity is reported to be about 90% in primary syphilis and up to 100% in the secondary stage. However, false-negative reactions occur in the presence of high titres of antibody (the prozone phenomenon) and false-positive reactions are seen in various acute and chronic conditions in the absence of syphilis (biological false-positive reactions). If performed quantitatively, the non-treponemal tests can be used to assess the stage of infection and the response to treatment.

Treponemal Tests

The FTA-abs is an indirect immunofluorescence test. It becomes reactive around the third week of infection and in primary syphilis has a sensitivity of about 85–100%. Although it has been regarded as the 'gold-standard' treponemal test, it is subjective and poorly

standardised and is becoming less widely used, at least in the UK, as its limitations are increasingly recognised (Young, 2000). The TPHA is based on the agglutination of red cells coated with *T. pallidum* antigen. It is less sensitive than the FTA in early primary syphilis but it is more specific. The TPPA, which is based on the use of gelatin particles rather than red cells, appears to be more sensitive and more specific than the TPHA and thus an acceptable alternative (Pope *et al.*, 2000) and it is replacing it as a confirmatory test.

There are now numerous commercially available treponemal EIAs, based on different formats and antigens and capable of detecting treponemal IgG, or IgG and IgM. Many are now based on recombinant antigens, such as one or more of the lipoprotein antigens Tpp15, Tpp17 and Tpp47. IgM-specific assays are also commercially available. There are few published comparative evaluations, but in one study the sensitivity of EIA in early primary syphilis was reported as up to 77% for combined IgG and IgM assays, compared to 87% for an IgM-specific EIA (Schmidt, Edjlalipour and Luger, 2000). An earlier study had reported a sensitivity of 93% in primary syphilis for an IgM-specific EIA (Lefevre, Bertrand and Bauriad, 1990); the assay is an antibody capture assay and more specific than the FTA-abs IgM test. It is recommended that an IgM test should be used in all cases of suspected primary infection, regardless of the screening test results (Young, 2000). IgM testing is also useful in congenital infection: serial testing is recommended because of the possibility that specific IgM may not be detectable at birth even in infected infants.

Developments in serodiagnosis are likely to follow the sequencing of the *T. pallidum* genome. For example, a putative outer membrane protein (Tp0453) appears to be highly sensitive for early syphilis (Van Voorhis *et al.*, 2003); surface-exposed antigens have theoretical advantages for the diagnosis of all stages of infection, but further work will be required to confirm this potential.

Immunoblots

Western blots and a line immunoassay for treponemal antibody are now commercially available; the line assay uses recombinant and synthetic polypeptide antigens and has been proposed as a confirmatory test (Hagedorn *et al.*, 2002), although this requires further evaluation.

Rapid Tests

Several simple, rapid tests for treponemal antibody are now commercially available; most are in the format of an immunochromatographic strip. An evaluation of these assays was recently published by the WHO Sexually Transmitted Diseases Diagnostics Initiative (WHO, 2003). Sensitivity, compared to TPHA or TPPA testing, varied from 85 to 98%. The rapid assays are potentially suitable for non-laboratory use in the developing world, and they may also have a role as point of care tests elsewhere.

Testing CSF

Laboratory confirmation of neurosyphilis remains problematic. CDC guidelines highlight the importance of considering serological tests, abnormalities of CSF cell count or protein or a reactive VDRL test on CSF. A reactive VDRL test on CSF, in the absence of blood contamination of the CSF, is considered diagnostic of syphilis (CDC, 2002), but false-negative VDRL results can occur. In contrast, a negative treponemal test result on CSF is generally accepted as excluding neurosyphilis. Various indices have been suggested for detecting intrathecal synthesis of treponemal antibody in order to confirm a diagnosis of neurosyphilis (for further details, see Young, 1992); however, routine experience of them is limited and none has been widely adopted.

Response to Treatment

The non-treponemal tests tend to become negative after treatment, particularly in early syphilis and, contrary to some teaching, this also occurs with the treponemal tests (Romanowski *et al.*, 1991). The rate of decline in non-treponemal test titres depends on the stage of infection, the initial titre and the history of previous syphilis. Titres decline approximately fourfold within 6 months in patients with primary or secondary syphilis; in early latent syphilis, it may take 12 months for a fourfold decline in titre to occur (Romanowski *et al.*, 1991). In late syphilis, the non-treponemal tests may remain positive at low titres for many years, the so-called 'serofast syphilis'. IgM testing is less useful than non-treponemal testing because IgM reactivity may persist for many months; quantitative non-treponemal tests are still preferred (Egglestone and Turner, 2000).

Molecular Typing

A PCR-based typing system for *T. pallidum* subspecies *pallidum* has been described (Pillay *et al.*, 1998), on the basis of a combination of size heterogeneity within the acidic repeat protein (*arp*) gene and RFLP patterns of three members of the *tpr* gene family (*tpr* E, G and J). This technique has been applied to genital specimens and blood samples from the USA, Madagascar and South Africa; in South Africa 35 subtypes were identified, with 82 of 161 (51%) specimens belonging to four subtypes (Pillay *et al.*, 2002). This pattern, with a limited number of predominant subtypes together with some strain diversity, suggests that this typing system may be useful in epidemiological studies.

TREATMENT

Penicillin remains the treatment of choice for syphilis and the endemic treponematoses. The efficacy of penicillin was established before randomised clinical trials became routine practice, so recommended regimes are based on a combination of data derived from rabbit models, extensive clinical experience, case series and limited clinical trials. The preparation used (benzathine, aqueous procaine or aqueous crystalline), the dose and duration of treatment depend on the stage and clinical manifestations of disease. The aim is to achieve treponemocidal levels of antimicrobial, which for penicillin is greater than 0.018 mg/l, for at least 7 days to cover a number of division times (30–33 h) of treponemes, with a subtreponemocidal interval of not more than 24–30 h, in early syphilis. A longer duration of treatment is used in late syphilis when the organisms are thought to divide more slowly. Parenteral rather than oral therapy has been the standard approach because of better bioavailability and because treatment is supervised. Recommendations on the preparation used vary; US guidelines are largely based on the use of benzathine penicillin (CDC, 2002); in the UK, although benzathine penicillin is also recommended, procaine penicillin is the treatment of choice (Goh and French, 1999); the WHO recommends benzathine penicillin as first-line therapy with procaine penicillin as an alternative (WHO Department of HIV/AIDS and STDs, 2001). These respective guidelines should be referred to for further details of management, including alternatives in penicillin allergy, treatment in pregnancy, treatment of HIV co-infected patients and of neurosyphilis, follow-up and partner notification.

PREVENTION AND CONTROL

The aims of control programmes are similar for syphilis and the endemic treponematoses: to interrupt transmission, to reduce the duration of infection and to prevent the development of complications of infection. For syphilis, this requires a range of well-established measures, including health education; promotion of safer sex;

provision of accessible, effective and acceptable care and early detection and treatment through case finding, screening and partner notification. Syphilis among women in the USA has largely been controlled by conventional methods and rates declined for the twelfth consecutive year in 2002. In contrast, the current outbreaks of syphilis among men who have sex with men are proving difficult to control and are probably the main obstacles to the current national plan to eliminate syphilis from the United States. One reason for this difficulty may be the high proportion of anonymous contacts, which makes conventional partner notification ineffective; however, evidence that the Internet is used increasingly as the initial means of meeting sexual partners has prompted public health authorities also to use the Internet for partner notification, with some success (CDC, 2004b). The need for additional novel strategies for outbreak control is recognised but they need to be developed and evaluated. Screening in venues where transmission is likely to occur is advocated in the UK (Doherty *et al.*, 2002) but is of unproven benefit. Targeted mass treatment with azithromycin failed to control an outbreak amongst heterosexuals. In Vancouver, Canada (Rekart *et al.*, 2003), a recent report of azithromycin treatment failures has cast doubt on its potentially valuable role (MMWR, 2004). The importance of antenatal screening is well recognised though, including additional testing in the third trimester and at delivery in areas with a high incidence of syphilis (CDC, 2002).

Clearly, there are even greater challenges in the developing world, both for syphilis and the endemic treponematoses. The control measures required for the endemic treponematoses include community screening programmes combined with mass treatment; adequate diagnosis of symptomatic patients with contact tracing and treatment; health education and improved hygiene. These activities need to be underpinned by effective surveillance and logistic support. Efforts to control the endemic treponematoses stalled in the late 1970s, leading to resurgent disease in many areas. Like syphilis, the endemic treponematoses have many of the characteristics that make them susceptible to elimination and the failure to eliminate them is more because of political and management issues than technical difficulties (Antal, Lukehart and Meheus, 2002).

There have been major advances in the understanding of the treponemes since Schaudinn and Hoffman first identified *Spirochaeta pallida* (*T. pallidum*) in syphilitic lesions in 1905, particularly in recent years, and there are realistic prospects for further advances, building on the information provided by the sequencing of the *T. pallidum* genome.

Borrelia spp.

Sudha Pabbatireddy and Benjamin J. Luft

Department of Medicine, Division of Infectious Diseases, Stony Brook, NY, USA

HISTORY

Lyme disease is a multisystem, vector-borne, zoonotic infectious disease caused by *Borrelia burgdorferi*: a thin, spiral, motile, extracellular bacterium belonging to the family Spirochaetaceae. The hallmark of infection, erythema migrans (EM), an annular erythematous skin lesion that usually appears at the site of the tick bite was first described by Afzelius in 1909. In the 1930s, Hellerstrom linked EM with the development of meningitis and in the early 1940s Bannwarth associated EM with a syndrome consisting of painful radiculopathy, limb pain, and cerebrospinal fluid pleocytosis. The French physicians Garin and Bujadoux reported the first case of a neurologic manifestation, meningoradiculoneuritis (Kristoferitsch, 1989). The first suggestion that this was a spirochetal infection came in 1948 when Lenhoff, a Swedish pathologist, observed spirochete-like structures in skin biopsies from EM lesions. In 1976 Allen Steere and colleagues noted an association between EM and a cluster of patients with knee arthritis in Old Lyme, Connecticut (Steere *et al.*, 1977b) and described a syndrome of Lyme arthritis. In the subsequent decade, Steere and colleagues defined the multisystem nature of the disease and modified the name to Lyme disease.

The first isolate of this disease-causing spirochete was only obtained in 1981 when Burgdorfer and colleagues demonstrated a new spirochete in *Ixodes* ticks collected on Shelter Island, NY (Burgdorfer *et al.*, 1982). In 1982, spirochetes were identified in the midgut of the adult deer tick, *Ixodes dammini*, and given the name *Borrelia burgdorferi*. Finally, conclusive evidence that *B. burgdorferi* caused Lyme disease came in 1984 when spirochetes were cultured from the blood of patients with EM, from the rash lesion itself, and from the cerebrospinal fluid of a patient with meningoencephalitis and history of prior EM.

DESCRIPTION OF THE ORGANISM

Borrelia are members of the Spirochaetaceae that also include the treponemes. They are helical organisms between 8 and 30 μm long and 0.2–0.5 μm wide. They have up to 10 loose spirals and are actively motile via flagella that wind around the cells. The organisms are readily killed by ultraviolet light and desiccation.

The *Borrelia* have a complex relationship with their vector hose. For *Borrelia burgdorferi* and related species *Borrelia garinii* and *Borrelia afzelii* the vector is the Ixotid tick. For the 15 species responsible for tick-borne relapsing fever the vectors are soft ticks of the *Ornithodoros* genus and for *B. recurrentis* it is the human body louse *Pediculus humanus*.

PATHOGENESIS

Antigenic Structure

Borrelia are flexible helical cells comprised of a protoplasmic cylinder surrounded by a cell membrane, seven to 11 periplasmic flagella and an outer membrane that is loosely associated with the underlying structures. *Borrelia burgdorferi* B31, a tick (*Ixodes scapularis*) isolate from Shelter Island, NY (Burgdorfer *et al.*, 1982), is the type strain of the species *B. burgdorferi* sensu stricto. The DNA sequence of *B. burgdorferi* type strain B31 was published in 1997 and contains 950-kb linear chromosome, nine linear plasmids and 12 circular plasmids (Barbour and Hayes, 1986; Fraser *et al.*, 1997). The remarkable aspect of the *B. burgdorferi* genome is its large number of sequences for predicted or known lipoproteins, including the plasmid-encoded outer-surface proteins (Osp) A through F. These and other differentially expressed outer-surface proteins presumably help the spirochete adapt to and survive in markedly different arthropod and mammalian environments (de Silva and Fikrig, 1997). In addition, during early, disseminated infection, a surface-exposed lipoprotein, called VlsE, has been reported to undergo extensive antigenic variation (Zhang and Norris, 1998). The organism has few proteins with biosynthetic activity and apparently depends on the host for most of its nutritional requirement. Furthermore, the high concentration of outer-surface lipoproteins encoded by the plasmids (Casjens *et al.*, 2000) in conjunction with the variability of plasmid sequences supports the view that these sequences are directly involved in parasite–host interactions and therefore are more than likely to be key virulence factors.

Two major outer-surface proteins, OspA and OspB, are encoded by the same 50-kb linear plasmid and share 56% sequence homology (Dworkin *et al.*, 1998). Along with lipoprotein 6.6, these proteins are expressed primarily in the arthropod phase of the enzootic cycle (Le, 1980; Rawlings, 1995). OspA has an antiparallel beta strand topology with a middle nonglobular region connecting globular N- and C-terminal domains (Sanford, 1976). During tick feeding, as the spirochete migrates from the midgut to the salivary gland, OspC, which is encoded by a 26-kb circular plasmid, is upregulated (Horton and Blaser, 1985). OspE and OspF are immunogenic in some patients (Galloway *et al.*, 1977). A number of proteins have been identified that are differentially expressed by the spirochete during early infection, including decorin-binding proteins A and B (DbpA and DbpB) (Beutler and Munford, 1996) and a 47-kD fibronectin-binding protein (Probert and Johnson, 1998). Additional spirochetal proteins include a 39-kD *Borrelia* membrane protein A (BmpA) (Simpson, Schrumpp and Schwan, 1990), the 41-kD flagellar antigen (Coleman and

Benach, 1989), 60- and 73-kD heat-shock proteins (Hansen *et al.*, 1988; Anzola, Luft and Gorgane, 1992), a 66-kD integral outer-membrane protein that may function as a porin (Skare *et al.*, 1997) and a 93-kD antigen that is a part of the protoplasmic cylinder (Luft *et al.*, 1992).

Genetic Variation

Globally, about 10 genomic species of the *B. burgdorferi* sensu lato species complex have been recognized (Balmelli and Piffaretti, 1996). Most *Borrelia* genomic species have restricted geographical distribution, a consequence of geographic isolation (Price, 1980), and possible adaptation to the local enzootic transmission cycle of ticks and vertebrate hosts (Baranton, Marti Ras and Postic, 1998; Baranton *et al.*, 2001). In the Northeast, where over 90% of Lyme disease cases in the US occur annually *B. burgdorferi* sensu stricto is the predominant genospecies. A survey of *Borrelia* carried by *I. scapularis* ticks along the East coast concluded that *Borrelia* and its tick vector share a common evolutionary history of co-expansion within this geographic region (Qiu *et al.*, 2002).

Borrelia strains isolated from local tick samples in the Northeast are highly diverse. The *Borrelia* local diversity is reflected by high sequence variation of ospC alleles, infection of single ticks by multiple ospA and ospC strains as well as by a nearly even allelic frequency distribution of these alleles at each locality (Guttman *et al.*, 1996; Wang *et al.*, 1999; Qiu *et al.*, 2002). Previous studies have shown considerable genetic variation in *B. burgdorferi* (Wilske *et al.*, 1988; Boerlin *et al.*, 1992; Wallich *et al.*, 1992). These and other studies have subdivided this species into a species complex, which includes *B. burgdorferi* sensu stricto, *B. afzelii*, *B. japonica* (Baranton *et al.*, 1992; Kawabata, Masuzawa and Yanagihara, 1993) and several other groups (Valsangiacomo *et al.*, 1993; Postic *et al.*, 1994; Balmelli and Piffaretti, 1995). The first three species, *B. burgdorferi*, *B. afzelii* and *B. garinii*, are the only ones that have been isolated from humans, and each has been shown to be associated with a set of symptoms in chronic disease (van Dam *et al.*, 1993; Balmelli and Piffaretti, 1995). In the United States, *B. burgdorferi* and three new genospecies have been isolated (*B. andersonii*, *B. bisettii* and *B. lonestari*), while in Europe, all three pathogenic genospecies and two of the others are known to occur. One genospecies (*B. turdae*) has been found only in Japan, while another (*B. sinica*) appears to be restricted to China. So far, *B. burgdorferi* is the only genospecies that has been found in both North America and Europe, which is consistent with the recent migration and geographic range expansion of this species.

The evolutionary cause of high local diversity of *Borrelia* is most likely the host-driven, immune-mediated selection for antigenic variation (Qiu *et al.*, 1997; Wang *et al.*, 2002), surface lipoproteins like OspC, which has been shown to be a key component in parasite-host interaction in animal models (Schwan, 1996), are the most likely targets of such selection.

The B31 genome encodes 136 putative lipoproteins; 38 of these putative lipoproteins are chromosomally encoded while 98 are plasmid encoded. It is, however, unknown how many of these putative lipoproteins are actually expressed or how they differ in their degree of immunoreactivity. Even though the chromosomal genes and ospA are quite homogeneous within *B. burgdorferi*, ospC is highly polymorphic within and between the various genospecies (Dykhuisen *et al.*, 1993; Thiesen *et al.*, 1995). In nature humans are a dead-end hosts for *B. burgdorferi*, i.e., humans do not play a prominent role in the life cycle of this organism. Therefore, the spirochete is not adapted to humans and, as a consequence, many genospecies seem not to be human pathogens. The extensive genetic and antigenic diversity of OspC in all three pathogenic genospecies of *B. burgdorferi* sensu lato has led us to lead to chronic infection and, therefore, be used as a marker to discover new protective antigens (Thiesen *et al.*, 1993). We have shown that alleles of OspC could be clustered into 19 major groups or types designated A–S based on DNA sequence homology (Wang *et al.*, 1999). Sequence variation within a major

group is <1% but 15% across all the groups. We have also shown certain OspC alleles are tightly linked to both infectivity and invasiveness. Of the 19 major groups, only four, designated A, B, I and K, contain invasive clones and cause infections of skin and extracutaneous sites, while the others are non-pathogenic for humans or infect only the skin (Seinost *et al.*, 1999). The analysis of ospC gene variability has recently been extended to the other pathogenic *Borrelia* species, *B. garinii* and *B. afzelii*. In that study, only two groups in *B. afzelii* and four groups in *B. garinii* caused invasive disease (Baranton *et al.*, 2001). Thus the ospC gene can be used to predict infectivity and pathogenesis in humans. Wormser and colleagues assessed the pathogenicity of *B. burgdorferi* clinical isolates to determine any potential association between severity of disease and genotype of the infecting *B. burgdorferi*. Isolates were characterized by RFLP analysis and grouped into three rDNA spacer+RFLP genotypes. A highly significant association was found between specific *B. burgdorferi* genotype and hematogenous dissemination in patients with early Lyme disease and disease severity in a murine model of Lyme borreliosis (Wormser *et al.*, 1999).

Despite availability of the B31 genome sequence, the pathogenesis of Lyme disease is not well elucidated; however, considerable anecdotal evidence indicates that *Borrelia* plasmids are important in pathogenesis. *In vitro* passage of *B. burgdorferi* is associated with loss of plasmids (Barbour, 1988). Plasmid loss after 10–17 passages is also coupled with decreased infectivity in mice and changes in spirochetal protein expression (Johnson, Marek and Kodner, 1984; Moody, Barthold and Tergwilliger, 1990). High- and low-infectivity phenotypes of *B. burgdorferi* coexist in an uncloned population, but the proportion of high-infectivity phenotypes decreases with serial *in vitro* passage (Norris *et al.*, 1995). Plasmid profiles vary among certain *B. burgdorferi* sensu lato strains (including *B. burgdorferi* sensu stricto, *B. garinii* and *B. afzelii*) as well as within high- and low-passaged cultures; this variance is associated with infectivity of *B. burgdorferi* in mice. Two recent studies have suggested that plasmids Lp25 and Lp28-1 encode virulence factors involved in *B. burgdorferi* pathogenicity (Purser and Norris, 2000; Labandeira-Rey and Skare, 2001). However, the association between the loss of specific plasmid and loss of infectivity has not been universally observed (McDowell *et al.*, 2001). Clearly, more complex mechanisms independent of plasmid loss appear to be at play. These may include loss of specific genes, small-scale mutations or rearrangements in essential genes and/or differences in gene-expression patterns among clonal populations.

EPIDEMIOLOGY

In the United States, surveillance for Lyme disease was begun by the Centers for Disease Control (CDC) in 1982. Since that time the number of reported cases has increased dramatically. The Council of State and Territorial Epidemiologists designated Lyme disease as a nationally notifiable disease in January 1991. In 2002, 23 763 cases were reported to the CDC, making Lyme disease the most common vector-borne disease in the United States (CDC, 2004). As many as 90% of Lyme disease cases may go unreported. The infection is reported in 49 of the 50 US states, but most cases occur in the Northeastern Midwest and North Central regions of the United States. Nine states account for more than 90% of the reported cases, with Connecticut leading the group. The other states are Rhode Island, New York, Pennsylvania, Delaware, New Jersey, Maryland, Massachusetts and Wisconsin (Melski, 2000; CDC, 2001). The rising incidence of Lyme disease in recent years in the United States may be explained by multiple factors, including an increase in the numbers of Ixodid ticks, the outward migration of residential areas into previously rural woodlands (habitats favored by Ixodid ticks and their hosts), rising deer population and increased recognition by patients and clinicians.

The infecting organism, *B. burgdorferi*, is maintained in and transmitted by ticks of the *Ixodes ricinus* complex, including *I. scapularis* in northeast and northcentral USA, *I. pacificus* on the west coast of the USA, *Ixodes ricinus* in Europe and *I. persulcatus* in Asia (Nadelman and Wormser, 1998). In Europe, three genospecies of the *B. burgdorferi* sensu lato complex are pathogenic, including *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelii*. *Borrelia burgdorferi* is the only pathogenic species in North America. The varying relative distribution of these genospecies from region to region throughout Europe and Asia may account for the relative variability of disease syndromes associated with Lyme disease. In the United States, the majority of affected individuals have had symptoms of the illness (Steere *et al.*, 1986; Lastavica *et al.*, 1989), whereas in Europe, the majority have been asymptomatic. Of 346 people who were studied in the highly endemic area of Liso, Sweden, 41 (12%) had symptoms of the illness and 89 (26%) had evidence of subclinical infection (Fahrer *et al.*, 1991). In a serosurvey of 950 Swiss orienteers, 26% had detectable IgG antibodies to *B. burgdorferi*, but only 2–3% had a past history of definite or probable Lyme borreliosis (Gustafson *et al.*, 1992). The ages of patients range from 2 to 88 years (median, 28 years), and the sex ratio is nearly 1:1 (Steere *et al.*, 1983a). Age-adjusted attack rates show a bimodal distribution, with the greatest risk of acquiring the illness in children and middle-aged adults. Additional borrelial species that have been identified are *B. valasiana* and *B. lusitanae*; although the role of the former in promoting human disease is not entirely clear, it has been detected by polymerase chain reaction (PCR) in skin biopsies of a few patients with symptomatic acute and chronic skin disease. However, the organism has not been cultured from these lesions (van Dam *et al.*, 1993; O'Connell *et al.*, 1998; Weber, 2001).

In field studies in Connecticut and New York, *B. burgdorferi* has been found in 10–50% of nymphal and adult *I. scapularis* (Magnarelli *et al.*, 1976; Bosler *et al.*, 1983). Although *B. burgdorferi* has been demonstrated in mosquitoes and deer flies (Magnarelli and Anderson, 1988), however only ticks of the *I. ricinus* complex seem to be important in the transmission of the spirochete to humans. The seasonal variation of onset in temperate climatic zones is explained by the ecology of the predominant tick vectors. Among the Ixodid tick vectors, the life cycle and feeding habits of *I. scapularis* are best understood. This tick has a three-stage life cycle (larva, nymph and adult) that spans 2 years. Larvae hatch from fertilized eggs in late spring and feed once for 2 or more days in midsummer. Preferred hosts include a broad range of small mammals. The next spring they molt into nymphs, and feed again from 3 or 4 days, with the same host range. After this second blood meal, the nymphs molt into adults. Adult *I. scapularis* has a narrower host range, with a preference for deer. Mating occurs on deer, and the female deposits her eggs and the cycle begins anew (Spielman *et al.*, 1985). During their 2-year life cycle, ticks typically feed once during each of the three stages, usually the late summer for larval ticks, the following spring for nymphs, and autumn for the adults. *Ixodes scapularis* nymphs appear to be the most important vector for transmission of *B. burgdorferi*. According to laboratory studies, a minimum of 36–48 h of attachment of the tick is required for transmission. In the United States, most cases involving *B. burgdorferi* occur between May and August, which corresponds with increased outdoor human and nymphal tick activity.

Lyme disease affects all age groups and both sexes, and transplacental transmission of *B. burgdorferi* has been reported, but seems to be very infrequent (Schlesinger *et al.*, 1985; Weber *et al.*, 1988).

Markowitz *et al.* (1986) retrospectively reviewed 19 cases of Lyme disease during pregnancy and noted adverse fetal outcomes in five cases.

The risk of infection in a given area depends largely on the density of these ticks as well as on their feeding habits and animal hosts, which have evolved differently in different locations. In the northeastern and north central United States, *I. scapularis* ticks are abundant, and a highly efficient cycle of *B. burgdorferi* transmission

occurs between immature larval and nymphal *I. scapularis* ticks and white-footed mice (Spielman, 1994), resulting in high rates of infection in nymphal ticks and a high frequency of Lyme disease in humans during the late spring and summer months (Orloski *et al.*, 2000). The proliferation of deer, which are the preferred host of the adult tick, was a major factor in the emergence of epidemic Lyme disease in the northeastern United States during the late twentieth century.

Ixodes scapularis is a vector for the agents of human granulocytic ehrlichiosis and *Babesia microti*. *Ixodes scapularis* and other ticks in the *I. ricinus* complex may transmit multiple pathogens. The proportion of *I. scapularis* or *I. ricinus* ticks coinfecting with both *B. burgdorferi* sensu lato and *Anaplasma phagocytophila* is generally low, ranging from <1 to 6% in six geographic areas. A higher prevalence of tick coinfection (26%) has been reported in Westchester county, NY. The proportion of *Ixodes* ticks coinfecting with *B. burgdorferi* and *Babesia microti* has ranged from 2% in NJ to 19% on Nantucket Island, Massachusetts. Among patients with a confirmed tick-borne infection, coinfection rates as high as 39% have been reported. The most commonly recognized coinfection in most of the eastern United States is Lyme borreliosis and babesiosis, accounting for approximately 80% of coinfections (Krause *et al.*, 1996).

An enzootic cycle of infection is maintained through passage of *B. burgdorferi* back and forth between ticks and their hosts. Infected nymphal ticks transmit *B. burgdorferi* to mice, which serve as a reservoir from which uninfected larvae may acquire infecting organisms. In this manner, a high rate of infection can be maintained in the tick population when the organism, ticks, mice, and deer are all present in the environment.

The establishment and maintenance of an enzootic cycle requires a competent reservoir host in addition to a tick vector. Variation in vector–host relationships provide the primary explanation for wide regional variation in the rate of infection in the tick population in California (Brown and Lane, 1992), southeast (Oliver *et al.*, 1993) and northeast United States.

On the west coast of the United States the nymphal stage of *I. pacificus* prefers to feed on lizards rather than rodents, and lizards are not susceptible to infection with *B. burgdorferi* (Manweiler, Lane and Tempelis, 1992). There, the spirochete is maintained in nature in a horizontal cycle between the dusky-footed woodrat *Neotoma fuscipes* and *I. neotomae*, a tick that does not feed on humans (Brown and Lane, 1992). The infection range of *I. pacificus* ticks is only 1–3%, and the number of cases on the West Coast is much less than that on the East Coast.

In Europe, Lyme borreliosis is widely established in forested areas. The highest reported frequencies of the disease are in middle Europe and Scandinavia, particularly in Germany, Austria, Slovenia, and Sweden (Stanek *et al.*, 1993). The infection is also found in Russia, China, Japan, and the UK.

CLINICAL MANIFESTATIONS

Lyme disease is a progressive infectious disease with a wide array of clinical manifestations. Infection begins locally in the skin after *B. burgdorferi* is inoculated by a feeding tick. In the majority of individuals, the initial sign of infection is the development of EM (Luft and Dattwyler, 1989). Even at this early phase of infection the clinical expression of the disease is highly variable. Some individuals are relatively asymptomatic, while others develop fever, arthralgias, myalgias, conjunctivitis, meningismus, or multifocal EM lesions, and still others develop more dramatic signs of infection, including acute meningitis, myocarditis with or without conduction block abnormalities, hepatitis, myositis, or frank arthritis. Up to 50% of infected individuals will go on to develop manifestations of late disease if not treated in the acute phase of the infection. In chronic phase of the illness, localized inflammatory processes may occur in one or more organ systems, particularly the nervous and the musculoskeletal systems.

Furthermore, it may be important to know the chronicity of the infection since the pathogenesis of the disease and the response to therapy may be different in patients with acute versus chronic disease. In general, three stages of the illness – early localized disease, early disseminated disease, and persisting late disease can be distinguished.

Coincident Infections

It is significant to note that other zoonotic diseases transmitted by *Ixodes* ticks may occur concomitantly with *B. burgdorferi*. Babesiosis and HGE can occur independently or together with Lyme disease. The first coinfection with *B. burgdorferi* and *B. microti* was reported in 1983 (Grunwaldt, Barbour and Benach, 1983) and the first coinfection of *B. burgdorferi* and *A. phagocytophila* in 1997 (Nadelman *et al.*, 1997). Coinfection may be common because 2.2–26% *I. scapularis* ticks may be coinfecting with *B. burgdorferi* and *A. phagocytophila* (Belongia *et al.*, 1999). A higher prevalence of tick coinfection (26%) has been reported in Westchester County, NY. The proportion of *Ixodes* ticks coinfecting with *B. burgdorferi* and *Babesia microti* ranged from 2% in New Jersey to 19% on Nantucket Island, Massachusetts. In humans, cross-sectional seroprevalence studies have found markers of dual infection in 9–26% of patients with a tick-borne infection, but such studies often fail to distinguish simultaneous coinfection from sequential infections. In a report of a fatal case of babesiosis, the autopsy revealed significant histopathological evidence of a fulminant myocarditis due to *B. burgdorferi* (Marcus, Steere and Duray, 1985). Among patients with a confirmed tick-borne infection, coinfection rates as high as 39% have been reported. The most commonly recognized coinfection in most of the eastern United States is Lyme borreliosis and babesiosis, accounting for approximately 80% of coinfections. Coinfections can modify the immune response and alter the severity of arthritis in animal models. DNA extracts from 701 ticks collected in 15 localities were examined by PCR for the simultaneous detection of these three pathogens. Overall, 14% were infected with *A. phagocytophilum* followed by 12.4% with *B. burgdorferi* and 2.3% with *B. microti*. In total, the percentage of infected females (32.9%) was 2.4 times higher than in males (13.7%) and 3.2 times higher than in nymphs (10.3%). Among adult ticks ($n=303$), 8.3% were dually infected with *A. phagocytophilum* and *B. burgdorferi*, 2.0% with the agent of human anaplasmosis and *B. microti*, and 0.3% with borreliae and *B. microti* (Stanczak *et al.*, 2004). A recent population retrospective survey in Nantucket Island, Massachusetts, found that serological evidence of exposure to babesiosis was not associated with increased severity of acute Lyme disease (Wang *et al.*, 2000).

Russian investigators, Putkonen *et al.* in 1962, have reported a relationship between tick-borne encephalitis due to flaviviruses and EM. Since Lyme borreliosis can be associated with a meningitis or meningoencephalitis, it is not clear whether these particular cases of tick-borne encephalitis associated with EM are due to a dual infection of *B. burgdorferi* and flavivirus or solely of infection with *B. burgdorferi* (Kristoferitsch, 1989). In Europe, species of *Babesia* and *Ehrlichia* are present in Ixozinus, which is also a vector for flavivirus causing tick-borne encephalitis (Telford *et al.*, 1997). Furthermore, Lyme borreliosis should be considered in all patients suspected of arboviral encephalitis (Edlinger, Rodhain and Perez, 1985; Rodhain and Edlinger, 1987). Recently, Bartonella henselae has been described as a novel coinfecting agent in patients whose CNS is infected with *B. burgdorferi*.

Skin

Erythema Migrans

The most common manifestation of early localized Lyme disease is EM occurring in up to 85% of patients and is frequently located around the knees, axilla, and in the groins (Barbour and Hayes, 1986;

de Silva and Fikrig, 1997; Fraser *et al.*, 1997). It generally appears at the site of a tick bite three to 30 days (typically within seven to 10 days) after the bite. EM usually begins as a red macule or papule, which expands over the course of days to weeks, presumably as the spirochetes spread centrifugally through the skin. Secondary cutaneous lesions without tick bites may develop after hematogenous spread of spirochetes. Local symptoms include pruritus, tenderness, or paresthesias but are generally rare or absent in secondary lesions. The EM may also appear as target lesion with variable degrees of central clearing and may occasionally have vesicular or necrotic areas in the center. In one US study, spirochetes were cultures from plasma samples in 50% of patients with EM (Wormser *et al.*, 2000a). Spreading through skin and other tissue matrixes may be facilitated by the binding of human plasminogen and its activators to the surface of the spirochete (Coleman *et al.*, 1997). During the dissemination and homing of specific sites, the organism attaches to certain host integrins (Coburn, Leong and Erban, 1993), matrix glycosaminoglycans (Guo *et al.*, 1998), and extracellular-matrix proteins (Probert and Johnson, 1998). Spirochetal lipoproteins, which bind the CD14 molecule and Toll-like receptors on macrophages, are potent activators of the innate immune response, leading to the production of macrophage-derived inflammatory cytokines (Hirschfeld *et al.*, 1999).

In humans, infiltrates of macrophages and T cells in EM lesions express messenger RNA for both inflammatory and anti-inflammatory cytokines (Muellegger *et al.*, 2000). Particularly in disseminated infection, adaptive T-cell and B-cell responses in lymph nodes lead to the production of antibody against many components of the organism (Krause *et al.*, 1991; Akin *et al.*, 1999). It has been shown that the epidermal Langerhans' cells are invaded by *B. burgdorferi* in early Lyme borreliosis. In addition, reduced numbers of CD1a-positive Langerhans' cells were found in EM lesions. Systemic complaints in patients with EM are more common in USA than in Europe (McAlister *et al.*, 1989) secondary to differences in genospecies or concurrent infection with babesiosis or ehrlichiosis (Nadelman *et al.*, 1997). The most frequent symptoms of culture-confirmed cases include fatigue (54%), myalgia (44%), arthralgia (44%), headache (42%), fever and/or chills (39%), and stiffness of the neck (35%) (Nadelman *et al.*, 1996). In an observational cohort study in 10 endemic states, 118 patients with microbiologically confirmed EM presented a median of 3 days after symptom onset. Early EM commonly had homogeneous or central redness rather than a peripheral erythema with partial central clearing. The most common associated symptoms were low-grade fever, headache, neck stiffness, arthralgia, myalgia, or fatigue. By convalescence, 65% of patients had positive IgM or IgG antibody responses to *B. burgdorferi*. Most patients responded promptly to antibiotic treatment (Hassler and Maiwald, 1994). Subsequent episodes of EM have been reported in patients who received appropriate antimicrobial therapy for an initial episode, while primary failure of antibiotic treatment is rare, about 0.14% according to Maraspin, Lotric-Furlan and Strle (2002).

Lymphocytoma

Borreliolymphocytoma (BL), which is characterized by a dense lymphocytic infiltrate in the dermis or subcutaneous tissue, has been associated with borreliolymphocytoma infection, is the least common manifestation of Lyme disease (5%), and occurs more often in children than in adults (Hovmark, Asbrink and Olsson, 1986). It is usually caused by *B. garinii* and *B. afzelii* and is seen more frequently in Europe than in the USA. It is a tumor-like nodule that typically appears on the ear lobe, nipple, or scrotum (van Dam *et al.*, 1991; Picken *et al.*, 1997b). The lymphocytoma may occur with other manifestations of infection such as meningitis, choroiditis, arthritis, or acrodermatitis atrophicans (Asbrink and Hovmark, 1988). Histopathologically, it may be difficult to differentiate the lymphocytoma from lymphoma. Although some patients with BL may be seronegative, *B. burgdorferi* (Bb) IgG and/or

IgM antibodies are found in the serum of 80% of all BL patients. Direct detection of Bb or Bb-specific DNA in lesional skin by culture or PCR is helpful addition to the diagnosis. Thirty-six cases of borrelial lymphocytoma were detected during the period 1986–1990 in Slovenia led to complete recovery within an average of 3 weeks in all cases with antibiotic therapy (Strle *et al.*, 1992).

Acrodermatitis Chronicum Atrophicans (ACA)

In European patients, especially elderly women with *B. afzelii* infection, a chronic, slowly progressive skin condition called acrodermatitis chronica atrophicans may develop on sun-exposed acral surfaces. The organism has been cultured from such lesions as long as 10 years after the onset of the disease (Asbrink and Hovmark, 1985). These lesions may be preceded by EM and may represent a late or chronic stage of infection. Early lesions have erythematous nodules or plaques with central clearing and involve the extensor areas of the extremities or joints. Later lesions become atrophic and poikilodermatous resembling scleroderma or lichen sclerosis et atrophicus.

In one study, the infiltrates of T cells and macrophages in these lesions had a restricted cytokine profile, with little or no production of interferon- γ (Aberer, Klade and Hobisch, 1991), which may explain in part why the immune response is ineffective in eradicating the spirochete. The CD1a-positive Langerhans' cells were normal or slightly raised in these lesions. Major histocompatibility complex class II molecules on Langerhans' cells were downregulated (Aberer, Koszik and Silberer, 1997). While this downregulation may protect from presentation of autoantigens, it may also cause the impaired capacities of Langerhans' cells to eliminate *B. burgdorferi* and, thus, permit the chronicity of the infection. Alternatively, downregulation of several *B. burgdorferi* genes and insufficient killing of *Borrelia* by complement and antibody has been reported (Liang, Nelson and Fikrig, 2002).

Superficial and deep perivascular and interstitial infiltrate of plasma cells, lymphocytes, and histiocytes. Later lesions show sclerosis with loss of adnexa and elastic fibers. Concomitant with the ACA, neurological (Hopf, 1975; Kristoferitsch *et al.*, 1988) and rheumatological (Herzer *et al.*, 1986) evidence of *B. burgdorferi* infection may be present. In approximately one-third of patients, there is evidence of a polyneuropathy. Patients complain of paraesthesias, hyperaesthesias, weakness, and muscle cramps. There have been reports of profound fatigue and weight loss associated with ACA. They may also have severe rheumatological involvement, with subluxation of the small joints of the hands and feet, arthritis of the large joints, and periosteal thickening of the bones. Bursitis, epicondylitis, and tendonitis have also been reported to occur with ACA. At times it may be difficult to differentiate between the pain of arthritis and the significant neuritis associated with this disease process.

Carditis

Within several weeks after the onset of disease, about 4–10% of untreated patients have acute cardiac involvement – most commonly fluctuating degrees of atrioventricular block, occasionally acute myopericarditis or mild left ventricular dysfunction, and rarely cardiomegaly or fatal pancarditis (Steere, 1989). Diffuse T-wave changes, ST-segment depression, and arrhythmias also are frequently observed. Steere *et al.* (1980) first described the cardiovascular manifestations of Lyme disease in 1980 with a report of 20 North American cases. Patients may complain of dizziness, palpitations, dyspnea, chest pain, or syncope (van der Linde, 1991; van der Linde and Ballmer, 1993). In a mouse model, cardiac infiltrates of macrophages and T cells secrete inflammatory cytokines (Kelleher Doyle *et al.*, 1998). In these mice, the killing of spirochetes through cellular immune mechanisms seems to be the dominant factor in the resolution of the cardiac lesion. In mice with severe combined

immunodeficiency, immune serum resolves arthritis but not carditis (Barthold *et al.*, 1997).

In Europe, *B. burgdorferi* has been isolated from endomyocardial biopsy samples from several patients with chronic dilated cardiomyopathy (Stanek *et al.*, 1990; Lardieri *et al.*, 1993). However, this complication has not been observed in the United States (Sonnesyn *et al.*, 1995). A Dutch group noted improvement in left ventricular ejection fraction in eight of nine *B. burgdorferi*-seropositive patients with idiopathic dilated cardiomyopathy who were treated with antibiotics (Gasser *et al.*, 1992). Further studies are warranted to clarify the role that *B. burgdorferi* in chronic and acute congestive heart failure. Gallium and anti-myosin Indium scans have been abnormal in individual cases with myocarditis. Although temporary pacing is frequently required for complete heart block, permanent pacing is rarely needed (McAlister *et al.*, 1989). The prognosis of the acute cardiac manifestations of Lyme disease is good.

Joint Involvement

In the USA, arthritis is the predominant manifestation of disseminated *B. burgdorferi* infection, with about 60% of untreated patients developing joint manifestations usually weeks to years after the initial infection. Popliteal (Baker's) cysts are common, and – if present – dactylitis and Achilles tendon involvement can be helpful as diagnostic signs if reactive arthritis, psoriatic arthritis, and spondyloarthropathies have been ruled out. Months after the onset of illness, patients begin to have intermittent episodes of joint swelling and pain, primarily in large joints, occasionally the temporomandibular joint (Steere, 1989). Musculoskeletal features include arthralgia; intermittent episodes of migratory arthritis, usually monoarthritis or asymmetric oligoarthritis; and chronic arthritis, usually of the knees (Steere, Schoen and Taylor, 1987). In an observational cohort study of 15 patients with Lyme arthritis or fibromyalgia or both, symptoms of Lyme arthritis resolved with antibiotic therapy, whereas symptoms of fibromyalgia persisted in 14 of 15 patients treated with antibiotic therapy (Dinerman and Steere, 1992). The development of articular manifestations was initially described in a cohort of 55 patients evaluated for EM before the role of antibiotic therapy in Lyme disease was identified, 80% experienced some sort of articular manifestation over the course of the mean 6-year follow-up (Steere, Schoen and Taylor, 1987). Approximately 20% of patients had brief episodes of arthralgias which involved multiple joints in a migratory fashion and 50% of patients had EM with or followed by intermittent arthritis. Ten percent of patients experienced chronic Lyme arthritis affecting one to three joints. A number of these patients share a B-cell alloantigen, HLA-DW2, but did not have the immunologic features of rheumatoid arthritis (Steere *et al.*, 1979).

In Wurzburg, Germany, an epidemiologic study suggested a yearly incidence rate of one case per 100 total population of chronic manifestations of Lyme disease with a higher prevalence of Lyme arthritis than of neuroborreliosis. Because of the increased frequency of certain HLA-DR4 and DRB1 alleles in these patients, an autoimmune mechanism has been proposed (Steere *et al.*, 2001). Synovia from affected patients shows synovial hypertrophy, vascular proliferation, and a marked infiltration of mononuclear cells, sometimes with pseudolymphoid follicles that are reminiscent of peripheral lymph nodes (Steere, Schoen and Taylor, 1987; Steere, Duray and Butcher, 1988). Synovial fluid analyses typically show a slightly increased protein and white cell count of a median of 24 000/ μ l with a polymorphonuclear predominance and a normal glucose level (Steere *et al.*, 1977a). During attacks of arthritis, innate immune responses to *B. burgdorferi* lipoproteins are found, and $\gamma\delta$ T cells in joint fluid may aid in this response (Vincent *et al.*, 1998). Furthermore, patients with Lyme arthritis usually have higher *Borrelia*-specific antibody titers than patients with any other manifestations of the illness, including late neuroborreliosis (Akin *et al.*, 1999).

While most patients respond favorably to antibiotic therapy, about 10% of adults and fewer than 5% of children with Lyme arthritis develop persisting inflammatory joint disease lasting for more than 1 year, which may eventually lead to joint destruction. In about 10% of patients, particularly those with HLA-DRB1*0401 or related alleles, the arthritis persists in the knees for months or even years (Akin *et al.*, 1999). This postinfectious syndrome occurs more frequently in patients whose symptoms are suggestive of early dissemination of the spirochete to the nervous system, particularly if treatment is delayed (Shadick *et al.*, 1999; Kalish *et al.*, 2001). Autoimmunity may develop within the inflammatory milieu of affected joints in these patients because of molecular mimicry between an immunodominant T-cell epitope of OspA of *B. burgdorferi* and human lymphocyte function-associated antigen-1 (LFA-1 $\alpha_{332-342}$), an adhesion molecule that is highly expressed on T cells in synovium (Gross *et al.*, 1998; Steere *et al.*, 2001). T cells that react to OspA₍₆₅₋₁₇₃₎ are concentrated in the joints of these patients (Meyer *et al.*, 2000). When LFA-1 $\alpha_{332-342}$ is processed and presented by HLA-DRB1*0401 molecules, this self-peptide may behave as partial agonist. Treatment-resistant and treatment-responsive arthritis differ primarily in the cellular and humoral immune responses to OspA (Kalish, Leong and Steere, 1993; Chen *et al.*, 1999). In a retrospective study of 88 patients with Lyme arthritis, Nocton *et al.* (1994) showed the presence of *B. burgdorferi* DNA in 85% of patients with active Lyme arthritis and in none of the control patients. Because culture of synovial fluid is not a practical method by which the diagnosis of Lyme arthritis can be made, serologic tests and PCR are useful methods to determine whether live spirochetes are present within joint fluid. Enzyme-linked immunosorbent assay (ELISA) and Western blot testing for anti-*B. burgdorferi* antibodies within the synovial fluid is an accurate and reliable method of proving that an arthritis is really caused by Lyme. Severe acute arthritis develops in C3H/HeJ mice that are infected with *B. burgdorferi* (Barthold *et al.*, 1990), antibody against a 37-kD arthritis-resolving protein of the spirochete is critical in the resolution of the arthritis (Feng, Hodzic and Barthold, 2000). In contrast arthritis does not develop in *B. burgdorferi*-infected C57BL/6 mice (Barthold *et al.*, 1990).

Nervous System

All the neurological syndromes associated with *B. burgdorferi* infection can occur without previous EM (Reik, Burgdorfer and Donaldson, 1986). Lyme borreliosis is associated with both acute and chronic neurological abnormalities, affecting both the central and peripheral nervous systems. Clinical data support the hypothesis that, in most individuals, *B. burgdorferi* invades the nervous system early in the course of the infection. The most compelling evidence for this is the frequency of complaints referable to the nervous system in patients with EM. In one series of 314 patients with EM, 80% of the patients had malaise, fatigue, and lethargy; 64% had headache; and 48% complained of a stiff neck (Steere *et al.*, 1983b). Additional evidence of the early invasion of the nervous system is shown by the finding that approximately 12–15% of patients develop one or more of these three acute disorders – meningitis, cranial neuritis, or painful radiculitis – within the first 3 months after infection (Pachner and Steere, 1985). In Europe, the frequency of neuroborreliosis seems higher, potentially due to the greater neurotropism of *B. garinii*, which has not been isolated in North America. In Europe, *B. garinii* may also occasionally cause chronic encephalomyelitis, characterized by spastic paraparesis, cranial neuropathy, or cognitive impairment with marked intrathecal production of antibodies against the spirochete (Oschmann *et al.*, 1998). Cranial and spinal cord magnetic resonance imaging usually show diffuse white matter lesions.

The distinguishing feature for patients who develop meningitis is the presence of CSF abnormalities, a mild pleocytosis largely consisting of polymorphonuclear leukocytes or mononuclear cells,

a modest elevation of CSF protein, and a normal CSF glucose. Papilloedema and increased CSF pressure can occur, resulting in a syndrome indistinguishable from pseudotumor cerebri (Raucher *et al.*, 1985). Local antibody production against *B. burgdorferi* and MRI abnormalities have been observed in the more severely affected patients. In the absence of local antibody production, the diagnosis of *B. burgdorferi* CNS infection is questionable although has been demonstrated to occur.

Localized CNS processes have been associated with *B. burgdorferi* infection (Broderick, Sandok and Mertz, 1987). These may present as acute myelitis (Rousseau *et al.*, 1986), localized encephalitis (Feder, Zalneraitis and Reik, 1988), or cerebellar ataxia. The Headache of disseminated Lyme disease tends to be persistent and may worsen with time. Mild-to-moderate neck stiffness and photophobia may occur and continue for several weeks. Meningoencephalitis may be a prominent feature, manifesting as difficulty with memory and concentration and emotional lability (Oschmann *et al.*, 1998; Coyle *et al.*, 1999). Lyme meningitis typically occurs in the fall, at the same time as the peak incidence of enteroviral meningitis. Clues to Lyme meningitis, which otherwise mimics aseptic viral meningitis, are an associated EM, facial nerve palsy occurring during the early dissemination stage most often involves the facial nerve. One unusual case of *B. burgdorferi*-induced meningoencephalitis has been reported, where a T-cell clone recovered from the cerebrospinal fluid responded to spirochetal epitopes and to autoantigens (Hemmer *et al.*, 1999).

Cranial neuropathies may occur with or without evidence of meningitis. Any cranial nerve may be affected by Lyme disease, but seventh nerve, both unilateral and bilateral (Clark *et al.*, 1985; Oschmann *et al.*, 1998), involvement is by far the most frequent, occurring in up to 10% of patients with this infection. One recent review of 43 cases of bilateral seventh nerve palsy in a nonendemic area found no patients with Lyme disease (Keane, 1994). By contrast, studies in highly endemic areas indicate that Lyme disease may account for up to 25% of cases of facial nerve palsy. Halperin and Golightly (1992) concluded that Lyme disease may be responsible for approximately 25% of new onset Bell's palsy in an endemic area, with the palsy sometimes developing before positive serologic testing. No antibody was found in the CSF of those patients tested, which supported this being a peripheral neuropathy.

Lyme disease can cause a painful radiculitis manifested by neuropathic symptoms such as numbness, tingling, and burning. This radiculoneuropathy may affect the limbs or trunk. Fifty percent of the patients have associated cranial nerve palsies. The peripheral nerve damage in Lyme disease is usually an axonopathy, rather than a demyelinating syndrome (Hansen and Lebech, 1992). Acute or subacute myelitis can occur, associated with spastic paraparesis and CSF pleocytosis (Logigian, Kaplan and Steere, 1990). Mononeuritis and a Guillain-Barré-like syndrome have rarely been reported. Acute painful radiculoneuritis is the most striking early dissemination neurologic syndrome. The most common late stage neurologic syndrome in the United States is a subtle Lyme encephalopathy, which seems to represent CNS infection. Less-common neurologic manifestations include sudden sensorineural hearing loss, cerebellitis, intracranial aneurysm, and myelitis (Finizia, Jonsson and Hanner, 2001).

Meningopolyneuritis (Garin-Bujadoux, Bannwarth's syndrome) is the most dramatic of the peripheral nervous system abnormalities (Henriksson *et al.*, 1986). Concomitant encephalitis and myelitis occur in over 20% of patients. In these patients, long-term sequelae such as spastic paraparesis and neurogenic bladder persist after appropriate therapy. Sensitive neurophysiological techniques reveal that more than 40% of patients with late disease have demonstrated abnormalities (Halperin *et al.*, 1987).

Some patients report persistent symptoms after the recommended antibiotic treatment (Bujak, Weinstein and Dornbush, 1996), which has been termed post-Lyme disease syndrome, post-treatment chronic Lyme disease (PTCLD), or chronic Lyme disease. Nonspecific symptoms, such as fatigue, cognitive impairment, headache, arthralgias,

and myalgias (Asch *et al.*, 1994; Shadick *et al.*, 1994; Seltzer *et al.*, 2000) have been reported. Patients with PTCLD report more symptoms of depression than healthy control subjects (Fallon *et al.*, 1992; Kaplan *et al.*, 1999) and patients who have recovered from Lyme disease (Bujak, Weinstein and Dornbush, 1996). The severe fatigue may simply be an indication of chronic CNS infection and, in many cases, the most recognizable symptom of a mild chronic encephalopathy of months to years duration (Bensch, Olsen and Hagberg, 1987). In one study, patients with Lyme disease were evaluated 10–20 years after their original infection (Kalish *et al.*, 2001). Among the facial nerve palsy patients, those who had not received antibiotics were more likely to have arthralgias and sleep difficulties, mild residual deficits, and physical limitations compared with patients who had received treatment. In up to 10% of untreated patients, *B. burgdorferi* may cause chronic neuroborreliosis sometimes after long periods of latent infection (stage 3), thus making correct diagnosis very difficult (Logigian, Kaplan and Steere, 1990). Neither single PET of the brain nor neuropsychological tests of memory have sufficient specificity to be helpful in the diagnosis.

Long-term follow-up of patients with culture-confirmed Lyme disease showed excellent outcomes for the 96 cases who were followed for a mean of 4.9 ± 2.9 years. Other studies have reported frequent somatic complaints in controls (Kaplan *et al.*, 1992; Gaudino, Coyle and Krupp, 1997; Barr *et al.*, 1999) such as fatigue (15 to 43%), joint pain (20 to 27%), muscle aches (19 to 57%), paresthesias (13 to 27%), difficulty concentrating (3 to 13%), and headaches (16 to 20%). As with many chronic illnesses, patients with Lyme disease with persistent physical symptoms, such as pain, are also often experiencing greater emotional distress, including depression and anxiety, than otherwise healthy people, although they do not always meet the clinical criteria for psychopathology. Furthermore, in a double-blind, placebo-controlled study to improve the outcomes of patients with chronic Lyme disease (Klempner *et al.*, 2001) who had persistent subjective symptoms did not improve outcomes with both parenteral (1 month) and oral antibiotics (2 months) directed at *B. burgdorferi* infection. In an observational study of 129 patients indicate that for patients who have been previously treated with recommended antibiotics for Lyme disease and with self-reported neurocognitive symptoms who do not show clear evidence of persisting *Borrelia* infection or evidence of cognitive impairment on objective testing, there is no efficacy to additional antibiotic therapy (Halperin *et al.*, 1988; Logigian, Kaplan and Steere, 1999).

Other Organ Systems

Borrelia burgdorferi will localize to other organ systems. Lyme disease may be characterized by myositis, liver, and spleen involvement. Myositis is characteristically localized near an involved joint or localized neuropathy. Histopathologic examination in 1993 study by Reimers, de Koning and Neubert (1993), revealed focal nodular myositis or interstitial myositis, interstitial lymphohistiocytic infiltrates with plasma cells often localized around small endomysial vessels. Nuclear imaging with gallium-67 may be useful for detection. Patients with EM have been observed to have liver function test abnormalities in the absence of symptomatic hepatitis (Kazakoff, Sinusas and Macchia, 1993). Lymphoplasmocellular infiltrates have been seen in liver and spleen (Duray, 1989). Splenomegaly has been noted infrequently (Nelson and Nemcek, 1992). Necrotizing eosinophilic lymphadenitis was described in a 2-year-old girl with chronic arthritis and positive Lyme serology by ELISA. Although the spirochete is known to induce glomerulonephritis in animals, a recent case of membranoproliferative glomerulonephritis has been reported in which the diagnosis was confirmed serologically, and the patient though was dialysis dependent for a protracted period of 5 months, regained normal urine volume with treatment (Kirmizis *et al.*, 2004). Cases of myositis, panniculitis, osteomyelitis, uveitis and pneumonitis due to

B. burgdorferi have been reported (Steere *et al.*, 1985a; Kramer *et al.*, 1986; Atlas *et al.*, 1988; Kirsch *et al.*, 1988). A nonspecific follicular conjunctivitis may occur in as many as 10% of patients during the flu-like illness of Lyme disease (Mombaerts, Maudgal and Knockaert, 1991). Periorbital edema, episcleritis, photophobia and subconjunctival hemorrhages have been noted (Mombaerts, Maudgal and Knockaert, 1991). Interstitial and ulcerative keratitis have also been observed (deLuise and O'Leary, 1991). It has also been reported to cause vitritis, anterior uveitis (Schubert, 1994). Optic neuritis and periopic neuritis associated with Lyme disease have been described in both Europe and the United States (Farris and Webb, 1988). Seventh nerve paresis can lead to neurotrophic keratitis. In 38 cases reported by Pachner and Steere (1985), one-half of the patients had facial palsy, a third of these with bilateral involvement. Optic disc edema can occur as a result of optic neuritis or increased intracranial pressure. Pupillary changes can occur, including the development of a Robertson Pupil (Schechter, 1986).

DIAGNOSIS

Until the discovery of the causative agent in 1982, the clinical diagnosis of Lyme borreliosis was based solely on the recognition of EM, either historically or by direct observation. In the absence of EM, the demonstration of an immune response to *B. burgdorferi* in an appropriate clinical setting forms the basis on which most diagnoses are made. In patients in the United States, the diagnosis is usually based on the recognition of the characteristic clinical findings, a history of exposure in an area where the disease is endemic, and except in patients with EM, an antibody response to *B. burgdorferi* by ELISA and Western blotting, interpreted according to the criteria of the Centers for Disease Control and Prevention and Association of State and Territorial Public Health Laboratory Directors (CDC, 1990, 1995).

Microscopy

Borrelia burgdorferi, a loosely coiled spirochete which is approximately 200 μm wide and 10–30 μm long, is difficult to visualize under bright-field conditions, but is readily visible in phase contrast or dark field. The organism is Gram negative and can also be stained with acridine orange, Giemsa, or by fluorescent antibody technique. Silver stains, either Warthin–Starry or a modified Dieterle stain, have proved to be successful in identifying spirochaetes in fixed, paraffin-embedded tissue. Apart from skin biopsy, spirochaetes have been observed in other tissues, such as the myocardium, synovium, and the nervous system, but the yields from them have been very poor because of low numbers of spirochaetes.

Cultural Methods

In patients presenting with EM, culture is virtually 100% specific and seems to be more sensitive (57–86%) (Lebech, 2002) than serology (about 50% in the USA and less than 50% in Europe) (Asbrink, Hovmark and Olsson, 1986). The culture of *B. burgdorferi* from specimens in Barbour–Stonner–Kelly medium permits a definitive diagnosis. Positive cultures have been obtained only early in the illness, primarily from biopsy samples (Berger *et al.*, 1992) of EM lesions, less often from plasma samples (Wormser *et al.*, 2000a), and only occasionally from cerebrospinal fluid samples in patients with meningitis (Coyle *et al.*, 1999).

Later in the infection, PCR testing is greatly superior to culture in the detection of *B. burgdorferi* in joint fluid (Nocton *et al.*, 1994). *Borrelia burgdorferi* has not been isolated from the cerebrospinal fluid of patients with chronic neuroborreliosis, and *B. burgdorferi* DNA has been detected in CSF samples in only a small number of

such patients (Nocton *et al.*, 1996). The Lyme urine antigen test, which has given unreliable results (Klempner *et al.*, 2001), should not be used to support the diagnosis of Lyme disease.

Immunological Tests

Immune Response

In order to understand the difficulties involved in the interpretation of the serological tests for Lyme disease, it is important to understand the kinetics of the immune response to this organism. Infected individuals develop an early and vigorous T-cell response to *B. burgdorferi* (Dattwyler *et al.*, 1988b); the B cell response evolves more slowly, frequently over the course of months. IgM responses against individual antigens appear first, followed by IgG response. Within 3 or 4 weeks after the onset of infection a rise in IgM against one or more spirochaetal antigens can be detected in most individuals. The IgM response usually peaks after 6 to 8 weeks and then gradually declines. Early in the course of infection, the IgM response is mainly directed against a 41-kD flagella-associated antigen (Luft, Bosler and Dattwyler, 1992) and outer-surface protein C (OspC). However, epitopes on this 41-kD antigen are cross-reactive with epitopes found on flagella of other borrelias and treponemes. The 41-kD antigen of *B. burgdorferi* has been shown to have a high degree of homology to the 33-kD protein of *Treponema pallidum* (Luft and Dattwyler, 1989). Antibodies against this antigen and 60-kD antigen also does not seem to be specific. Humoral responses to other antigens gradually develop as the disease progresses. Although there are antigenic differences between North America and Europe, antibodies against one or more of the major protein antigens (OspC, 31, 34, 60, or 66-kD) develop as the infection continues. Craft *et al.* (1986) found that, in untreated patients, specific IgM antibodies to the 34-kD OspB antigen developed later in the course of the infection. This could explain also why IgM titers may remain elevated late in the course of the infection. Specific IgG and IgA responses gradually increase during the second and third months of infection and, once established, may remain detectable for years.

Cross Reactions

Some epitopes of antigenic components of *B. burgdorferi*, such as proteins with molecular masses of 41 and 60 kD, are common to *T. pallidum*, oral treponemes, and even *Escherichia coli* (Russell *et al.*, 1984; Magnarelli *et al.*, 1990). False-positive reactions have been reported when sera from patients who were diagnosed with juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, and subacute bacterial endocarditis were analyzed for antibodies to *B. burgdorferi* (Zemel, 1992; Kaelin *et al.*, 1993).

Currently Used Assays

Serologic assays for Lyme disease were first used in 1983. Serodiagnostic tests are insensitive during the first several weeks of infection. In the United States, approximately 20–30% of patients have positive responses, usually of the IgM isotype, during this period (Dressler *et al.*, 1993; Engstrom, Shoop and Johnson, 1995), but by convalescence 2 to 4 weeks later, about 70–80% have seroreactivity, even after antibiotic treatment. After 1 month, the majority of patients with active infection have IgG antibody responses (Dressler *et al.*, 1993). In persons who have been ill for longer than 1 month, a positive IgM test alone is likely to represent a false-positive result; therefore, such a response should not be used to support the diagnosis after the first month of infection. In patients with acute neuroborreliosis, especially those with meningitis, the intrathecal production of IgM, IgG, or IgA

antibody against *B. burgdorferi* may often be demonstrated by anti-body-capture enzyme immunoassay (Steere *et al.*, 1990), but this test is less often positive in those with chronic neuroborreliosis.

Immunofluorescence and ELISA are the two most commonly used methods for the detection of antibodies to *B. burgdorferi*. ELISAs are most sensitive than IFAs and offer the advantage of having the capability of screening large numbers of patient samples more easily. Although potentially useful and constantly improving, *B. burgdorferi* antibody tests have limited sensitivity (primarily in early disease) and specificity and have not been standardized to date (Steere *et al.*, 1993; Tugwell *et al.*, 1997; Jespersen *et al.*, 2002). These limitations have led to erroneous diagnoses and may have contributed to fundamental misunderstandings of Lyme borreliosis. Therefore, a straightforward two-step serological approach has been proposed (Stanek *et al.*, 1996; CDC, 1997) by CDC in 1994. A positive or equivocal first test, usually an ELISA or indirect immunofluorescence assay (IFA), is followed by an immunoblot test on the same serum sample (Norman *et al.*, 1996), which can detect IgM and IgG antibodies to individual *B. burgdorferi* antigens.

Criteria for Immunoblot Interpretation: Positive IgM blot: presence of two of three significant bands (23-kD(OspC), 39, and 41 kD). Positive IgG blot: presence of five of 10 significant bands: 18 kD, OspC, 28, 30, 39, 41, 45, 58, 66, and 93 kD. If the Western blot is negative, the reactive ELISA or IFA very probably was a false-positive result. Neither ELISA nor immunoblot permits detection of fourfold rises in antibody titer (seroconversion). However, antibodies to *B. burgdorferi* flagella antigens decrease markedly after successful treatment compared with 271 ± 115 SD days after unsuccessful therapy (Panelius *et al.*, 1999). Some individuals lack diagnostic levels of specific antibody in their serum, yet have neurological involvement and diagnostic levels of antibody in their CSF (Dattwyler *et al.*, 1988b; Stiernstedt *et al.*, 1988) as *B. burgdorferi* reaching this immunologically privileged site remain viable and induce a local immune response. The demonstration of intrathecal production of anti-*B. burgdorferi* antibody may be demonstrated by using the formula:

$$\frac{\text{Anti-}B. \text{ burgdorferi} \text{ titer CSF} \times \text{Serum IgG concentration}}{\text{Anti-}B. \text{ burgdorferi} \text{ titer serum} \times \text{CSF IgG concentration}}$$

If the ratio is greater than 1, localized production of anti-*Borrelia* antibodies has occurred.

More recently, sensitive ELISAs using recombinant chimeric *Borrelia* proteins of different types, as well as those devoid of OsPA, have been introduced for serological detection of *B. burgdorferi* antibodies (Gomes-Solecki *et al.*, 2000; Gomes-Solecki *et al.*, 2002) which helps distinct between individuals that have been vaccinated with OspA. Furthermore, epitope mapping of the OspA has been introduced by using a panel of monoclonal antibodies (Kharitononkov *et al.*, 2002). After antibiotic treatment, antibody titers fall slowly, but IgG and even IgM responses may persist for many years after treatment (Kalish *et al.*, 2001). Thus, even an IgM response cannot be interpreted as a demonstration of recent infection or reinfection unless the appropriate clinical characteristics are present.

Other Serological Tests

An ELISA assay has been developed based on a conserved immunodominant portion of the variable surface antigen (VlsE) which can be used in vaccinated patients. The *B. burgdorferi* C6 peptide antibody test (Lyme C6 EIA) identifies antibodies to a newly discovered conserved peptide called C6, which is a component of the VlsE of *B. burgdorferi*. The Lyme C6 EIA is important because it detects both IgM and IgG antibodies in patients with Lyme disease but not in vaccines. The Lyme borreliacidal antibody test (BAT) has been proposed as a sensitive and highly specific diagnostic test (Callister

et al., 1993). Agger and Case (1997) compared the BAT, indirect immunofluorescence assay (IFA), and ELISA for detection of antibodies to *B. burgdorferi* in 307 patients who had had previous serological tests for Lyme disease. The BAT was less sensitive in active Lyme disease (11%) and did not correlate with the conventional antibody assays.

Schutzer and colleagues have utilized *Borrelia*-specific immunoassays to detect antibody and antigen in patients with active Lyme disease. Brunner and Sigal (2000) have recently confirmed these results and reported that the test can demonstrate *B. burgdorferi* antigen in otherwise seronegative patients. Of 168 patients who fulfilled the CDC criteria for Lyme disease, Lyme immune complexes were found in 25 of 26 patients with early disease, 13 of 13 patients with neuroborreliosis and in 105 of 107 patients who were seropositive and had clinically defined EM. In only two of 147 control patients were Lyme immune complexes, and IgM in immune complexes may be a marker of active infection (Brunner and Sigal, 2000).

MOLECULAR DIAGNOSIS

Specific PCR methods of diagnosis have been described for Lyme disease in skin biopsy. Although possessing the potential to provide a more rapid diagnosis some studies suggest that it is not more sensitive than culture *Borrelia* because the organisms appear to be unevenly distributed throughout biopsy (Picken *et al.*, 1997a). However, others suggest that the sensitivity is superior (Lebech, 2002). The most frequent and serious manifestation of disseminated Lyme borreliosis is neuroborreliosis. In patients with very early neuroborreliosis (<2 weeks), still being negative for specific intrathecal antibody synthesis, a positive PCR was more frequent than in patients with longer disease duration. PCR can be used as a diagnostic aid in these patients. However, in general the measurement of specific intrathecal antibody production in patients with neuroborreliosis was superior to PCR (Lebech, 2002). New oligonucleotide primers based on *B. burgdorferi* sensu lato 16S rRNA gene sequences have been designed for the detection of the bacteria in blood, cerebrospinal, and synovial fluid specimens with PCR. The procedure has been shown to be a rapid and sensitive method for specimens derived from patients with the clinical symptoms of Lyme borreliosis. It can be utilized for both basic research and routine laboratory diagnosis (Chmielewski *et al.*, 2003).

TREATMENT

The primary goals of therapy for Lyme disease are the control of inflammation and the eradication of the infection. Lyme disease is most responsive to antibiotics early in the course of the disease. In one report, the leading reason for failure to respond to antibiotic therapy for Lyme disease was incorrect diagnosis (Sigal, 1990). About 10% of patients with early Lyme disease experience a Jarisch-Herxheimer-like reaction (higher fever, redder rash, or greater pain) during the first 24 h of antibiotic therapy (Steere, 1989). If antibiotic therapy is initiated early in the course of Lyme disease, EM typically resolves promptly and later stage disease is prevented (Steere *et al.*, 1983c; Dattwyler *et al.*, 1990). Early localized infection, limited to a single skin lesion, with mild or no systemic symptoms, is uniformly responsive to short-course oral antibiotic therapy with a number of agents. Of the antibiotics studied to date, amoxicillin 500 mg daily for 8 h, doxycycline 100 mg daily for 12 h, or cefuroxime axetil 500 mg daily for 12 h have been the most effective for this stage of disease (Massarotti *et al.*, 1992; Nadelman *et al.*, 1992). In a prospective trial, 72 adults with EM were randomized to treatment with amoxicillin plus probenecid or doxycycline (Luft *et al.*, 1996). Both drugs were equally effective; mild fatigue and arthralgia were the only post-treatment complaints, and they resolved within 6 months. No patient required further antimicrobial therapy for Lyme disease. An advantage of doxycycline is its efficacy against the agent of human

granulocytic ehrlichiosis, a possible coinfecting agent. Amoxicillin should be used in children and pregnant women. The optimal duration of therapy is addressed in a randomized, double-blind trial in 180 patients with EM compared 10 days of doxycycline to one dose of intravenous ceftriaxone followed by 10 days of doxycycline. There was no difference among the groups in outcome at the follow-up at 3, 12, and 30 months (Nadelman *et al.*, 1992). Another study suggested that 14 days of antibiotic therapy is adequate for the treatment of EM (Nadelman *et al.*, 1997). In multicenter studies of patients with EM, similar results were obtained with doxycycline, amoxicillin, and cefuroxime axetil, and more than 90% of patients had satisfactory outcomes (Dattwyler *et al.*, 1990; Nadelman *et al.*, 1992). Intravenous ceftriaxone, although effective, was not superior to oral agents as long as the patient did not have objective evidence of neurologic involvement in early disseminated disease with multiple EM lesions and arthralgias (Dattwyler *et al.*, 1997). The first-generation cephalosporins were ineffective (Nadelman *et al.*, 1992).

Although carditis resolves spontaneously, in patients with atrioventricular nodal block with a PR interval greater than 0.3 s, therapy with one of the intravenous regimens for at least part of the course and cardiac monitoring are recommended, but the insertion of a permanent pacemaker is not necessary (Lopez *et al.*, 1991). Facial palsy itself resolves completely or nearly completely in all patients (121 of 122 patients in one series) (Clark *et al.*, 1985). Patients who have facial palsy should undergo a careful neurologic evaluation, including a CSF examination. If facial palsy is the only clinical abnormality and CSF is normal, current practice is to administer oral antibiotics for 21–30 days, a practice that has resulted in favorable outcomes. In one small series, intravenous ceftriaxone for 14 days was superior to a 10-day course of penicillin (Dattwyler *et al.*, 1988a). Most experts prefer a 30-day course of treatment, however, because of the occasional occurrence of late neurologic relapses after shorter courses of therapy. It is not necessary to document clearing of all CSF abnormalities before discontinuation of therapy because clearing of inflammation may lag behind bacteriologic cure. Experience with doxycycline is limited (Dotevall *et al.*, 1988), one patient who had severe neurologic involvement, unresponsive to penicillin responded favorably to chloramphenicol (Diringer, Halperin and Dattwyler, 1987). Arthritis may respond to either oral (Steere *et al.*, 1994) or parenteral (Steere *et al.*, 1985; Roberts *et al.*, 1995) antibiotic therapy, but antibiotic failures occur with either approach. Despite treatment with either oral or intravenous antibiotic therapy, about 10% of patients in the United States have persistent joint inflammation for months or even several years after 2 months or more of oral or 1 month or more of intravenous antibiotic therapy (Steere *et al.*, 1994). If patients have persistent arthritis despite this treatment and if the results of PCR testing of joint fluid are negative, they may be treated with anti-inflammatory agents or arthroscopic synovectomy. In one report, only one-half of patients who had late neurologic symptoms showed either resolution or sustained improvement after 6 months of follow-up after a 2-week course of ceftriaxone (Logigian, Kaplan and Steere, 1990). Those who did not respond, however, did not show progressive worsening. Long-term follow-up of this patient group is essential. In a European trial ceftriaxone and penicillin for 2 weeks were both effective for later neurologic involvement (Hassler *et al.*, 1990). *Borrelia burgdorferi* has not been linked statistically to congenital anomalies, and no increased risk of an adverse outcome of pregnancy has been associated with asymptomatic seropositivity (Williams *et al.*, 1988) or history of previous Lyme disease. It is appropriate to maintain a lower threshold for institution of aggressive antibiotic therapy for suspected Lyme disease during pregnancy, but women should be reassured that no cases of fetal Lyme disease have occurred with currently recommended antibiotic regimen.

After appropriately treated Lyme disease, a small percentage of patients continue to have subjective symptoms – primarily musculoskeletal pain, neurocognitive difficulties, or fatigue – that may last for years. This disabling syndrome, which is sometimes called

'chronic Lyme disease' is similar to chronic fatigue syndrome or fibromyalgia (Dinerman and Steere, 1992). However, in a large study, the frequency of symptoms of pain and fatigue was no greater in patients who had had Lyme disease than in age-matched subjects who had not had this infection (Seltzer *et al.*, 2000). In a study of patients with post-Lyme disease syndrome who received either intravenous ceftriaxone for 30 days followed by oral doxycycline for 60 days or intravenous and oral placebo preparations for the same duration, there were no significant differences between the groups in the percentage of patients who said that their symptoms had improved, gotten worse, or stayed the same (Klempner *et al.*, 2001). Treatment with the standard antibiotics is generally successful for each of the stages of Lyme disease. Some cases of reinfection with a different strain of *B. burgdorferi* have been documented (Asch *et al.*, 1994; Shadick *et al.*, 1999). In one retrospective cohort study from Nantucket, patients with a history of treated Lyme disease were more likely than controls to report subjective complaints without objective evidence (Krupp *et al.*, 2003). There is no evidence that treatment of asymptomatic seropositive individuals is beneficial.

PREVENTION AND CONTROL

Primary prevention strategies will help reduce Lyme disease cases, and some strategies may also prevent other tick-borne illnesses, including babesiosis and granulocytic ehrlichiosis in the United States and tick-borne encephalitis in Europe. The first line of defense is avoidance of tick-infested habitats, use of personal protective measures (e.g. repellents and protective clothing), and checking for and removing attached ticks, and modifications of landscapes in or near residential areas (CDC, 1999). Surveys in such areas have indicated that less than 54% of people tuck their pants into their socks to prevent Lyme disease, 38–79% use repellents, but 79–93% check themselves for ticks (Herrington *et al.*, 1997). Tick control (burning or removing vegetation, acaricide use, and deer elimination) reduces *I. scapularis* populations by up to 94%, and acaricide application to wildlife decreases nymphal *I. scapularis* populations by up to 83%. The effect of these strategies on incidence of Lyme disease in humans is unknown. Studies show that only 40–50% of adults take precautions against tick bites even when they are aware of Lyme disease (Herrington *et al.*, 1997).

In addition, a vaccine for Lyme disease (LYMERix), consisting of recombinant outer-surface protein A (rOspA) for persons aged 15–70 years in the United States, was commercially available in 1998. Results of a large-scale, randomized, controlled (Phase III) trial of safety and efficacy of LYMERix in disease-endemic areas of the north-eastern and northcentral United States indicate that the vaccine is safe with an efficacy rate of 76% when administered on a three-dose schedule of 0, 1, and 12 months. The efficacy of the vaccine in preventing asymptomatic infection was 83% in the first year and 100% in the second year (Steere *et al.*, 1998). But Shadick *et al.* (2001) demonstrated that the vaccination against Lyme disease appears only to be economically attractive for individuals who have a seasonal probability of *B. burgdorferi* infection of greater than 1%. Researchers have proposed that an autoimmune reaction might develop within the joints of some Lyme arthritis patients as a result of molecular mimicry between the dominant T-cell epitope of OspA and human leukocyte function-associated antigen 1. Vaccine against Lyme disease was withdrawn from the market in February 2002 because of low sales. The other controversial issue regarding prevention is the prophylactic treatment of Ixodid tick bite with antibiotics.

In 1992, Shapiro *et al.* (1992) demonstrated that even in an area in which Lyme disease is endemic, the risk of infection with *B. burgdorferi* after a recognized deer-tick bite is so low that prophylactic antimicrobial treatment is not routinely indicated. According to Magid *et al.* (1992) empirical treatment of patients with tick bites is indicated when the probability of *B. burgdorferi* infection after a bite is 0.036 or

higher, and this treatment may be preferred when the infection ranges from 0.01 to 0.035. When the probability of infection after a tick bite is less than 0.01, empirical therapy is not warranted. A recent randomized clinical trial showed that a single 200-mg dose of doxycycline administered within 72 h after a recognized *I. scapularis* bite had an efficacy of 87% (95% confidence interval, 25–98%) in preventing EM (Nadelman *et al.*, 2001). None of the people treated with antibiotics in this or any of the previous clinical trials had asymptomatic *B. burgdorferi* infection or any late manifestations of Lyme disease during follow-up periods that ranged from 6 weeks to 3 years.

Many clinicians argue that this practice is unwarranted any may promote the development of antibiotic resistance (Shapiro, 2001). A meta-analysis of several prospective, randomized trials did not indicate that antimicrobial prophylaxis is effective (Wormser *et al.*, 2000b). The cooperative engagement of public health officials, clinicians, and residents of the affected communities will make it possible to reduce the incidence of Lyme disease.

PATHOGENESIS OF RELAPSING FEVER

Borrelia infect the blood stream during infection when large numbers of organisms can be present up to 100 000/ml. As a result of the immune pressure against the surface protein variable major protein the organism undergoes antigenic variation mediated by intermolecular and intramolecular recombination. This allows further rounds of bacterial multiplication to occur and clinical relapse. Up to 30 different antigenic variants can be produced but as time progresses the organism reverts to earlier types and this may allow eradication of disease.

CLINICAL MANIFESTATIONS OF RELAPSING FEVER

The clinical features of relapsing fever are similar but the case fatality rate is very different being 4–40% for louse borne disease and less than 5% for tick-borne infection. The initial febrile stage lasts for just under a week stopping abruptly. Subsequent febrile relapses last for 2 or 3 days with an interval between relapses of just over a week. Most patients suffer only a few relapses but more than 12 may occur. Louse-borne relapsing fever is usually associated with a single relapse, whereas multiple relapses are the rule with tick-borne disease. Clinically, the patient may have a cough and examination is likely to reveal hepatosplenomegaly. Hemorrhage is common but is rarely severe. Myocarditis with its associated arrhythmias is the most common cause of death followed by cerebral hemorrhage and hepatic failure.

DIAGNOSIS

The diagnosis of relapsing infection is usually established on epidemiological grounds during an epidemic. In sporadic cases the differential diagnosis includes malaria, typhoid, leptospirosis, rat bite fever, and dengue. The definitive diagnosis is established by detecting *Borrelia* in the peripheral blood of febrile patients. This is achieved by examination of wet blood films or darkground microscopy. Organisms are rarely seen in patient specimens during non-febrile patients. Serodiagnosis detecting the present of specific antibodies to a glycerophosphodiester phosphodiesterase (Porcella *et al.*, 2000).

Section Five

Obligate Anaerobic Bacteria

Anaerobic Cocci

D. A. Murdoch

Department of Medical Microbiology, Royal Free Hospital NHS Trust, London, UK

INTRODUCTION

Watt and Jack (1977) published a useful definition of anaerobic cocci as 'cocci that grow well under satisfactory conditions of anaerobiosis and do not grow on suitable solid media in 10% CO₂ in air even after incubation for 7 days at 37 °C'. Anaerobic cocci are a major component of the normal flora and are commonly isolated from human infections (Finegold and George, 1989; Murdoch, 1998), but remarkably little is known about their role in pathogenesis. One reason is that they are usually isolated from polymicrobial infections; until recently, it has been very difficult to identify the more important pathogens. In addition, classification has been unsatisfactory and there have been few identification methods available for routine laboratories. In the last 15 years, there have been several major developments; the classification is finally on a more secure, genomically based footing; with the introduction of preformed enzyme kits, identification is much easier; and molecular techniques can be applied to examine the complex flora of the gingival crevice, genito-urinary and gastro-intestinal tracts. There has also been considerable interest in the pathogenicity of two of the most prominent members of the group, *Finegoldia magna* and *Micromonas micros*.

GRAM-POSITIVE ANAEROBIC COCCI (GPAC)

Classification

'Anaerobic streptococci' were frequently described from human infections in the early part of the 20th century, but the classification was confused by a profusion of poorly defined species (Hare, 1967). The term 'anaerobic streptococcus' is now meaningless and redundant, yet regrettably it is still often used. Rogosa (1971) brought some order to a chaotic situation with the description of the family Peptococcaceae, based on the obligately anaerobic nature of the organisms and their Gram-stained morphology; this led to the removal of micro-aerophilic species such as *Peptostreptococcus intermedius* to the genus *Streptococcus*. When the Approved List of Bacterial Names was published (Skerman, MacGowan and Sneath, 1980), the Peptococcaceae comprised five genera, *Peptococcus*, *Peptostreptococcus*, *Ruminococcus*, *Coprococcus* and *Sarcina*. With the introduction of taxonomic methods based on nucleic acid techniques, first using DNA-DNA hybridisation and later 16S rRNA sequencing, nine new species were described (Ezaki *et al.*, 1983; Li *et al.*, 1992; Murdoch *et al.*, 1997). They were all assigned to the genus *Peptostreptococcus*, which became a placement of convenience.

Recently, there have been major changes (Table 44.1). As a result of 16S rRNA sequence data, there has been a radical revision of the

classification and a recognition that the microscopic morphology does not always reflect an organism's genetic affinities.

The long-standing division of clinically significant strains into the genera *Peptococcus* and *Peptostreptococcus* is now obsolete. The genus *Peptococcus*, with a G+C ratio of 50–51 mol% (Ezaki, Oyaizu and Yabuuchi, 1992), is only very distantly related to other Gram-positive anaerobic cocci (GPAC – a useful term in the diagnostic laboratory), most of which have G+C ratios of 28–37 mol%. The only species now in the genus *Peptococcus* is *Pc. niger*, which is very rarely isolated from human clinical specimens. The type species of the genus *Peptostreptococcus* is *Peptostreptococcus anaerobius*, which has been shown by 16S rRNA sequence analysis to be located in Clostridial cluster XI in the scheme of Collins *et al.* (1994). Collins *et al.* assigned most species in the genus *Peptostreptococcus* to Cluster XIII, phylogenetically distant from *P. anaerobius*. With the removal of these species from the genus *Peptostreptococcus* (Murdoch *et al.*, 2000), six new genera have been described. Murdoch and Shah (1999) constructed the genus *Finegoldia* for *Peptostreptococcus magnus* and the genus *Micromonas* for *Peptostreptococcus micros*. Species of *Finegoldia* form acetic acid as their terminal volatile fatty acid (VFA), are strongly proteolytic but only weakly saccharolytic; *F. magna*, the species most commonly isolated from human clinical material, is the only species at present in this genus. Species of *Micromonas* form acetic acid as their terminal VFA, are very strongly proteolytic and asaccharolytic; *M. micros*, another species of clinical importance, is the only species at present in this genus. The recent construction of a genetic map for *Finegoldia*, which disclosed a chromosome of size 1.9 Mb and a megaplasmid of 200 kb (Todo *et al.*, 2002), supported its reclassification.

The classification of the butyrate-producing GPAC has long been confused. Ezaki *et al.* (2001) recently separated the group into two new genera, *Anaerococcus* and *Peptoniphilus*. The saccharolytic genus *Anaerococcus* includes six species, some frequently isolated from human clinical material, and the asaccharolytic genus *Peptoniphilus* five, including *P. asaccharolyticus*, one of the most important species. However, the taxonomy particularly of *Anaerococcus* is incomplete, with several species awaiting description, and the identification criteria for both genera are still unsatisfactory. Ezaki *et al.* also created the genus *Gallicola* for *Peptostreptococcus barnesae*, a non-fermenting species apparently isolated only from chicken faeces.

Further rationalisations have included the reclassification of *Peptostreptococcus heliotrinreducens* in a new genus, *Slackia*, with an organism previously classified as *Eubacterium exiguum*; these species are now assigned to the family Coriobacteriaceae in the high G+C Gram-positive phylum (Wade *et al.*, 1999). They are closely related to *Atopobium parvulum*, an obligately anaerobic coccus originally

P., *Peptostreptococcus*; *Pc.*, *Peptococcus*; *Pp.*, *Peptoniphilus*; (T) denotes type species of genus.

described as *Peptostreptococcus parvulus* but placed until recently in the genus *Streptococcus*.

Other anaerobic species of Gram-positive cocci are rarely isolated from human clinical material and have been very little studied. The genus *Sarcina*, which forms spores but is morphologically a coccus, is located in Cluster I and is closely related to *Clostridium perfringens*. The genus *Ruminococcus* is known to be heterogeneous; the type species, *R. flavefaciens*, is placed in Cluster IV and is only distantly related to other ruminococci. A group of other ruminococci are assigned to Cluster XIVa, including *R. productus*, a strongly saccharolytic species placed until recently in the genus *Peptostreptococcus*. The genus *Coprococcus* also falls into Cluster XIVa.

It is likely that future reviews of GPAC will not consider *P. anaerobius* with former members of the genus *Peptostreptococcus*. As these radical taxonomic revisions are very recent, it is much simpler at this stage to consider these organisms together – keeping in mind that they are genetically and therefore phenotypically very diverse. The following abbreviations will be used: *P.* for *Peptostreptococcus*, *Pc.* for *Peptococcus* and *Pp.* for *Peptoniphilus*.

Aerotolerance, Specimen Transport, Laboratory Isolation and Maintenance

Anaerobes involved in human infections are usually relatively (sometimes remarkably) tolerant of oxygen; they require an anaerobic atmosphere in which to multiply, but many can survive prolonged periods in an aerobic atmosphere. Tally *et al.* (1975) reported that 14 clinical strains (not speciated) all survived exposure to atmospheric oxygen for 8 h; nine (63%) survived more than 72 h. When four fresh clinical isolates of *F. magna* and *M. micros* were exposed to air (Murdoch, 1998), 1% of cells were still viable after 48 h. Whilst many GPAC are moderately aerotolerant, it is likely that intestinal organisms such as *Coprococcus* and *Ruminococcus* are much more sensitive to oxygen; unfortunately, many of these organisms have been little studied.

The best specimens for culturing obligate anaerobes are aspirates or tissue specimens. The best means of maximising recovery rates are anaerobic transport systems, which are essential if the specimens sent are swabs. It is important that specimens reach the laboratory as quickly as possible and are not allowed to dry out. Specimens should be processed as soon as possible and must be incubated in an anaerobic atmosphere that includes 10% CO₂ and a palladium catalyst to remove traces of oxygen.

Very little is known about the nutritional requirements of GPAC. As they are phylogenetically diverse, generalisations are hazardous. (Heginbottom, Fitzgerald and Wade, 1990) compared several commercial non-selective solid media and reported that Fastidious Anaerobe Agar (Lab M, Bury, UK) consistently gave the best growth. Supplements such as vitamin K, haemin (Holdeman Moore, Johnson and Moore, 1986) and sodium oleate (Tween 80; final concentration 0.02%) may enhance the growth of some species (Hare, 1967), but none of them appear to be essential. A blood-free medium, Gifu anaerobic medium (GAM; Nissui, Tokyo, Japan), can support the growth well (Ezaki, Oyaizu and Yabuuchi, 1992). For liquid media, there is a great variation in the quality of chopped meat broths, with some commercial products appearing not to support growth at all; other products have maintained fastidious GPAC for several years at room temperature on the open bench, providing a very convenient method of storage (Murdoch, 1998). The best methods of long-term storage are either in liquid nitrogen or lyophilisation in the early stationary phase of growth in a medium containing less than 0.2% fermentable carbohydrate (Holdeman Moore, Johnson and Moore, 1986).

Most strains of *Ruminococcus*, *Coprococcus* and *Sarcina* are considerably less tolerant of oxygen and are unlikely to grow in the conditions encountered in routine laboratories (Ezaki, Oyaizu and Yabuuchi, 1992). Carbohydrates are essential for the growth of ruminococci and sarcinae and stimulate the growth of coprococci (Ezaki, Oyaizu and Yabuuchi, 1992). Excellent guidelines for their isolation and culture are available (Bryant, 1986; Ezaki, Oyaizu and Yabuuchi, 1992).

There are no selective media for GPAC as a group. As GPAC are heterogeneous, a single medium is unlikely to support the growth of all representatives yet be reasonably selective. Most antibiotics, including neomycin and polymyxin, have some activity against some strains of GPAC (Murdoch, 1998). Nalidixic acid–Tween blood agar (nalidixic acid 10 mg/l and 0.1% Tween 80) has been reported to give better isolation rates than neomycin blood agar (neomycin 75 mg/l) (Wren, 1980). Turng *et al.* (1996) have described *P. micros* medium, a selective and differential medium for *P. micros*, which contains colistin–nalidixic acid agar (CNA; Difco) supplemented with glutathione and lead acetate. Strains of *P. micros* use the reduced form of glutathione to form hydrogen sulphide, which reacts with lead acetate to form a black precipitate under the colony. The development of selective media for genetically homogeneous groups, e.g. *F. magna* or *Anaerococcus*, would be realistic and valuable. As most clinical isolates grow relatively slowly on standard media and are usually present in mixed culture, they are frequently overgrown by more robust organisms, and many clinical studies therefore give a falsely low estimate of their frequency.

Laboratory Identification

The lack of an adequate identification scheme undoubtedly held back studies of GPAC for many years (Watt and Jack, 1977). Older schemes (Holdeman Moore, Johnson and Moore, 1986) required equipment such as gas-liquid chromatography (GLC), which was rarely available in routine diagnostic laboratories. However, now that identification is based on preformed enzyme profile (PEP) kits (Murdoch, 1998), which can be used in most diagnostic laboratories, well over 90% of clinical strains can be placed in a phylogenetically valid genus and probably 80% can be identified to the species level. As the relative clinical importance of different species of GPAC is little known, all microbiologists are urged to identify the strains they isolate as fully as they can.

The first stage of identification is to decide to which general group an apparently anaerobic isolate belongs; this can be surprisingly difficult. Some Gram-positive anaerobes, such as *P. asaccharolyticus*, retain Gram's stain poorly, and colonies can appear Gram-negative after 48 h incubation. A simple trick is to test susceptibility to vancomycin, using a 5 µg disc, to which strains of GPAC are sensitive and Gram negatives are usually resistant. A rapid method using a 3% solution of potassium hydroxide (KOH) can also be used; the solution usually becomes viscous and mucoid in the presence of Gram-negative bacteria (Halebian *et al.*, 1981). GPAC must be distinguished from micro-aerophilic organisms, such as many strains of streptococci, *Staphylococcus saccharolyticus* and *Gemella morbillorum*. Streptococci and gemellae are strongly saccharolytic and produce large quantities of lactic acid, which can be detected by GLC. It is effective and simpler to test susceptibility to metronidazole (Watt and Jack, 1977); a 5 µg disc is applied to the edge of an inoculum (not to the centre; some strains of GPAC are extremely sensitive and may not grow at all) and susceptibility read within 48 h. Metronidazole-resistant strains of GPAC appear to be very rare. The decision whether an organism is a rod or a coccus can be very subjective; the cell morphology of *P. anaerobius*, in particular, is very variable. Similarly, strains of *Slackia exigua*, previously identified as *P. heliotrinreducens* (Murdoch and Mitchelmore, 1989), can be coccobacillary; they are easily confused with strains of *M. micros*, and they can be isolated from similar (and sometimes highly significant) clinical specimens (Murdoch, 1998). *Slackia* and *Micromonas* can be distinguished by their PEP (Wade *et al.*, 1999).

Second-stage identification of GPAC relied for many years on the standard biochemical tests used for anaerobes, notably carbohydrate fermentation reactions (Table 44.2). These tests are useful for clostridia and *Bacteroides* but are not appropriate for GPAC, most of which appear not to use carbohydrates, much less ferment them.

Nevertheless, demonstration that an organism is strongly saccharolytic may be a useful way of identifying organisms with which GPAC may be confused, e.g. *Staphylococcus saccharolyticus* and streptococci. Members of the genus *Anaerococcus* are able to ferment carbohydrates, though sometimes weakly (Ezaki *et al.*, 2001); the classification and characterisation of this group are still unclear, and it would be worth evaluating their carbohydrate fermentation reactions using commercial kits as a potential method of identification.

GLC was a mainstay of anaerobic identification for many years, but few laboratories still maintain the equipment. It is of limited use for GPAC (Table 44.3). It divides them into an 'acetic group' (the clinically relevant groups being *Finegoldia*, *Micromonas* and *Slackia*); a large butyrate group, which is heterogeneous and still inadequately characterised; and a few species that produce longer-chain fatty acids, notably isocaproate (*P. anaerobius*), isovalerate (*Pp. ivorii*) and *n*-caproate (*A. octavius*). Production of non-volatile fatty acids by GPAC has been little studied; streptococci form large quantities of lactic acid.

Most GPAC use the products of protein decomposition as a major energy source. Ezaki and Yabuuchi (1985) demonstrated that most strains of clinical importance had consistent amidase and oligopeptidase activities; individual species had consistent PEPs that could be used to distinguish between them. Several of these tests have been incorporated into commercially available PEP kits. The use of PEPs has provided a simple, powerful and widely available means of identification; for instance, *F. magna* and *M. micros*, which had previously only been separable by the size of the cell, are reliably differentiated by several tests available in commercial kits. PEPs have been discriminatory enough to distinguish undescribed groups of GPAC from recognised taxa, such as *Pp. ivorii* and *A. octavius*. Wilson *et al.* (2000) reported that PEPs were valuable for characterising strains in the newly described genus *Anaerococcus*. However, it has become increasingly clear that they will rarely discriminate reliably within the new genus *Peptoniphilus*. Further, it must be emphasised that a heavy inoculum of the test organism (MacFarland standard 4 or more) is required; using a lighter inoculum will lead to misidentification. It is often necessary to inoculate several plates to harvest a sufficient quantity of the test organism. Finally, though they are marketed as 'rapid' kits, the manufacturers neglect to mention the 48 h period required to grow sufficient of the organism for inoculating the kit. The commercially available kits are designed to identify as wide a range of anaerobes as possible; they include many tests of little relevance to GPAC. Development of kits specifically for GPAC on an in-house basis would be valuable.

Few other techniques have been shown to be of use in the routine laboratory. There is one important exception; strains of *P. anaerobius* are sensitive to sodium polyanethol sulphate (SPS) or liquid, whereas almost all other strains of GPAC are resistant (Graves, Morello and Kocka, 1974). SPS discs are available, making this a simple and reliable test.

Nucleic acid-based techniques have been adapted to the identification of GPAC with considerable success, although they are at present too expensive for routine use. Dymock *et al.* (1996) used conserved random amplification of 16S rRNA genes by means of eubacterial primers to detect a non-culturable organism related to *M. micros* from a dento-alveolar abscess. Wang *et al.* (1997) described a polymerase chain reaction (PCR)-based technique for the detection of rumino-cocci in faecal specimens. PCR methods for the identification of *M. micros* and *P. anaerobius* have also been published; they were valuable for their detection in polymicrobial samples from dental specimens (Riggio, Lennon and Smith, 2001; Riggio and Lennon, 2002; Siqueira *et al.*, 2003). Hill *et al.* (2002) recently used amplification of the 16S–23S intergenic spacer region for differentiation of a group of reference and clinical strains. They reported considerable heterogeneity within described butyrate-forming species. A set of multiplex PCR probes have been validated against the known sequences of recognised species of GPAC and found to be superior to identification

Table 44.2 Differential characteristics of GPAC

Data on G + C contents from Ezaki *et al.* (1983), Li *et al.* (1992), Murdoch *et al.* (1997) and Wade *et al.* (1999).

Data on production of VFAs and major energy sources from Holdeman Moore, Johnson and Moore (1986) and Murdoch and Mitchelmore (1991).

by PEP (Song *et al.*, 2003). A range of probes for the detection and enumeration of anaerobes in human faeces have recently been extended to include *Ruminococcus* and related species (Harmsen *et al.*, 2002).

Suggested Laboratory Identification Scheme for GPAC

Using the following scheme, experienced laboratory workers should be able to place at least 80% of clinical strains in the correct genus 48 h after the isolation of individual colonies.

Primary Isolation (First Stage)

Specimens should be processed and placed in an anaerobic environment as rapidly as possible. Enriched blood agar should be used for culture, preferably Fastidious Anaerobe Agar (Lab M). Test for susceptibility to metronidazole by placing a 5 µg disc on the primary inoculum, on the edge of the plate and well away from secondary streaking; this positioning is necessary to prevent metronidazole suppressing growth of very sensitive organisms.

Examine the primary plate after incubation for 48 h and 5 days; plates should not be removed from their anaerobic environment at 24 h unless essential (e.g. possible clostridial infections). It is recommended that plates should not be discarded before 5 days, as many anaerobes grow very slowly – particularly if the plates are old.

When the primary plate is examined, experienced workers can use the Gram stain, colonial morphology and smell to make a presumptive identification of most strains (25–50% isolates) of *P. anaerobius*, *M. micros* and *Pp. asaccharolyticus*. Unfortunately, characteristic features for *F. magna*, the commonest species in human specimens, have not yet been described.

Subculture (Second Stage)

Subculture onto enriched blood agar, which should be as fresh as possible and compatible with PEP kits. Several plates must be used for slowly growing GPAC (colony diameter <1 mm after incubation for 48 h), otherwise it will be impossible to harvest enough organisms to inoculate the PEP kit. One plate must be streaked so that single colonies are present. Also inoculate a plate to detect capnophilic organisms, incubating it in an aerobic atmosphere containing 6% CO₂. When GLC is available, a broth culture may be inoculated.

After incubation for 48 h, a PEP kit can be inoculated and read (Table 44.2). It is essential to use an adequate inoculum for the kit (MacFarland standard 4 as a minimum). Strains of *P. anaerobius*, *F. magna* and *M. micros* should be identified without difficulty. The profiles of *A. hydrogenalis* and *A. octavius* should be distinctive enough to allow species level identification, but most strains of *Anaerococcus* can only be identified to the genus level. Likewise, *Pp. ivorii* and *Pp. lacrimalis* can be fully identified using their PEP, but cell and colonial

morphology are at present important for speciation of the *asaccharolyticus/hareii/indolicus* group.

Inspect cell and colonial morphology again, checking that they are consistent with PEP identification. If the PEP does not give a clear identification and GLC is available, examine for VFA production; GLC of unidentified strains will usually place them in the butyrate group, which contains a number of undescribed species. If the strain ferments any sugars in the PEP kit and forms butyrate, it can probably be assigned to the genus *Anaerococcus*.

After 5 days, it is good practice to check both aerobic and anaerobic plates again (recording all observations), particularly if the PEP does not give a clear identification (often because of mixed culture). Colonial morphology and smell are most distinctive after 5 days and help distinguish *Pp. hareii* from *Pp. asaccharolyticus*. However, by 5 days, many strains (of species such as *F. magna* and *A. tetradius*) will show marked heterogeneity in their colonial morphology, making assessment more difficult.

It is regrettable that a significant proportion of clinical isolates, perhaps 10–20%, cannot yet be identified to phylogenetically valid species. If they are cultured from important specimens, they should be sent to a reference laboratory for further investigation.

Modifications

1. When presumptive strains of *P. anaerobius* are subcultured, an SPS disc should be placed on the primary streaking; the plate can be inspected after 18 h. Organisms susceptible to SPS with appropriate cell and colonial morphology do not need further characterisation. Some strains of *Pp. ivorii* are sensitive to SPS, but their cell morphology is coccoid and regular rather than coccobacillary and pleomorphic, and they do not form α -glucosidase or the VFA isocaproic acid.
2. When the cell morphology from the primary plate suggests a very decolourised strain of GPAC, for example *Pp. asaccharolyticus* or *Pp. indolicus*, place a vancomycin 5 μ g disc on the primary inoculum to check the Gram reaction; GPAC are sensitive whereas most Gram-negative anaerobes are resistant.

Normal Flora

Although little studied, GPAC are found on most or all body surfaces (Finegold and George, 1989; Murdoch, 1998). They are major components of the normal flora of the mouth, upper respiratory and gastro-intestinal tracts and female genito-urinary system and are also present (though less commonly) on the skin, certain species having a predilection for specific anatomical sites.

GPAC are a major constituent of the oral flora and are found in plaque and the gingival sulcus; the dominant species is *M. micros*. Many species of GPAC are found in the gut, but they are often poorly characterised; they include *Coprococcus*, *Ruminococcus* and *Sarcina* (particularly in vegetarians; Crowther, 1971). Using optimal culture techniques, Finegold, Attebery and Sutter (1974) showed that '*Peptostreptococcus productus*' (now placed in the genus *Ruminococcus*) is one of the commonest organisms in the gastro-intestinal flora, which has been confirmed using 16S rRNA probes (Harmsen *et al.*, 2002). The significance of GPAC in the vaginal ecology is unclear, though large numbers of many species are found in the female genito-urinary tract. The GPAC present on the skin appear to have been little studied; *F. magna*, *P. asaccharolyticus* and *A. vaginalis* are likely to be present, as they have been isolated from superficial wound infections.

Clinical Importance

Comprehensive surveys of anaerobic pathogens have reported that GPAC are second only to *Bacteroides* and account for 25–30% of all

isolates from human clinical specimens. Their clinical significance has been underestimated, because most infections involving GPAC are polymicrobial, and the technical problems of classification and identification. Most reports of isolation in pure culture refer to *F. magna* (Murdoch, 1998), but there are also reports of *P. anaerobius*, *Pp. asaccharolyticus*, *Pp. indolicus*, *Pp. hareii*, *M. micros* and *A. vaginalis*.

Oral and Respiratory Tract Infections

GPAC have been isolated from a wide variety of infections involving the upper respiratory tract, but usually in mixed growth (Murdoch, 1998). Most dental infections are polymicrobial but are dominated by anaerobic organisms. *Micromonas micros*, a strictly anaerobic, strongly proteolytic organism, being well suited to the subgingival ecosystem (Shah and Gharbia, 1995); it has been implicated in periodontitis and various more serious intra-oral infections, but causation is very difficult to prove in a microbial flora as complex as that of the subgingival plaque (Socransky *et al.*, 1991). Species clusters of potential pathogens, including *M. micros*, *Prevotella melaninogenica* and *P. gingivalis*, have been associated with dental disease (Socransky *et al.*, 1988). *Micromonas micros* has been isolated from endodontic and peritonsillar abscesses (Mitchellmore *et al.*, 1995) and complications such as retropharyngeal and brain abscesses (Murdoch, Mitchellmore and Tabaqchali, 1988b). Chronic sinusitis yields a mainly anaerobic flora, of which *F. magna* and *M. micros* are frequent constituents (Brook, Yocum and Frazier, 1996). Anaerobic infections of the lower respiratory tract are probably much commoner than generally realised (Bartlett, 1993); in the days when transtracheal aspiration was an acceptable technique, GPAC were recognised as one of the major pathogenic groups. They were isolated mainly from cases of aspiration pneumonia, lung abscess and empyema, in association with *Prevotella* spp., *Fusobacterium nucleatum* and microaerophilic streptococci (Bartlett, Gorbach and Finegold, 1974).

Intra-Abdominal Infections

GPAC are usually said to be less common in serious abdominal infections than *Bacteroides* spp., but they predominated in a recent series of retroperitoneal abscesses (Brook and Frazier, 1998a), as well as to identify intra-abdominal isolates to the species level. GPAC have been the commonest anaerobes in two series of liver and spleen abscess (Sabbaj, Sutter and Finegold, 1972; Brook and Frazier, 1998b).

Infections of the Genito-Urinary Tract

GPAC are commonly implicated in gynaecological and obstetric sepsis, but their precise role is still unclear largely because of problems with identification and a wide range of species being present (Murdoch, 1998). Schottmüller in 1910 was the first to associate puerperal sepsis (now rare in developed countries) with 'anaerobic streptococci'; several later papers established their importance in this condition. Complications included abscess formation and infertility, but septicaemia and metastatic abscess formation were rare, in contrast to *Streptococcus pyogenes* (Murdoch, 1998).

Bacterial vaginosis (BV) is now recognised to predispose to various gynaecological and obstetric problems. The place of GPAC in complications associated with BV has been less studied than for anaerobic Gram-negative rods such as *Prevotella*. Hillier *et al.* (1993) compared the vaginal flora of groups of pregnant women with normal flora and BV; they reported that women with BV were more likely to have counts of GPAC $>10^5$ /ml, with significantly increased counts of '*P. tetradius*' but not other species of GPAC. High carriage rates of '*P. asaccharolyticus*', '*P. prevotii*' and '*P. tetradius*' have been reported from the vaginal flora of non-pregnant women with BV. There has recently been great interest in the role of BV in various obstetric

complications; GPAC have been reported from studies of chorioamnionitis, post-Caesarean endometritis and preterm labour and delivery.

Laparoscopic studies of the upper genital tract flora of women hospitalised for pelvic inflammatory disease have revealed that GPAC are often present (Soper *et al.*, 1994). However, their precise pathogenic role is unclear although they are one of the commonest groups of organisms isolated from tubo-ovarian abscesses, along with *Escherichia coli* and *Bacteroides fragilis* (Landers and Sweet, 1983).

It is clear that the female genito-urinary tract (in health and disease) hosts a complex flora and that many of the GPAC present cannot yet be adequately characterised (in either phylogenetic or phenotypic terms). When a polymicrobial flora is being analysed, traditional identification methods that use biochemical identification methods such as PEPs are very laborious; this is a field where analysis by molecular probes will be very effective. But, as many of the organisms present appear to belong to the poorly studied genera *Anaerococcus* and *Peptoniphilus*, further taxonomic studies of these groups will be needed before their role in the female genito-urinary tract is properly understood.

Superficial and Soft-Tissue Infections

GPAC are frequently isolated from superficial and soft-tissue infections and post-operative surgical wounds (Brook, 1988; Murdoch, Mitchelmore and Tabaqchali, 1994). The classic study by Bourgault, Rosenblatt and Fitzgerald (1980) established the pre-eminence of *F. magna*.

Brook and Frazier (1990) emphasised the importance of the location of the infection in determining the organisms involved; they reported that superficial infections of the trunk most often yielded *F. magna*, but *Pp. asaccharolyticus* and *P. anaerobius* were commonest in perirectal abscesses, infections of the leg and external genitalia. They reported that GPAC were the commonest anaerobic group in cases of cellulitis, necrotising fasciitis, mediastinitis, pyomyositis and other soft-tissue infections. There appears to be a strong association between GPAC and infections of the feet, particularly in diabetics (Wheat *et al.*, 1986), and non-puerperal breast abscesses (Edmiston *et al.*, 1990), when *F. magna* is again the commonest species isolated.

Musculoskeletal Infections

Anaerobic septic arthritis, formerly a very rare condition, has now become much more frequent, being most often seen as a complication of hip and knee joint replacements. GPAC are the commonest pathogens; they cause a low-grade infection that is frequently missed or diagnosed late, so a high index of suspicion by both clinician and laboratory is necessary. Bourgault, Rosenblatt and Fitzgerald (1980) isolated *F. magna* from 32 bone and joint infections (14%) from 222 positive specimens; they recovered *F. magna* in pure culture from 18 patients (15 with foreign bodies). GPAC have also been associated with various orthopaedic infections including post-traumatic joint infections, traumatic fractures of long bones and osteomyelitis associated with sinus, ear or dental infections. Diabetic foot infections linked to peripheral vascular disease are often complicated by osteomyelitis; *F. magna* is the commonest anaerobe (Wheat *et al.*, 1986).

Septicaemia and CNS Infections

GPAC are only occasionally isolated from blood cultures (Brook, 1989); cases of bacteraemia are probably missed as cultures of some species, including *F. magna* and *P. anaerobius*, may remain signal negative in commercial systems (van der Vorm *et al.*, 2000). Obstetric patients, particularly after septic abortion, appear to be at highest risk (Topiel and Simon, 1986). Analyses of anaerobic septicaemia have not reported deaths linked to GPAC, in contrast to cases yielding clostridia or *Bacteroides* group organisms.

GPAC very rarely cause meningitis, polymicrobial abscesses being the commonest condition (Finegold and George, 1989). Direct spread can occur from infections of the middle ear, sinuses and mouth (usually teeth), and haematogenous seeding can result from pleuropulmonary infections or, occasionally, from cardiovascular abnormalities. Murdoch, Mitchelmore and Tabaqchali (1988b) described three brain abscesses that yielded *M. micros*, fusobacteria, '*Bacteroides*' spp. (*sensu lato*) and micro-aerophilic streptococci.

Pathogenesis and Virulence Factors

This area is little studied although there has been some work to identify virulence factors, particularly for *F. magna* and *M. micros*, and several studies have attempted to define the relative importance of GPAC in polymicrobial infections.

Most species of GPAC are isolated from mixed infections with facultative organisms and/or other anaerobes; a synergistic interaction appears likely but it is technically difficult to evaluate the relative importance of the different components. In an elegant series of experiments from the pre-antibiotic era, Smith (1930) demonstrated the principle of microbial synergy in the development of anaerobic abscesses. He used as his model the development of anaerobic lung infections in mice and rabbits. He injected pus into the trachea and cultured the resulting lung abscesses, isolating 17 different organisms. He then injected pure cultures of each organism back into fresh animals, without producing lung abscesses, but then tested combinations of organisms. He found that a combination of an 'anaerobic streptococcus', an anaerobic spirochaete (probably *Fusobacterium*) and an anaerobic Gram-negative rod was necessary to reproduce the disease. Unfortunately, we do not know which organisms he was studying, but they bear a remarkable resemblance to those from a series of polymicrobial deep organ abscesses described by Murdoch, Mitchelmore and Tabaqchali (1988b) that yielded *M. micros*. Brook and co-workers (Brook and Walker, 1984) developed a subcutaneous abscess model in the mouse. They examined a range of bacteria in pure and mixed growth, testing their ability to induce abscesses, enhance the growth of bacterial components and increase mortality. They showed that GPAC could interact with facultative and anaerobic bacteria, including *Staphylococcus aureus*, *Pseudomonas aeruginosa* and several species of streptococci and *Enterobacteriaceae*, in causing abscess formation, but they did not report clear differences between the species of GPAC studied. Possible mechanisms for microbial synergy have included mutual protection from phagocytosis (Ingham *et al.*, 1977) and lowering of oxidation/reduction potentials in host tissue.

Many anaerobes form potential virulence factors, but this characteristic appears less marked for GPAC than, for instance, clostridia. Brook (1987) showed that capsule formation was an important virulence mechanism, capsulate organisms being able to seed more successfully to distant organs. Freshly isolated strains have been shown to produce gelatinase, collagenase and hyaluronidase (Steffen and Hentges, 1981) and DNAase, RNAase, coagulase and haemolysins (Marshall and Kaufman, 1981), but these studies did not find a clear correlation between the species and the potential virulence factor.

More recently, there has been interest in a range of virulence factors formed by *F. magna* which is the most studied GPAC. Krepel *et al.* (1992) reported that clinical strains of *F. magna* from different sites varied in their ability to form a range of potentially significant enzymes; they found that strains of *F. magna* from non-puerperal breast abscesses and diabetic foot infections were more likely to form collagenase and gelatinase than strains from intra-abdominal sepsis. A specific protein receptor on the cell wall described by Myhre (1984) can bind significant amounts of human serum albumin; this receptor was not found in a range of other anaerobic pathogens such as *B. fragilis*. Some strains of *F. magna* form Protein L, a cell surface protein that binds to the κ light-chain variable domain of human and many mammalian immunoglobulin molecules (Nilson *et al.*, 1992). Protein

L can trigger the release of histamine and leukotriene C4 from mast cells and basophilic granules (Patella *et al.*, 1990) and can act as an immunoglobulin superantigen (Genovese *et al.*, 2000). The isolation from the vaginal flora of strains of *F. magna* expressing Protein L has been associated with the presence of BV (Kastern *et al.*, 1990). de Chateau and Björck (1994) described a mosaic albumin-binding protein, Protein PAB, which shows substantial relatedness to Protein L and a virulence factor elaborated by some β -haemolytic streptococci, Protein G.

Micromonas micros is of interest to oral microbiologists, as strains are frequently isolated from intra-oral infections and their complications. Murdoch, Mitchelmore and Tabaqchali (1988a) noted the intrinsically strong proteolytic activity of *M. micros* and suggested that this could be important in abscess formation. Carlsson, Larsen and Edlund (1993) examined the ability of oral bacteria to form the cytotoxin hydrogen sulphide from glutathione, a tripeptide involved in the intracellular defences against reactive oxygen metabolites; *M. micros* was the most active organism of 37 species studied. van Dalen *et al.* (1993) described a rough morphotype of *M. micros* present in plaque samples that differs from the 'normal' smooth morphotype in its haemolytic ability and hydrophilicity; it possesses long fibrillar structures that appeared to support cellular aggregation. Rough and smooth morphotypes cluster separately when examined by genetic or electrophoretic techniques (Kremer *et al.*, 1997). Both types show synergism with oral strains of *Prevotella* in their ability to form abscesses in a mouse model (van Dalen *et al.*, 1998).

Antibiotic Susceptibility

Unfortunately, most reports on anaerobic susceptibility to antibiotics have presented data for GPAC as a group rather than for individual species; considering their genetic diversity, this information must now be considered of little value. When GPAC have been identified to the species level, differences in susceptibility patterns have been reported, but these are rarely consistent between reports; it is not clear whether these differences are due to true geographical variations, methodological differences or, indeed, misidentification.

Most workers have reported that almost all GPAC are susceptible to metronidazole (Finegold and George, 1989); resistance has frequently been reported (Summanen *et al.*, 1993), but it is possible that some resistant strains were micro-aerophilic streptococci, as their identity has often not been reported. Some strains in the *prevotii/tetradisi* group are partially or even completely resistant by disc testing (Murdoch, 1998). Strains of *Pp. asaccharolyticus*, *F. magna* and *M. micros* have been reported to be exquisitely susceptible to metronidazole, but two of the nine strains of *P. anaerobius* tested were of intermediate susceptibility (MIC 2–4 mg/l) (Bowker *et al.*, 1996).

Peptoniphilus asaccharolyticus, *F. magna* and *M. micros* are almost always susceptible to penicillins, but some strains of *P. anaerobius* are much more resistant (Reig and Baquero, 1994; Bowker *et al.*, 1996). Cefoxitin predictably is the most active cephalosporin, other extended spectrum cephalosporins having higher MICs (Wexler and Finegold, 1988). GPAC appear to be very sensitive to carbapenems. Occasional strains of *P. anaerobius* are resistant to penicillin G, cefoxitin and cefotaxime, although β -lactamase production by GPAC has never been demonstrated (Garcia-Rodriguez, Garcia-Sanchez and Munoz-Bellido, 1995).

The macrolides erythromycin, clarithromycin and azithromycin are not active enough to be recommended as first-line therapy. Clindamycin is widely used as anti-anaerobic treatment, but high rates of resistance have often been reported; this may be a result of local use, as there appears to be considerable geographical variation within individual countries (e.g. Spain and the United States). Reig, Moreno and Baquero (1992) and Sanchez, Jones and Croco (1992) have described inducible macrolide-lincosamide resistance in several species of GPAC; they recommended that erythromycin susceptibility be assessed

before individual isolates were reported as sensitive to clindamycin. There are few data on glycopeptides, but resistance has not been reported. Resistance to chloramphenicol, mediated via acetyl transferase activity, has occasionally been reported. The older quinolones such as ciprofloxacin are moderately effective, but the newer agents such as moxifloxacin are extremely active with an MIC₉₀ for *Peptostreptococcus* spp. of 1 mg/l (Fung-Tomc *et al.*, 2000).

Treatment with a penicillin or metronidazole (preferred because of better penetration) will usually be effective first-line therapy. A β -lactamase inhibitor will add little to penicillin therapy for GPAC, though in mixed infections it may be essential for associated organisms. Susceptibility to clindamycin varies widely; erythromycin susceptibility should simultaneously be tested. Cephalosporins are usually and carbapenems always effective.

Future studies must present data by species, in particular *P. anaerobius* is genetically so distantly related to other species of GPAC that its data should at least be presented separately.

Characteristics of the More Significant Species of GPAC

Collins Cluster XI

Peptostreptococcus anaerobius: This is now the only species in the genus *Peptostreptococcus* (Murdoch *et al.*, 2000); it was assigned by Collins *et al.* (1994) to *Clostridium* cluster XI with ten species at present in the genus *Clostridium*. It is phenotypically very different from the species with which it was formerly classified (Murdoch, 1998): the cell morphology is highly pleomorphic but usually coccobacillary; it forms distinctive colonies with a sickly sweet smell; proteolytic activity is feeble; several VFAs are formed, notably isocaproic acid; and strains are sensitive to SPS. A molecular identification method based on PCR has been reported (Riggio and Lennon, 2002). *Peptostreptococcus anaerobius* is part of the gut flora and is often grown from clinical specimens, but rarely in pure culture. It is regularly isolated from gastro-intestinal and high vaginal infections, usually abscesses, with other components of the faecal flora such as coliforms and other anaerobes. Its role in causing infections is unclear. It appears not to be involved in periodontitis or associated diseases (Riggio and Lennon, 2002), though the data are contradictory (Murdoch, 1998). Some strains are resistant to a range of β -lactams, probably mediated via modified penicillin-binding proteins.

Collins Cluster XIII

Finegoldia magna: Clinically the most important species in the group, *F. magna* can undoubtedly act as a primary pathogen, causing a range of infections from infected sebaceous cysts to life-threatening infections (Murdoch, 1998). 16S rRNA data place *F. magna* in *Clostridium* cluster XIII (Collins *et al.*, 1994) but in a genus of its own (Murdoch and Shah, 1999). Both cell and colonial morphology are variable (Murdoch and Mitchelmore, 1991), but the Gram-stained appearance always reveals clumps of cocci. Saccharolytic activity is very weak but proteolytic activity is strong (Murdoch and Mitchelmore, 1991); the only VFA formed is acetate. Strains are easily distinguished from those of *M. micros* by their PEP. There are contradictory reports about its role in the normal flora; it is probably present on the skin and in the urogenital tract and possibly in the faecal flora and mouth. It is one of the most common anaerobic pathogens and is frequently recovered in pure culture from a wide range of serious infections, some of which have been fatal. Bourgault, Rosenblatt and Fitzgerald (1980) associated *F. magna* with soft-tissue and bone/joint infections; prosthetic joints are particularly at risk. It can be isolated from abscesses from many sites and appears to have a predilection for diabetic foot infections (Wheat *et al.*, 1986). Unlike other GPAC, it is usually co-cultured with facultative organisms rather than other obligate anaerobes. The few reports on antibiotic susceptibility are not always consistent, but they indicate that

most or all strains are sensitive to metronidazole and β -lactams and some strains are resistant to clindamycin (Sanchez, Jones and Croco, 1992).

Micromonas micros: *Micromonas micros* is the only species at present in its genus. Cells are smaller than those of *F. magna* and are usually arranged in chains; the colonial morphology of the smooth morphotype is usually distinctive, with domed, glistening white colonies surrounded by a yellow-brown halo of discoloured agar (Murdoch and Mitchelmore, 1991). A rough morphotype described from gingival plaque forms dry, white, haemolytic colonies with crinkled edges (van Dalen *et al.*, 1993). Strains of *M. micros* are asaccharolytic but very strongly proteolytic; the only VFA formed is acetic acid. The PEP, supported by cell size, should distinguish isolates of *F. magna*; strains of *Slackia exigua* can be more difficult to separate. A selective medium (Turng *et al.*, 1996) and PCR-based methods for detection in polymicrobial dental specimens (Riggio, Lennon and Smith, 2001; Siqueira *et al.*, 2003) have been reported.

Micromonas micros is found in the gingival crevice and the gastro-intestinal tract; it may be part of the normal vaginal flora (Murdoch, 1998). It has been linked with other oral pathogens in the causation of periodontitis and peritonsillar abscesses (Mitchelmore *et al.*, 1995). It has been isolated from a wide range of extra-oral sites, usually in association with other anaerobes, in a mixed anaerobic abscess flora, typically consisting of micro-aerophilic streptococci (*S. milleri*), *Prevotella*, *M. micros* and fusobacteria (Murdoch, Mitchelmore and Tabaqchali, 1988b). Reports on antibiotic susceptibility are conflicting but most strains appear highly sensitive, and resistance to metronidazole and cefoxitin has been reported in strains from periodontitis (Rams *et al.*, 1991).

Peptoniphilus asaccharolyticus: *Peptoniphilus asaccharolyticus* is one of the commonest species of GPAC in clinical specimens (Murdoch, Mitchelmore and Tabaqchali, 1994), but with the radical changes in classification and identification; many older reports referring to *Pp. asaccharolyticus* undoubtedly included strains now assigned to other species, notably *A. hydrogenalis*. An asaccharolytic and proteolytic species that forms butyric acid as its terminal VFA, it was made the type species of the new genus *Peptoniphilus* by Ezaki *et al.* (2001); however, laboratory methods for its separation from two other species in the genus, *Pp. indolicus* and *Pp. hareii*, are at present inadequate. As the commercial PEP kits in use at present do not separate these species reliably, undue weight must be placed on the subjective criteria of cell and colonial morphology. *Peptoniphilus asaccharolyticus* has been reported as part of the normal flora of the gastro-intestinal and genito-urinary tracts, causing infections at the latter site (Brook, 1988). There are few data on pathogenicity or susceptibility to antibiotics; Brook (1987) reported that capsule formation was an important virulence determinant.

Anaerococcus vaginalis: This saccharolytic, butyrate-producing species was described as *Peptostreptococcus vaginalis* by Li *et al.* (1992) and re-assigned by Ezaki *et al.* (2001) to the genus *Anaerococcus*. It is easily identified by its distinctive PEP (Murdoch, 1998; Wilson *et al.*, 2000). It appears to be part of the normal vaginal flora and causes gynaecological infections. It accounted for 6% of all strains of GPAC in one survey (Murdoch, Mitchelmore and Tabaqchali, 1994). Murdoch and Kelly (1997) reported its isolation in pure culture and suggested that a large proportion of the organisms identified in previous surveys as *P. prevotii* actually refer to this species. It has been isolated from superficial sites (from leg ulcers with *S. aureus*), and recently from cerebral abscesses (Wilson *et al.*, 2000). There appear so far to be no studies of its pathogenicity, but the range and severity of the infections from which it has been isolated indicate that it is one of the more significant species of GPAC.

Clostridium Cluster I

Sarcina: This genus of strict anaerobes is highly unusual in that the cell morphology which is Gram-positive cocci arranged in 'packets' of eight that can form spores. 16S rRNA data have shown that the two

species, *S. maxima* and *S. ventriculi*, fall into *Clostridium* cluster I of Collins *et al.* and are closely related to *C. perfringens*; they are therefore phylogenetically distant from 'true' GPAC. The G+C ratio is 28–31 mol%. *Sarcinae* require carbohydrates to ferment and are common soil organisms, being able to thrive in acid environments as low as pH 1 (Canale-Parola, 1986; Ezaki, Oyaizu and Yabuuchi, 1992). They are part of the faecal flora, particularly of vegetarians (Crowther, 1971; Finegold, Attebery and Sutter, 1974) but are rarely isolated from human pathological specimens.

Clostridium Clusters IV and XIVa

Ruminococcus: This genus is a genetically heterogeneous collection of strictly anaerobic, strongly fermentative organisms. The type species, *R. flavefaciens*, is a member of Cluster IV but many other species are assigned to Cluster XIVa, including *R. productus*, previously classified in the genus *Peptostreptococcus*. Cell morphology is variable, depending on the species. Most species do not use peptides and require carbohydrates for their growth; some can digest cellulose. The major VFA formed is acetic acid. The atmospheric requirements for their growth are stringent (Bryant, 1986), which may explain why they are very rarely isolated from human clinical material. Nevertheless, they are major constituents of the gastro-intestinal flora (Finegold, Attebery and Sutter, 1974; Harmsen *et al.*, 2002).

Coprococcus: This little studied genus (similar to ruminococci) was proposed by Holdeman and Moore (1974) for organisms isolated from the human faecal flora.

Coriobacteriaceae (High G+C Gram-Positive Phylum)

Slackia exigua: Nucleic acid sequence data have shown that *Slackia* is not placed in the clostridial radiation and is closely related to *Atopobium* in the high G+C Gram-positive phylum (Wade *et al.*, 1999). This species fulfils the definition of a GPAC, as the Gram-stained appearance reveals tiny cocci or coccobacilli, and strains are strictly anaerobic (probably why they are rarely isolated from clinical material), forming very slowly growing colonies. *Slackia exigua* is strongly proteolytic and forms no VFAs other than acetate; strains can most easily be distinguished from *M. micros* and *A. parvulum* by their PEP. It is frequently isolated from periodontitis and periapical infections. Strains initially identified as *Peptostreptococcus heliotrinreducens* have been isolated from polymicrobial deep organ abscesses where they were very similar to *M. micros* (Murdoch and Mitchelmore, 1989). Antibiotic susceptibility data are limited, but metronidazole and β -lactams were effective against the extra-oral strains reported.

Atopobium: This genus of obligately anaerobic Gram-positive cocci includes *A. parvulum*, which was initially placed in the genus *Peptostreptococcus*; it was then reclassified in *Streptococcus* because its G+C ratio is 46 mol% and it produces large quantities of lactic acid. *Atopobium parvulum* is strongly saccharolytic but weakly proteolytic. It is probably part of the normal flora of the gastro-intestinal tract and has been isolated from abdominal abscesses and wounds (Hardie, 1986). It is sensitive to the same range of antibiotics as other GPAC, including metronidazole.

GRAM-NEGATIVE ANAEROBIC COCCI

These organisms are rarely cultured from human infections and have been much less studied; however, they are part of the normal human flora, for which reason alone they deserve further investigation.

Veillonella

The genus was described by Prevot in 1933; subsequently using DNA-DNA hybridisation techniques, Mays *et al.* (1982) recognised

seven species, but the authors were unable to differentiate them on phenotypic characteristics. The G+C content is 40–44 mol%. The cell morphology consists of small cocci arranged in pairs or short chains. Colonies grow slowly on normal laboratory media, their growth being encouraged by factors such as lactate, pyruvate and nitrate. All species form the VFAs acetic and propionic acid and reduce nitrate to nitrite, some form catalase. Otherwise they are rarely reactive in carbohydrate fermentation reactions or PEP kits, making differentiation within the genus difficult. A method of identification using RFLP analysis of PCR-amplified 16S rRNA has been described (Sato *et al.*, 1997). A red fluorescence under long-wave UV light formerly recommended for picking out colonies in mixed culture depends on the medium used and is unreliable (Brazier and Riley, 1988). Little is known about their potential pathogenicity; they contain a lipopolysaccharide that is a potential virulence factor. *Veillonellae* are part of the normal flora of the mouth and can reach high counts in the saliva. A recent study using 16S rRNA probes reported that they were minor but regular constituents of human faeces (Harmsen *et al.*, 2002). They have been isolated from oral infections but are rarely found in infections outside the mouth. Brook (1996) cultured them from 4% of paediatric specimens received, the most frequent sites being abscesses, aspiration pneumonias, burns, bites and sinuses (Bhatti and Frank, 2000). There are few data on their susceptibility to antibiotics; most strains tested have been sensitive to metronidazole, β -lactams and clindamycin, but resistant to vancomycin and aminoglycosides.

Acidaminococcus

The sole species at present in the genus, *A. fermentans*, does not ferment sugars but uses amino acids as its energy source. The G+C content is 56 mol%. The VFAs formed are acetic and butyric acids. It has been isolated from the human gastro-intestinal flora and, on very rare occasions, from human pathological specimens.

Megasphaera

The only species at present in the genus, *M. elsdenii*, forms very large cocci (2.5 μ m diameter) arranged in pairs or chains. It ferments carbohydrates, lactate and pyruvate and forms several VFAs, with *n*-caproic acid as the major metabolite. It is found in the stomachs of ruminants and occasionally of man. Human infections appear to be very rare.

Non-Sporing Gram-Negative Anaerobes

Sheila Patrick¹ and Brian I. Duerden²

¹Department of Microbiology and Immunobiology, School of Medicine, Queen's University of Belfast, Belfast; and ²Anaerobe Reference Laboratory, Department of Medical Microbiology, University of Wales College of Medicine, and National Public Health Service for Wales, Heath Park, Cardiff, UK

INTRODUCTION

The major Gram-negative non-sporing anaerobic bacteria of medical interest are classified within the families Bacteroidaceae and Fusobacteriaceae. They are a major component of the normal microbiota of mucosal surfaces of man and the whole range of animals from invertebrates such as termites to primates and are also important pathogens, usually in infections related to those colonised mucosal sites. Their contribution to human infection was first recognised in a report of pulmonary gangrene and appendicitis by Veillon and Zuber from the Institute Pasteur in 1898 although organisms now classified as *Fusobacterium necrophorum* had already been shown to cause calf 'diphtheria' (by Loeffler in 1884), liver abscesses in cattle and facial necrosis in rabbits. In 1861, Pasteur himself had introduced the term anaerobe for microbes that would grow only in the absence of free oxygen. Before 1900, the role of non-sporing anaerobes in suppurative diseases of the middle ear, mastoid and sinuses, pulmonary gangrene and genital tract infection was established by the group of researchers at the Faculté de Médecin de Paris. However, with a few notable exceptions, non-sporing anaerobes were largely ignored in mainstream medical microbiology for most of the 20th century, until the 'anaerobic renaissance' of the 1970s when improved laboratory methods for reliable routine anaerobic microbiology became more widely available. The findings of the early workers were then rediscovered, and the widespread role of these organisms in infections of the abdomen, perineum and genitalia, mouth and respiratory tract, and compromised soft tissues at other sites became more generally recognised (Finegold, 1994).

DESCRIPTION OF THE ORGANISMS

Development of Taxonomy

Veillon and Zuber named their isolates *Bacillus fragilis*, *Bacillus fusiformis* and others, and the current classification dates from 1919 when Castellani and Chalmers proposed the name *Bacteroides* for all obligately anaerobic, non-sporing bacilli; this definition was modified to exclude Gram-positive organisms by Weiss and Rettger in 1937. Knorr introduced the name *Fusobacterium* in 1922 for the spindle-shaped Gram-negative anaerobes. Despite various subsequent proposals for new genus names, all of which were subsequently deemed to be invalid, these two genera were the basis of the classification presented in the eighth (1974) edition of Bergey's Manual of Determinative Bacteriology, with the addition of the single-species genus *Leptotrichia*

(*L. buccalis*) for fusiform organisms that produce lactic acid rather than butyric acid as their major metabolic product (Holdeman and Moore, 1974). The genus *Bacteroides* contained five groups of species: 1. *B. fragilis*, divided into five sub-species; 2. bile-sensitive non-pigmented species such as *B. oralis*; 3. *B. melaninogenicus* including all strains that produced black- or brown-pigmented colonies on lysed blood agar and divided into three sub-species; 4. non-saccharolytic non-pigmented species; and 5. other, unrelated saccharolytic species. This was the starting point for the rapid growth of clinical and taxonomic studies with Gram-negative anaerobes (Duerden, 1983).

It should be remembered that although these bacteria are Gram negative, they are not closely related taxonomically to facultative and aerobic Gram-negative bacteria generally encountered in infections such as the Enterobacteriaceae and the pseudomonads. *Bacteroides* and the related *Porphyromonas* and *Prevotella* spp. belong to the Bacteroidetes/Chlorobi superphylum. This group diverged early in evolutionary terms from other eubacteria, and this is thought to have occurred well before the divergence of the Gram-positive bacteria from the phylum that contains Gram-negative species such as *Escherichia coli*, the Proteobacteria. Similarly, the fusobacteria are within their own separate phylum and have similarities at the genome sequence level with low mol% G+C Gram-positive bacteria.

The early taxonomic studies on these bacteria were based upon conventional cultural and biochemical tests, which were difficult to perform reliably and to interpret in anaerobic growth conditions. The use of gas-liquid chromatography (GLC), introduced into this area of work in the late 1960s, was a significant advance in showing the possession of distinct metabolic pathways giving reproducible patterns of fatty acid end products. A recent description of GLC methodology for anaerobes is detailed in the Wadsworth-KTL anaerobic bacteriology manual (Jousimies-Somer *et al.*, 2002). However, the significant advances since 1980 have been based upon a combination of chemotaxonomy and genetic analysis in particular, for example, phylogenetic 16S rRNA gene sequencing. rRNA gene sequencing is now a standard method for the validation of culture identity, and suitable methodology is detailed in, for example, Stubbs *et al.* (2000). A comprehensive taxonomic listing of old and new nomenclature can be found in Jousimies-Somer and Summanen (2002). The reader is directed to the following publications for detailed information on taxonomic history and recent updates (Shah and Garbia, 1991; Jousimies-Somer, 1997; Shah, Garbia and Duerden, 1998; Jousimies-Somer and Summanen, 2002). The chemotaxonomic characters of the main genera are summarized in Table 45.1.

Table 45.1 Chemotaxonomic characters of the main genera of Gram-negative anaerobes of clinical importance

Character	<i>Bacteroides</i>	<i>Bilophila</i>	<i>Prevotella</i>	<i>Porphyromonas</i>	<i>Fusobacterium</i>	<i>B. ureolyticus</i>
Major products	Acetate, succinate	Acetate succinate	Acetate succinate	Butyrate	Butyrate	Acetate, propionate
Dehydrogenases	G-6-PDH, 6-PDGH, MDH, GDH	...	MDH, GDH	MDH, GDH	GDA	...
DNA G + C (mol%)	40–48	39–40	40–50	48–54	27–32	28
Peptidoglycan diamino acid	<i>meso</i> -DAP	...	DAP	DAP, lysine	DAP, lanthionine	...
Fatty acids	Straight saturated <i>anteiso</i> - and <i>iso</i> -methyl branched		Straight saturated <i>anteiso</i> - and <i>iso</i> -methyl branched	<i>iso</i> -methyl branched	Straight chain, monounsaturated	...
Quinones	MK-10, MK-11		MK-10, MK-11, MK-13	MK-9	–	...
Sphingolipids	+	...	–	–	–	–
Urease	–	+	–	–	–	+

6-PGDH, 6-phosphogluconate dehydrogenase; DAP, diaminopimelic acid; G-6-PDH, glucose-6-phosphate dehydrogenase; GDH, glutamate dehydrogenase; MDH, malate dehydrogenase.

Bacteroides

The sub-species of *B. fragilis* were given species status, and several new species were added to this fragilis group of intestinal *Bacteroides*. As other species have been removed to new genera, the genus *Bacteroides sensu stricto* should now encompass only those species of the fragilis group. It was also recognised that a single species *B. melaninogenicus*, which had been described by Oliver and Wherry in 1921, could not include organisms as diverse as the saccharolytic subsp. *intermedius* and subsp. *melaninogenicus* and the non-saccharolytic but highly proteolytic subsp. *asaccharolyticus*. *Bacteroides asaccharolyticus* was first separated as a distinct species and then assigned to a new genus, *Porphyromonas*, together with related isolates from diseases of the mouth, *P. gingivalis* and *P. endodontalis*; further new species of human and animal origin were added subsequently. The saccharolytic pigmented species were shown to share many properties with the group 2 non-pigmented organisms that were mostly of oral or genital tract origin. These became the 'melaninogenicus-oralis group' and were then assigned to a new genus as *Prevotella* spp. The other '*Bacteroides*' species that do not belong to these three main genera of human isolates have mostly been assigned to various new genera although a few remain with the inappropriate name '*Bacteroides*' while awaiting reclassification. With the exception of '*B. ureolyticus*' and *Bilophila wadsworthia*, these are of little concern in medical microbiology.

Fusobacterium

The genus *Fusobacterium* is now defined in biochemical and genetic terms as encompassing Gram-negative non-sporing anaerobes with DNA G+C content of 27–33 mol% that produce butyric and propionic acids as major metabolic products. Many that conform with this description do not exhibit the classical fusiform appearance. The more significant members of the genus in human disease are *F. necrophorum* and *F. nucleatum*.

General Properties

All members of the families Bacteroidaceae and Fusobacteriaceae are obligately anaerobic, Gram-negative bacilli, although many are highly pleomorphic and microscopic appearances range from cocco-bacillary to long filamentous forms. Their susceptibility to oxygen varies; some, such as *B. fragilis*, can remain viable (sub-cultivable) after exposure to oxygen for many hours after growth on agar media, whereas some others cannot withstand exposure for more than a few minutes. Most of those of concern in medical microbiology are at the more tolerant end of this spectrum and can be manipulated on the open bench, although the speed of regrowth and percentage viability

are generally better if bacteria are handled in an anaerobic cabinet without exposure to air. Anaerobic conditions for growth are provided by incubation in anaerobic jars, or cabinets or other small-scale culture systems that exclude air and have a chemical system for removing traces of oxygen. The most commonly used gas mixture is H₂ 10%, CO₂ 10%, N₂ 80% for cabinets, or jars that incorporate a palladium catalyst to ensure the removal of remaining oxygen by reaction with the hydrogen. The species assigned to the main genera of are listed in Table 45.2. The genera *Bacteroides*, *Prevotella* and *Porphyromonas* all fall taxonomically within the class Bacteroides, whereas the genera *Fusobacterium* and *Leptotrichia* are within the class Fusobacteria. Details of the taxonomic status and classification of bacteria, including anaerobes, can be found at the NCBI taxonomy web site <http://www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html>.

Bacteroides

Bacteroides fragilis and other members of the genus *Bacteroides sensu stricto* are indistinguishable by microscopy or by colonial appearance. They are small, moderately pleomorphic, non-motile Gram-negative bacilli; cocco-bacilli are common but long filaments

Table 45.2 Gram-negative anaerobic bacteria of clinical significance

*Black- or brown-pigmented *Prevotella* spp.

**Non-pigmented *Porphyromonas* spp.

are rare. They grow well on conventional laboratory media containing blood to form circular, low convex, smooth, shiny, translucent or semi-opaque, grey colonies, 1–3 mm in diameter, that are often moist or frankly mucoid after incubation for 24–28 h. Most strains are non-haemolytic, but a few are slightly haemolytic and a small proportion are distinctly β -haemolytic. They are strongly saccharolytic organisms, producing acid from a range of carbohydrates, and moderately proteolytic. The main end products of metabolism detected using GLC are acetic and succinic acids, with smaller amounts of various other acids but not *n*-butyric or lactic acids. Growth is generally stimulated by whole bile but inhibited by sodium deoxycholate and isolates are tolerant of the bile salt sodium taurocholate. *Bacteroides splanchnicus* is an intestinal *Bacteroides* that differs from the other true *Bacteroides* spp. in producing propionic and *n*-butyric acids and in genetic and chemotaxonomic characters; it probably represents a distinct genus.

Prevotella

The various species of *Prevotella* cannot be distinguished by cell morphology. Most are short pleomorphic Gram-negative bacilli, often with many cocco-bacillary forms. They are divided into pigmented and non-pigmented groups by the ability of some to assimilate haemoglobin from blood in the medium, converting it to protohaemin which accumulates in the cells, making the colonies dark brown or black after incubation for several days. Most pigmented strains are haemolytic, and pigmentation depends upon lysis of the red cells in the medium and develops most rapidly on lysed blood agar. Pigmentation can vary from almost black to pale brown. Colonies of the non-pigmented species are indistinguishable from each other and very similar to those of the *Bacteroides* spp. – 1–2 mm in diameter, circular, shiny, convex and light buff or grey coloured; most are non-haemolytic. *Prevotella* spp. are moderately to strongly saccharolytic. All produce acid from glucose and various other carbohydrates and, like *Bacteroides* spp., their major metabolic products are acetic and succinic acids; *n*-butyric acid is not produced. Most species are moderately to strongly proteolytic. They are inhibited by bile and bile salts.

Porphyromonas

Formerly known as the asaccharolytic *B. melaninogenicus* strains, *Porphyromonas* spp. are similar to pigmented *Prevotella* spp. in microscopic and colony morphology. They are small, mainly cocco-bacillary organisms with few long filaments. Growth is slower than with *Bacteroides* spp. and some *Prevotella* spp.; small colonies may be visible after incubation for 24 h but many do not appear until 48 h when they are <1 mm in diameter, smooth, shiny and grey. Dark brown or black pigmentation develops after 3–7 days on blood agar, more rapidly on lysed blood agar. After 4–5 days, they are 1–2 mm in diameter and haemolytic – lysis of the cells being essential for pigmentation. Most strains have a characteristically strong, putrid smell, even more noticeable than those of other non-sporing anaerobes. They do not produce acid from glucose or other carbohydrates but their metabolism, as with all anaerobes, is fermentative. The major metabolic end product is *n*-butyric acid. Like *Prevotella* spp., *Porphyromonas* spp. are inhibited by bile or bile salts. They are vigorously proteolytic, and this is considered to be a factor in their virulence.

Fusobacterium

Fusobacteria are anaerobic Gram-negative bacilli of varied size and morphology. Classical fusobacteria, such as *F. nucleatum* are fairly long (4–6 μ m), regular bacilli with tapered or pointed ends. Spheroplasts and spindle forms are common. Others (e.g. some strains of *F. necrophorum*) are pleomorphic with a mixture of long, filamentous organisms with rounded ends and many short or even cocco-bacillary

forms and numerous spheroplasts and L-forms. Yet others are mostly cocco-bacillary. Colonial appearance is also varied, but most fusobacteria produce moderate to large colonies, 1–3 mm in diameter, generally with an irregular or dentate edge. They vary from translucent to granular and opaque. Their metabolism varies; carbohydrates are fermented only feebly or not at all but most species are proteolytic and the more virulent species such as *F. necrophorum* produce a range of enzymes that can break down tissue components (see p. 536 Tissue damage line 50–62). The major metabolic products of fusobacteria, which help define the genus, are *n*-butyric and propionic acids, the latter produced by deamination of threonine. The G+C content of fusobacteria is low at 27–33 mol%, and these and *Leptotrichia* are phylogenetically distinct from the Bacteroidaceae.

Leptotrichia

The species *L. buccalis* may be synonymous with the original fusiform organism described by Vincent. It has typical, long fusobacterial cells, 5–15 μ m long, many with pointed ends. Its colonies are lobate or convoluted, opaque and grey/yellow in colour. Although it is within the Fusobacteriaceae, it differs from *Fusobacterium* spp. in that it produces acid from several sugars and the only major metabolic product is lactic acid, with a small amount of acetic acid; *n*-butyric acid is not produced. Complete 16S rDNA sequencing and DNA-DNA hybridisation of strains initially assigned to *L. buccalis* reveals sufficient genetic diversity to warrant the designation of five different species (including *L. buccalis*) within this group (Eribe *et al.*, 2004).

Bilophila

The single species *Bil. wadsworthia* is a slow-growing, small Gram-negative bacillus that is stimulated by bile, requires pyruvate for growth and is asaccharolytic and urease positive (Baron *et al.*, 1992). It has no genetic homology with *Bacteroides* spp. and is classified within the Desulfobacteriaceae in the phylum Proteobacteria (Laue, Denger and Cook, 1997).

'*Bacteroides*' *ureolyticus*

This slender Gram-negative anaerobe typically forms pitting colonies on agar media (hence its former name *B. corrodens*). It is asaccharolytic, strongly proteolytic and urease positive. Its G+C content of 28 mol% clearly sets it apart from the other genera of Bacteroidaceae. Genotypically it is related to the Campylobacteraceae, in the phylum Proteobacteria (Jousimies-Somer, 1997). It is likely that it will be renamed once further similar bacteria have been isolated and studied.

Growth Conditions

As well as requiring anaerobic conditions, most Gram-negative anaerobic bacilli require enriched media for growth; none grows readily on minimal media or unsupplemented nutrient agar. Most require a source of haemin for synthesis of the menaquinones that are essential components of their anaerobic electron transport systems. Some *Prevotella* and *Porphyromonas* spp. also require menadione (vitamin K). Media for optimal growth comprise a rich nutrient base, e.g. Fastidious Anaerobe Agar (Lab M), Columbia agar base (Oxoid), Brucella agar or Wilkins Chalgren agar, with 5–10% blood plus haemin and menadione. *Bacteroides* spp. and some of the more vigorous *Prevotella* spp. produce reasonable growth after 24 h, but other species grow more slowly and require undisturbed anaerobic incubation for 48–72 h, or even longer, for recognisable growth. Details of the growth conditions for anaerobes of clinical importance can be found in the following references (Moore and Moore, 1977; Summanen *et al.*, 1993; Jousimies-Somer *et al.*, 2002).

NORMAL HUMAN MICROBIOTA

All the Bacteroides and Fusobacteria associated with man are part of the normal resident microbiota of the gastrointestinal, oral or genitourinary mucosae where they form a major part of the complex and interdependent ecosystems. However, the species found at the three sites are quite distinct and each species appears to have a distinct ecological niche (Drasar and Duerden, 1991).

Gastrointestinal Tract

This is the normal habitat of all the species of *Bacteroides sensu stricto* (*B. fragilis* group). They are one of the predominant groups of organisms in the faecal and colonic microbiota, having populations of approximately 10^{12} cfu/g wet weight of faeces and outnumbering the facultative enterobacteria by at least 1000:1. Not all species are equally common. The main components of the normal faecal microbiota are *B. vulgatus*, *B. distasonis*, *B. thetaiotaomicron* and *B. uniformis*. Within the gut, *Bacteroides* spp. contribute to the degradation of ingested material, in particular heterologous polysaccharides in plant material, that the mammalian system is incapable of degrading. This process results in the production of short-chain fatty acids, which once absorbed from the gut are potential substrates for energy metabolism in the intestinal mucosal epithelium. The potential for intimate interaction between the normal microbiota and the human host is illustrated by *B. thetaiotaomicron*. Within the environment of the small intestine, *B. thetaiotaomicron* appears to induce villus cells to fucosylate their cell surface glycoconjugates. *Bacteroides thetaiotaomicron* also secretes an α -fucosidase which cleaves the fucose from the villus cell glycoconjugates, thus releasing the fucose, which then becomes a potential carbon and energy source for the bacterium (Hooper *et al.*, 1999). Studies of the adherent mucosal microbiota indicate considerable variation amongst individuals. Mucosal biopsies of the proximal colon and rectum of 12 individuals showed that in different people one or two species of *Bacteroides* predominated by culture (Poxton *et al.*, 1997). For example, *B. fragilis* was the major isolate in one individual, the second most common isolate in three individuals and not detected in six, whereas *B. vulgatus* was the most common isolate in four individuals. Although *B. fragilis* accounts for fewer than 10% of faecal isolates and was not detected in some of the biopsy patients, it is the principal pathogen in gut-associated sepsis (approximately 75% of isolates from abdominal infections). This indicates that *B. fragilis* has a greater pathogenic potential than the other *Bacteroides* spp. *Bil. wadsworthia* is also a common but not dominant member of the faecal microbiota. The gastrointestinal tract is probably also the normal habitat of *P. asaccharolytica* and '*B.*' *ureolyticus*, but these are present only in small numbers.

Genitourinary Tract

Gram-negative anaerobes are part of the normal microbiota of the vagina although present in relatively small numbers (approximately 10^6 cfu/g of secretions) and outnumbered by Gram-positive species such as lactobacilli. Most isolates belong to the genus *Prevotella*, principally *Pr. bivia* and *Pr. disiens* which are uncommon elsewhere in the body; the pigmented species *Pr. melaninogenica* is also present, but in smaller numbers and less frequently (Drasar and Duerden, 1991).

Mouth

The oral microbiota have long been recognised as a source of a wide range of Gram-negative anaerobic species. The main habitat for these organisms in the mouth is the gingival crevice where both *Prevotella* and *Fusobacterium* spp. make a major contribution to the complex microbiota. The most commonly reported isolates are *Pr. melaninogenica*,

Pr. oralis and other non-pigmented *Prevotella* spp. and fusobacteria, mainly *F. nucleatum*. *Prevotella intermedia* is also isolated from the normal gingival microbiota but, like *B. fragilis* in the colon, represents a much smaller proportion of the total count of *Prevotella* spp. than do other species. *Porphyromonas gingivalis* is rarely isolated from healthy gingivae (Drasar and Duerden, 1991).

PATHOGENICITY

A wide range of Bacteroidaceae and Fusobacteriaceae have been isolated at one time or another from infections of man but a high proportion of these infections are caused by only a few, more virulent species. Three main features are common to most of these infections: 1. the source of infection is the endogenous microbiota of the patient's own gastrointestinal, oropharyngeal or genitourinary mucosa; 2. alterations of the host tissue, e.g. trauma and/or hypoxia, provide suitable conditions for the development of secondary opportunist anaerobic infections; and 3. the infections are generally polymicrobial, often involving mixtures of several anaerobic and facultative species acting synergically to cause damage. The initiation of infection generally depends on host factors, but even in such opportunist situations, some species show particular pathogenic potential not evident for the majority of related species from the same normal habitat. Thus, most species have some pathogenic capability but the majority of serious anaerobic infections are caused by the small number of more virulent species (Duerden, 1994).

The types of infection generally associated with Gram-negative anaerobes are listed in Table 45.3. The species most commonly isolated and considered to be significant pathogens in these situations are: *B. fragilis* in abdominal infections; *Pr. intermedia*, *P. gingivalis*, and *F. nucleatum* in periodontal disease and other infections related to the mouth; *P. asaccharolytica* and '*B.*' *ureolyticus* in superficial necrotising infections; and *F. necrophorum* in the invasive disease necrobacillosis (Lemmiere's disease). *Fusobacterium necrophorum* (including subsp. *necrophorum*, formerly Biovar A, and subsp. *funduliforme*, formerly Biovar B) has more of the characteristics of a virulent primary pathogen than other anaerobic species; typically, it causes severe purulent tonsillitis with pseudomembrane formation and lymph node involvement, septicaemia and metastatic abscess formation. It may be fatal even for a previously healthy person.

To establish an infection, bacteria must attach to target cells (generally mucosal or epithelial cells), invade the tissues, establish themselves by multiplying at the site of infection and avoiding elimination by the

host's defence mechanisms and cause damage both to local tissues and, in systemic infections, to the whole patient. A factor that may impact on each of these events is within-strain surface variation in the form of phase and antigenic variation. This type of variation is mediated by genomic rearrangements and is reversible within a single strain (Patrick and Larkin, 1995). Multiple variants may arise during the progression of infection of a single individual or indeed during one subculture in the laboratory. The more virulent Gram-negative anaerobes exhibit virulence factors that help elicit the different stages of infection. A review of the major potential virulence factors of *Bacteroides fragilis* can be found in Patrick (2002). Whole-genome sequencing programmes have added considerably to our knowledge and understanding of pathogenic bacteria and will continue to do so in years to come. Gram-negative non-sporing anaerobe whole-genome sequencing programmes are listed in Table 45.4.

Surface Variation

A single strain of *B. fragilis* may have the capability to reversibly produce three different encapsulating surface structures, namely a large capsule or small capsule, both visible by light microscopy, or an electron-dense layer (EDL) outwith the outer membrane, visible by electron microscopy. In addition, polysaccharides associated with the EDL and large capsulate bacteria (but which do not appear to form the bulk of the large capsule structure) exhibit within-strain antigenic variation (Lutton *et al.*, 1991). This is mediated, at least in part, by invertible promoter regions upstream of the polysaccharide biosynthesis operons. The invertible regions are bound by inverted repeats of 30 or 32 bp in length with striking similarity to the *Salmonella typhimurium* H flagellar antigen inversion cross-over (*hix*) recombination sites of the invertible *hin* region (Patrick *et al.*, 2003). In *B. fragilis* NCTC 9343, there are ten different polysaccharide biosynthesis operons. The genes within these operons indicate that some may be similar to enterobacterial 'O-antigen' rather than classical capsules. Analysis of the entire genome has revealed a further 16 regions with similar sequence characteristics, suggesting that these may also be active invertible promoters. Most of these are upstream of conserved putative secreted and outer membrane proteins of unknown function. Also there is evidence of large scale (5–120 kb) DNA inversion events within the genome (Cerdeno-Tarraga *et al.*, 2005).

Whether this phenomenal variation relates to the increased frequency of association of *B. fragilis* with infection when compared with other gastrointestinal tract *Bacteroides* or survival in the gastrointestinal tract remains to be determined.

Adhesion

Bacteroides fragilis can attach to both host cells and components of the extracellular matrix; however, studies of adhesion have rarely taken into account the considerable within-strain surface variation

p. 535 Surface Variation line 19–41. Haemagglutination and attachment to host cells in *B. fragilis* is demonstrable in EDL-enriched populations (Patrick *et al.*, 1988). Sodium periodate treatment of the bacteria abolishes haemagglutination, which suggests that saccharides are involved. Populations of strain NCTC 9343 enriched for either a large or small capsule do not haemagglutinate (Patrick *et al.*, 1996). As recent clinical isolates vary considerably in the proportion of bacteria that express the different capsules, this probably accounts for the variation in adhesion observed with different strains. Furthermore, the EDL/non-capsulate bacteria release extracellular vesicles which by themselves will cause haemagglutination. Despite reports of fimbrial expression by *B. fragilis*, fimbrial genes have not been reliably identified, although a gene with similarity to a putative non-fimbrial adhesin described in *Pr. intermedia* is present in *B. fragilis* NCTC 9343 (Cerdeno-Tarraga *et al.*, 2005). Studies of the attachment to components of the extracellular matrix have generally not taken into account the within-strain variability and the potential attachment of bacterial extracellular components; however, there is clear evidence that *Bacteroides* spp. can attach to some host components. Examples include fibronectin, collagen type 1 and vitronectin.

Periodontal pathogens also exhibit adhesive properties. *Fusobacterium nucleatum*, *P. gingivalis* and *Pr. intermedia* adhere to crevicular epithelium and cause haemagglutination. It seems likely that, as with *B. fragilis*, both proteinaceous haemagglutinins and surface saccharides are involved. More than ten genes encoding haemagglutinin-related proteins have been identified in the *P. gingivalis* genome sequence (Nelson *et al.*, 2003). Another aspect of adhesion that may be important in polymicrobial infections is the ability of bacterial species to coaggregate. These coaggregates may be important in creating appropriate conditions for the symbiotic metabolism and pathogenic interaction characteristic of anaerobic infections. This feature is manifest by oral *Prevotella* and *Porphyromonas* spp. together with streptococci, actinomyces and other oral species.

Fusobacterium necrophorum haemagglutinates erythrocytes from a range of species, including humans, and some will also aggregate human platelets. It is suggested that this causes intravascular coagulation which contributes to the establishment of infection (Hagelskjaer Kristensen and Prag, 2000).

Invasion

Most anaerobic pathogens are not primarily invasive. Initiation of infection depends on initial damage due to trauma, hypoxia, neoplasia or some other alteration to provide the route of entry for the anaerobes. *Fusobacterium necrophorum* is an exception to this rule, as although it may be present as part of the normal microbiota, in some patients it penetrates the mucosa. The reasons for this are unknown but may relate to underlying bacterial or viral pharyngitis leading to a reduction in the host defence at the mucosal surface (Hagelskjaer Kristensen and Prag, 2000).

Establishing Infection

Once the initial damage has allowed the anaerobes to penetrate the tissues, they must establish a focus of infection by multiplying and avoiding elimination by the host's defence mechanisms. Most anaerobic infections are polymicrobial, and the metabolic interdependency of the bacterial mixtures involved (both anaerobic and facultative species) is important to their establishment in the tissues, the satisfaction of their nutritional requirements and the expression of their synergic pathogenicity (e.g. Rotstein, Kao and Houston, 1989); thus, the virulence of anaerobic species is a reflection of their ability to exploit a compromised host environment. Tissue damage and necrosis, a reduction in blood supply leading to hypoxia and the presence of a blood clot or foreign body or substance (especially CaCl₂) create conditions appropriate for anaerobic growth. The capacity of facultative species such as *E. coli* to consume oxygen may help create reduced conditions favourable to the growth of anaerobes. *Bacteroides fragilis* has a cluster of genes, the aerotolerance operon, whose products aid its survival on exposure to oxygen. A similar cluster had been identified in the *P. gingivalis* genome. In addition, *B. fragilis* can grow in the presence of nanomolar concentrations of oxygen and this is linked to the presence of a cytochrome *bd* oxidase (Baughn and Malamy, 2004).

Gram-negative anaerobes require several growth factors and nutrients produced by damaged host tissues or by other bacteria acting in synergy. For example, *B. fragilis* uses haemoglobin and haemoglobin-haptoglobin complexes as sources of iron and the porphyrin component. It has an iron-repressible haem-binding outer membrane protein involved in the uptake of this essential growth factor (Otto *et al.*, 1996). *Porphyromonas gingivalis* demetalates protohaem to protoporphyrin, providing for its iron needs. Novel putative haemolysin genes with sequence similarity have been identified in *B. fragilis*, *Pr. melaninogenica*, *Pr. intermedia* and *P. gingivalis*. Hydrolytic enzymes and proteases produced by *P. gingivalis* (e.g. gingipains), *P. asaccharolytica*, *Pr. intermedia* and *Pr. denticola* release nutrients from growth factors for these species themselves and for other members of the polymicrobial ecosystems. Some of the proteases of *P. gingivalis* are subject to the post-translational addition of oligosaccharides within the catalytic domain (Gallagher *et al.*, 2003). *Bacteroides fragilis* produces a serine-thiol-like protease that hydrolyses the α -chain of fibrinogen (Chen *et al.*, 1995). As soluble fibrinogen is converted to insoluble fibrin as part of the normal blood-clot formation and wound healing, this enzyme has the potential to slow clot formation. It also produces heparinase and chondroitin sulphatase, which hydrolyse heparin and chondroitin sulphate, allowing their use as nutrients. The activities of these enzymes are likely to encompass tissue destruction and, where cells and molecules of the immune system are attacked, evasion of the immune response (see p. 536 Evasion of the host defence line 16–34 and Tissue damage line 38–61).

Evasion of the Host Defence

The host response to anaerobic infection includes phagocytosis and opsonisation and killing by serum immunoglobulin and complement. The virulent species of Gram-negative anaerobe have various means of avoiding and resisting these defence mechanisms. *Bacteroides fragilis* and some black-pigmented, Gram-negative anaerobes produce various extracellular polysaccharides that may form encapsulating structures, not all which are visible by light microscopy (see p. 535 Surface Variation line 21–24). In *B. fragilis* some of these various components have been implicated in adhesion (Patrick *et al.*, 1988), protection against phagocytosis, resistance to killing mediated by the alternative complement pathway (Reid and Patrick, 1984) and the induction of abscess formation (Tzianabos *et al.*, 1993).

Bacteroides fragilis also inhibits macrophage migration and impairs the phagocytosis of other species involved in the polymicrobial infections. Succinic and other short-chain fatty acid metabolic

products have also been shown to inhibit chemotaxis, phagocytosis and intracellular killing by phagocytic cells (Rotstein *et al.*, 1989). *Porphyromonas gingivalis* (Laine and von Winkelhoff, 1998) also produces a capsule that protects against phagocytosis and intracellular killing and generates metabolic products that compete with chemotactic peptides, heat-labile opsonins and complement components to block chemotactic receptors on polymorphs. Abscess-derived neutrophils are reported to harbour viable bacteria and be less efficient at killing *B. fragilis* than neutrophils derived from either peritoneal aspirates or peripheral blood (Finlay-Jones *et al.*, 1991). The potential for excreted extracellular polysaccharide and extracellular outer membrane vesicles to mop up opsonin, activate complement and interact with phagocytes, thus diverting the host defence from the bacterial cell, should not be overlooked. Proteases that degrade cytokines, produced by for example *P. gingivalis*, may also interfere with the immune response including phagocytic function.

Fusobacterium necrophorum isolated from animal infection secrete a well-characterised leukotoxin with specific toxicity for cattle and sheep neutrophils (Narayanan *et al.*, 2002); however, it is not clear whether isolates from human infections secrete similar molecules with specificity for human neutrophils.

Several virulent anaerobic species generate products that inhibit or destroy the humoral components of the host's defences. The black-pigmented species produce proteolytic enzymes active against immunoglobulins and complement and most anaerobic bacteria produce soluble metabolites that are leukotoxic, inhibit chemotaxis and damage mucosal cells.

Neuraminidases, which cleave sialic acid from oligosaccharides on host cell glycoproteins and glycolipids, produced by *B. fragilis* could play a key role in virulence (Godoy *et al.*, 1993). There are more than 20 known naturally occurring sialic acids formed by various substitutions and additions to neuraminic acid (Schauer, 1985). There is growing evidence that these sugar residues are involved in the biological activities of the host cells and molecules, in particular in relation to immune system function.

Tissue Damage

Once infection is established, several virulence factors appear to act in combination to produce damage that is manifest as tissue necrosis and abscess formation. Some products of anaerobic metabolism are toxic to mammalian cells: volatile fatty acids and sulphur compounds (e.g. H₂S and amines). Most pathogenic anaerobes also produce extracellular enzymes that hydrolyse tissue components and are thought to play a significant role in pathogenesis (e.g. Rudek and Haque, 1976). *Bacteroides fragilis*, *P. gingivalis*, *P. asaccharolytica*, *Pr. intermedia*, *Pr. melaninogenica* and *Pr. denticola* produce hyaluronidase, chondroitin sulphatase, heparinase and a range of enzymes that hydrolyse carbohydrates. All of these enzymes play dual roles, causing tissue damage and providing nutrients for the infecting microbes. *Fusobacterium necrophorum* produces membrane-damaging lipases that may be related to haemolytic activity (Hagelskjaer Kristensen and Prag, 2000).

Proteolytic activity is associated with the strongly proteolytic *Porphyromonas* spp. and some *Prevotella* spp. Proteases, such as the trypsin-like cysteine proteases (gingipains) of *P. gingivalis* (Curtis *et al.* 2001), are thought to be important in the destruction of gingival tissue and of the collagen bridges in the gingival crevice in periodontal disease. Proteases may also be important in the contribution of *P. asaccharolytica* and '*B.*' *ureolyticus* to tissue damage in ulcerative and gangrenous lesions such as genital and perineal ulcers, decubitus and varicose lesions and diabetic gangrene.

Systemic Inflammatory Response Syndrome

Systemic inflammatory response syndrome (SIRS) or 'sepsis' is the most common cause of death in patients who are critically ill in

non-coronary intensive care units. Endotoxin, containing lipopolysaccharide (LPS), is one bacterial component that is known to play a central role. In patients where there is no obvious bacterial septicaemia, it is thought that the source of the endotoxin is the normal intestinal microbiota. *Bacteroides fragilis* LPS is 5000-fold less toxic in a mouse lethality model than enterobacterial LPS, but given the high numbers of *Bacteroides* spp. in the intestinal tract, where enterobacteria may be outnumbered by up to 1000–1, even allowing for the lower toxicity, it is likely that the numerical dominance of *Bacteroides* LPS means that it plays some role in endotoxic shock and SIRS (Delahooke, Barclay and Poxton, 1995a, b). LPS triggers inflammatory events via the Toll-like receptors (TLRs). LPS from *E. coli* and *Salmonella* spp. interacts with TLR4, whereas LPS from *P. gingivalis* interacts with TLR2, resulting in a less efficient production of proinflammatory cytokines (Erridge, Bennett-Guerrero and Poxton, 2002; Netea *et al.*, 2002). It is now known that the mutation in C3H/HeJ mice that are hyporesponsive to enteric LPS but react with *Bacteroides* spp. LPS (Delahooke, Barclay and Poxton, 1995b) is in the TLR4 gene. The differences in the reactivity of the different LPS molecules appear to relate to their chemical composition, the number, length and composition of the fatty acid chains (or acyl groups) attached to the diglucosamine backbone of the LPSs being different. The lipid A of *P. gingivalis* is less conical in shape than that of *E. coli*. In addition, enterobacterial lipid A diglucosamine is bisphosphorylated whereas in *B. fragilis* it is monophosphorylated; the distal glucosamine residue of the lipid A molecule is lacking in a phosphate group. Also, the core polysaccharide sugar keto-deoxyoctonate (KDO) is phosphorylated which renders it undetectable in the standard KDO thiobarbituric acid assay (Beckmann *et al.*, 1989; Fujiwara *et al.*, 1990).

Whether or not the LPS of *Bacteroides* spp. possesses or is lacking in an O-antigen similar to that found in the enterobacteria is subject to controversy. In the literature, there are reports that extended repeating O-antigen is absent in *Bacteroides* (Lindberg *et al.*, 1990; Comstock *et al.*, 1999). The suggestion is that LPS is more like the lipo-oligosaccharides of, for example, *Nisseria meningitidis* (Jennings *et al.*, 1999) or 'rough' type mutants of the enterobacteria. Other publications, however, quite clearly illustrate silver-stained LPS polyacrylamide gel electrophoresis (PAGE) profiles with ladder patterns characteristic of smooth LPS in *B. fragilis* (Poxton and Brown, 1986) and *B. vulgatus* (Delahooke, Barclay and Poxton, 1995a). The controversy over the presence or absence of an 'O-antigen' component in *Bacteroides* spp. can be explained by the use of different chemical extraction procedures by different laboratories and the variation in the expression of the polysaccharide biosynthesis operons. The *in silico* identity of the genes within the polysaccharide biosynthesis operons, which are controlled by invertible promoters (see p. 535 Surface Variation line 26–28), suggests that some of these are related to the O-antigens of other bacteria (Cerdano-Tarraga *et al.*, 2005). The LPS of *P. gingivalis* appears to play a significant role in the pathogenesis of periodontal disease, in which (like the LPS of *B. fragilis*) it reduces the opsonic activity of serum, stimulates gingival inflammation, increases the secretion of collagenase from host cells and reduces collagen formation, and induces localised bone resorption around the tooth root. These effects are attributable to the release of biologically active agents, including the cytokines interleukin-1 and tumour necrosis factor from host cells.

Fusobacterium necrophorum is an exception, as its LPS contains classical KDO and displays endotoxic activity similar to that of enterobacterial LPS, particularly during the septicaemic phase of human necrobacillosis.

Enterotoxin

Enterotoxigenic *B. fragilis* were first described as a cause of acute watery diarrhoeal disease in animals and subsequently humans, in particular children (Myers *et al.*, 1987). The enterotoxin is a zinc-dependent metalloprotease of approximately 20 kDa. The possible

relationship of the enterotoxin to the virulence of *B. fragilis* in other types of infection remains to be proven as only between 9 and 26% of isolates harbour the gene encoding the toxin (Patrick, 2002).

CLINICAL FEATURES OF ANAEROBIC INFECTIONS

Infections with Gram-negative anaerobes are principally endogenous in source and related to the body sites where these microbes are part of the normal microbiota. Several features are typical of most anaerobic infections: they are necrotising or gangrenous conditions in tissues rendered susceptible by trauma, reduced blood supply and poor oxygenation, often in the presence of a foreign body or blood clot, and producing copious amounts of foul-smelling pus; thrombophlebitis of surrounding blood vessels is common, enhancing the anaerobic conditions. The characteristic smell of anaerobic infections is caused by the volatile end products of anaerobic metabolism. Infections are rarely 'pure', i.e. monobacterial. Anaerobic species are usually present in association with other anaerobic or facultative species in synergic mixtures (see p. 534 pathogenicity line 17–19), but the anaerobes appear to be the principal causes of tissue damage and abscess formation in these mixed infections. From a clinical perspective, infections may be divided into five broad groups: 1. those derived from the gastrointestinal tract, 2. genito-urinary infections in men and women, 3. infections of the head and neck related to the oral microbiota, 4. infections of other soft tissues, and 5. bacteraemia (Finegold and George, 1989; Duerden, 1990).

Gut-Associated Infections

Bacteroides spp. represent a large proportion of the normal microbiota of the lower intestinal tract and are the main cause of serious sepsis associated with surgery, injury, perforation or other underlying abnormality of the large intestine. *Bacteroides* spp. are the main components of the microbiota of post-operative abdominal wound infections, peritonitis and intra-abdominal abscesses (appendix, diverticular or paracolic, pelvic, sub-phrenic etc.). *Bacteroides fragilis* is the most common species isolated from these infections, representing about 75% of the *Bacteroides* isolates in contrast with between 4 and 13% of *Bacteroides* isolates from the faecal microbiota. Thus, *B. fragilis* clearly appears to have particular pathogenic potential and a much greater capacity to cause infection than the other *Bacteroides* spp., as described in the pathogenicity. Amongst the remaining 25% of isolates, *B. thetaiotaomicron* is the most common, with smaller numbers of *B. distasonis* and *B. vulgatus* (Patrick, 2002). The species other than *B. fragilis* are usually found in mixtures of multiple anaerobic species, often representing gross faecal soiling of the tissues. *Bilophila wadsworthia* is associated with gangrenous appendicitis and other intra-abdominal sepsis.

Gram-negative anaerobes are predominant components of the mixed microbiota of peri-anal, pilonidal and perineal abscesses (Duerden, 1991). *Bacteroides fragilis* is again the most common species isolated, but *P. asaccharolytica* and '*B.*' *ureolyticus* appear more frequently in these infections than in abdominal infections, as they do in other superficial soft-tissue infections such as sebaceous abscesses and decubitus or diabetic ulcers (Duerden, Bennett and Faulkner, 1982) (see p. 539 Superficial soft-tissue infections).

Liver abscesses form a specific clinical group of intra-abdominal abscesses. They are generally polymicrobial and anaerobes, particularly *Bacteroides* spp. and anaerobic cocci often predominate. The route of infection is usually via the portal venous system, and the common underlying causes are colorectal malignancy, ulcerative colitis, Crohn's disease and other intra-peritoneal abscesses. The most common species isolated is, again, *B. fragilis*, and *Bacteroides* bacteraemia is a well-recognised complication. Anaerobes are responsible for only a minority of biliary tract infections, being restricted mainly to obstructive empyema of the gall bladder.

Commonly associated facultative bacteria include *E. coli* and *Streptococcus* spp., in particular *Strep. milleri*, which forms pinpoint colonies and with a characteristic smell.

Genito-Urinary Infections

Gram-negative anaerobes are significant pathogens in a wide range of infections of the genito-urinary tract in both men and women (Duerden, 1991). In men, the infections are principally ulcers and abscesses of the external genitalia and perineum, but in women there are also infections of the vagina and of the uterus and deep pelvic tissues.

In local abscesses associated with the secretory glands in women, e.g. Bartholin's and Skene's abscesses, obstruction of the ducts leads to a build up of secretions and infection with a mixed bacterial microbiota, predominantly anaerobic, that is similar to the microbiota of sebaceous cysts and pilonidal abscesses; *P. asaccharolytica* is a common and important isolate. Anaerobes are also frequent isolates from genital ulcers, a common problem in both men and women. They are probably not primary causes (genital herpes or trauma are common primary diagnoses) but whatever the cause of the initial damage, anaerobes form a major part of the microbiota of established ulcers and contribute to the progressive tissue damage. The term genital ulceration covers a range of superficial necrotising conditions, from erosive balanitis/balanoposthitis in men and superficial labial ulceration in women, through deep, spreading ulcers, typically with undermined edges, to the more severe forms of synergic gangrene. In all groups, regardless of initiating factors, anaerobic bacteria are the predominant cultivable bacteria once the superficial debris is removed. Gram-negative anaerobes are not normally present on the external genitalia but are the most common isolates from infected ulcers. Although *Bacteroides* spp. may be present in some cases, the most common apparently significant isolates are the asaccharolytic and strongly proteolytic *P. asaccharolytica* and '*B.*' *ureolyticus* which have a particular association with superficial necrotising and ulcerative lesions at various body sites. *Prevotella* spp., principally *Pr. intermedia* (which appears to be the most virulent of the *Prevotella* spp.), are also common isolates – being less common than *P. asaccharolytica* in men but about equally common in women, in whom *Prevotella* spp. are part of the normal vaginal microbiota (Masfari, Kinghorn and Duerden, 1983; Masfari, Duerden and Kinghorn, 1986).

Vaginal discharge is a common complaint of women attending Genito-urinary Medicine clinics and anaerobes are involved in many cases (Duerden, 1991). The most common condition is bacterial (anaerobic) vaginosis in which a disturbance of the normal vaginal microbiota with the loss of predominant lactobacilli and their replacement by increased numbers of Gram-negative anaerobes results in a discharge with an offensive, fishy smell. With the proliferation of *Prevotella* spp., *Gardnerella vaginalis* and *Mobiluncus* spp., the vaginal pH rises, the lactate concentration falls and the amounts of succinate, acetate, propionate and butyrate increase, together with volatile amines that cause the smell. These same metabolites may induce the excessive secretion from the vaginal mucosa, but the factors that initiate the condition, other than its clear association with sexual activity and a relationship with the presence of seminal fluid in the vagina, are still not clear. The other main causes of vaginal discharge – gonorrhoea, chlamydia and trichomonas infection – also cause a major disturbance of the normal microbiota with significant increases in the numbers of Gram-negative anaerobes (Masfari, Duerden and Kinghorn, 1986).

Ascending infections of the uterus and pelvis with vaginal anaerobes (mainly *Prevotella* spp.) or with *B. fragilis* or *P. asaccharolytica* are the cause of serious gynaecological sepsis. Some of these infections are the classical infective complications of pregnancy, parturition or abortion such as post-partum or post-abortion uterine infections in which retained products of conception provide ideal conditions for anaerobes to proliferate. With the control of streptococcal puerperal infection, anaerobes have become the most common cause of post-partum sepsis. The same microbes also contribute to deep pelvic infections

unrelated to pregnancy – endometritis, parametritis, tubo-ovarian and pelvic abscesses, generally grouped together as pelvic inflammatory disease – and wound infections and abscesses complicating gynaecological surgery. Laboratory confirmation of the cause of pelvic sepsis is difficult without surgical exploration; laparoscopy does not provide adequate samples for bacteriological culture but evidence from cases that have required open surgery supports the role of anaerobes in these infections (Kinghorn, Duerden and Hafiz, 1986). In gynaecological surgery, the underlying pathology has often resulted in colonisation of the usually sterile deep sites and the incidence of wound infection, before antibiotic prophylaxis was routine, was about 20% and most were anaerobic, with both the vaginal *Prevotella* spp. and *B. fragilis* being common isolates.

Fusobacterium nucleatum, along with *Mobiluncus curtisii*, has been recovered from the amniotic fluid of women with preterm delivery (Citron, 2002).

Infections with Oral Anaerobes

The Gram-negative anaerobes that are part of the normal microbiota of the gingival crevice cause suppurative infections of the gingiva and immediate surrounding tissues related to dental problems but can also cause various abscesses and soft-tissue infections throughout the head, neck and chest (Hardie, 1991).

Gingivitis and periodontal disease are probably the most common anaerobic infections, if not the most common of all infections worldwide, and are the most important cause of tooth loss. Acute ulcerative gingivitis (also known as Vincent's angina, Plaut-Vincent's infection or trench mouth) was one of the first anaerobic infections of man to be recognised. It is associated with poor oral hygiene, malnutrition and general debility and is now seen as a complication of AIDS. Clinically, there is pain, haemorrhage, inflammation and destruction of gum tissue and a foul odour. Spirochaetes and fusiform organisms are seen readily in stained films of the exudate and they may play a role in the disease, but the oral Gram-negative anaerobes, principally *Prevotella* and *Porphyromonas* spp., are also present in large numbers and may be more important in the pathogenesis of the condition. In other forms of periodontal disease, *P. gingivalis* and *Pr. intermedia* have been implicated as significant pathogens in rapidly progressive disease. *Fusobacterium nucleatum* and non-pigmented *Prevotella* spp. are also present in large numbers in periodontal disease and may have a pathogenic role (Tanner and Stillman, 1993).

The oral anaerobes are also important in dental abscesses, root canal infections (a particular association of *P. endodontalis*) and soft-tissue abscesses, e.g. buccal and pharyngeal abscesses. In the normal healthy state, these anaerobes do not colonise other sites in the head and neck and do not cause acute primary infections of the throat, middle ear, mastoid or sinuses. However, when pre-existing damage or prolonged infection leads to the development of chronic otitis media, mastoiditis or sinusitis, these compromised air passages become infected with a mixture of oral streptococci and anaerobes such as *Prevotella* spp. These anaerobes are also the most common cause of brain abscess, especially those originating from chronic otitis media, mastoiditis or sinusitis; cholesteatoma is an important predisposing factor. Infection spreads by direct extension, often with localised osteomyelitis and thrombosis of the lateral sinus. Dental infection may also give rise to brain abscess either by direct extension or by haematogenous spread (Ingham and Sisson, 1991). Similarly, the oral anaerobes can cause lung abscesses as a result of aspiration of organisms from the mouth when there is already some abnormality such as obstruction due to a malignant tumour or an inhaled foreign body (Civen *et al.*, 1995).

Fusobacterium necrophorum subsp. *necrophorum* (previously *F. necrophorum* Biovar A) differs from almost all other Gram-negative anaerobes in being a primary pathogen capable of causing disease in previously healthy people, although there may be synergic involvement of other viruses or bacteria that cause pharyngitis in the initial invasion of the mucosa (Hagelskjaer Kristensen and Prag, 2000).

Epstein–Barr virus infection (infectious mononucleosis) may be a predisposing factor.

Classically, the infection (necrobacillosis or Lemmiere's syndrome) begins as a suppurative tonsillitis with pus formation and a pseudomembrane, which spreads to involve the local lymph nodes in the neck and from there to invade the bloodstream causing septicaemia and disseminating the organisms widely in the tissues to form multiple soft-tissue abscesses at many sites in the body (liver, lung, kidney etc.). It may also occur in children with otitis media, adults with tooth infections and spread from other foci such as sinusitis or mastoiditis in all ages. *Fusobacterium necrophorum* may also cause necrobacillosis arising from sites other than the head and neck in elderly patients with other predisposing disease. In patients with anaerobic sepsis arising from the oropharynx, *F. necrophorum* should immediately be considered as a potential cause, as it is the most frequently isolated species. The classical symptoms of Lemmiere's syndrome are oropharyngeal pain, neck swelling, pulmonary symptoms, arthralgia and fever. It should be considered in patients with severe sepsis and pulmonary symptoms after acute pharyngotonsillar infection. Unilateral suppurative thrombophlebitis of the internal jugular vein is characteristic and can be diagnosed by ultrasonography, axial CT scan or magnetic resonance angiography of the neck. Multiple bilateral necrotic infiltration of the lungs with pleural effusion, empyema and/or pulmonary abscesses is reported in up to 85% of cases (Hagelskjaer Kristensen and Prag, 2000).

Lemmiere's syndrome was first described in the pre-antibiotic era. It became very uncommon during the second half of the 20th century, possibly due to widespread and indiscriminate use of antibiotics for upper respiratory tract infections, but increasing numbers of cases have been reported in the United Kingdom during the past decade (Brazier *et al.*, 2002) and also recently in the United States (Ramirez *et al.*, 2003).

Bone and Joint Infection

Anaerobic bacteria, often along with facultative species, may be associated with both osteomyelitis and septic arthritis. *Bacteroides fragilis* was the predominant anaerobic isolate from osteomyelitis in a 10-year study. In addition, *Prevotella*, *Porphyromonas*, *Fusobacterium* and other *Bacteroides* spp. were isolated. *Bacteroides fragilis* was associated most frequently with infections of the hands and feet where there was underlying vascular disease or neuropathy, whereas *Prevotella*, *Porphyromonas* and *Fusobacterium* were more frequently recovered from skull and bite infections (Brook and Frazier, 1993). Gram-negative non-sporing anaerobes are rarely isolated from prosthetic joint-associated infection, where *Propionibacterium acnes* is the most frequently isolated anaerobe (Tunney *et al.*, 1998). *Bacteroides fragilis* and *Fusobacterium* spp., however, may cause septic arthritis. In approximately 50% of instances this arises from haematogenous spread from a distant focus of infection.

Superficial Soft-Tissue Infections

As well as infections related to the normal carriage sites of Gram-negative anaerobes, another group of soft-tissue infections occurs at sites not immediately adjacent to the mucosae but in tissue damaged by trauma or hypoxia, or where secretory glands become blocked. These infections include sebaceous and pilonidal abscesses, breast abscesses in non-lactating women and infection secondary to inadequate perfusion and oxygenation of the skin and subcutaneous tissues – decubitus and varicose ulcers, diabetic gangrene etc. (Adriaans, Drasar and Duerden, 1991). Although a wide range of anaerobes and facultative species can be isolated from these lesions, there is a particular association between progressively destructive infections and the presence of *P. asaccharolytica* and/or '*B.*' *ureolyticus* (Duerden, Bennett and Faulkner, 1982). There is a specific association of *F. ulcerans* with tropical ulcers – deep eroding ulcers, usually of the lower limb, occurring across many tropical regions (Adriaans Hay and Drasar, 1987; Adriaans *et al.*, 1987). Since the initial description

of this bacterium, further isolates have not been reported. This may have arisen from a phenotypic similarity to *F. varium* (a gastrointestinal species). Many commercial identification kits lack a test for nitrate reduction, a distinguishing feature of *F. ulcerans*. Therefore, an incorrect identification of *F. varium* is generated by the kit database (Citron, 2002).

Bacteraemia

Primary bacteraemia with Gram-negative anaerobes is extremely rare. It is an integral part of necrobacillosis in which *F. necrophorum* invades the bloodstream as part of the spread of infection from the primary site in the throat (see p. 538 Infections with oral anaerobes line 3–5). In most other cases, the bacteraemia is secondary to localised infections at some site in the body, e.g. intra-abdominal abscess and pelvic sepsis, may be the first indication of some serious underlying condition such as a brain abscess (Goldstein, 1996). Bacteraemia with a *Bacteroides* spp. may be the first indication of a malignant tumour of the colon, rectum or cervix. The most common anaerobic species isolated from blood cultures is *B. fragilis*. Mortality and morbidity of *Bacteroides* bacteraemia depends generally upon the underlying cause. A matched-pair study in the United States reported a potential mortality of up to 19% for *B. fragilis* group bacteraemia (Redondo *et al.*, 1995).

LABORATORY DIAGNOSES

The site and nature of the infection (e.g. an abdominal abscess or a necrotising or gangrenous ulcer) may give a clear indication that anaerobes are likely to be involved, and the presence of a foul-smelling exudate or pus is the strongest clinical indication of an anaerobic infection. The diagnosis is confirmed by careful anaerobic culture methods and the identification of the isolates obtained. Because these infections are often associated with sites that have a complex normal bacterial microbiota (often including the organisms that may be the putative pathogens), and because anaerobes are, by their nature, more or less susceptible to exposure to oxygen, care is needed in specimen collection and transport to try to ensure that the organisms sought do not die in transit to the laboratory and that any cultures obtained represent the microbiota at the infected site and not contamination from the normal mucosal microbiota (Drasar and Duerden, 1991; Summanen *et al.*, 1993). Information on all aspects of laboratory diagnosis of anaerobic bacteria and detailed identification protocols can be found in the Wadsworth-KTL Anaerobic Bacteriology Manual (Jousimies-Somer *et al.*, 2002).

Specimen

The most reliable specimens are pus or exudates from the depths of an open lesion or a closed lesion. Specimens such as sputum collected from sites with a normal mucosal microbiota are not suitable for anaerobic culture. Swabs used traditionally to sample wounds and exudates are not ideal for anaerobes that suffer from desiccation and exposure to oxygen, as well as being entrapped in the interstices of the swab. Whenever possible, pus should be aspirated into a sterile container and delivered promptly to the laboratory (Finegold, 1995).

Transport

Direct plating of a sample at the patient's bedside and immediate anaerobic incubation are likely to give the best results, but this is an unattainable ideal in most clinical situations. If pus, or a piece of necrotic tissue obtained by biopsy, is the specimen, it should be transported to the laboratory without delay in a sterile container. Sealed containers with an oxygen-free atmosphere, or from which oxygen can be removed by a simple chemical reaction, are available for optimal transport of such specimens. Pus is generally regarded as

its own best transport medium. If there is no alternative to the use of swabs, these should be placed in semi-solid anaerobic transport medium to prevent both desiccation and the toxic effects of oxygen.

Laboratory Examination

Direct microscopy of pus samples may be helpful in some cases; most of the Gram-negative anaerobes are small, pleomorphic organisms that are difficult to see in direct smears. The most useful immediate examination is direct GLC to detect the presence of the volatile fatty acid products of anaerobic metabolism (Jousimies-Somer *et al.*, 2002). This will not, generally, give any indication of the specific identity of the anaerobes present, but the demonstration of a mixture of short-chain fatty acids confirms the presence of anaerobic bacteria.

Isolation of Gram-negative anaerobes is by anaerobic culture on selective and non-selective media. Anaerobic culture conditions can be provided in sealed anaerobic chambers equipped with air locks and functioning as anaerobic incubators as well as workstations, or in anaerobic jars. The anaerobic atmosphere generally used in cabinets is N₂ 80%, H₂ 10% and CO₂ 10%, as the growth of many anaerobes is stimulated by CO₂. The same gas mixture can be used in jars operated by an evacuation and refill system and equipped with room-temperature-active catalysts (e.g. palladium) to remove any remaining oxygen. Alternatively, jars can be used with sachets that generate H₂ and CO₂ when water is added and depend upon the H₂ to remove all the oxygen from the jar with the help of the catalyst. There are many variations on the basic anaerobic jar methodology but all must be carefully controlled to ensure that as much as possible of the O₂ is removed and that air cannot leak back into the system.

Many anaerobes grow more slowly than most common aerobic pathogens, and anaerobic cultures must be incubated for at least 48 h without exposure to oxygen and for an overall minimum of 72–96 h; however, some of the more virulent anaerobes (e.g. *Clostridium perfringens* and *B. fragilis*) produce acceptable growth in 24 h, and most laboratories would not wish to delay the diagnosis by 24 h. If the use of duplicate sets of plates where anaerobic jars are in use (one for examination after 24 h and the other to remain undisturbed for 72–96 h) is considered too extravagant of resources, a useful compromise is for the one set of plates to be examined quickly after 24 h and then re-incubated after as little exposure to air as possible for another undisturbed 48–72 h. This difficulty is overcome by the use of anaerobic cabinets in which the initial examination can be done without removing the plates from the anaerobic atmosphere.

Various media have been recommended for the optimal growth of Gram-negative anaerobes. All comprise a rich nutrient base with added blood. *Bacteroides fragilis* grows well on most formulations of blood agar, but better growth of a wider range of more fastidious species needs more specially enriched media. Most species grow more quickly and produce larger colonies on media such as Fastidious

Anaerobe Agar, Brucella agar or BM medium with ingredients such as proteose peptone, trypticase and yeast extract. Menadione and haemin enhance the growth of some species, especially of *Prevotella*; other demanding strains such as '*B. ureolyticus*' require formate and fumarate for good growth and *Bil. wadsworthia* has an absolute requirement for pyruvate. The use of lysed blood assists in the early recognition of pigment production.

As anaerobic bacteria are generally present in mixed infections, their isolation is aided by the use of selective media containing antibiotics inactive against anaerobes. Aminoglycosides have been widely used for many years. The neomycin blood agar developed for the selective isolation of clostridia is too inhibitory for many Gram-negative anaerobes, and kanamycin (75 mg/l) gives better results. An alternative that may be preferred is the use of nalidixic acid (10 mg/l). When it is desirable to eliminate Gram-positive bacteria, the addition of vancomycin (2.5 mg/l) provides a medium highly selective for *Bacteroides* spp. Selective media should never be used without parallel non-selective cultures and growth on the selective media generally requires extended incubation.

Identification of Gram-Negative Anaerobes

Detailed identification to species level of all isolates of Gram-negative anaerobes is beyond the scope of most diagnostic laboratories and would require excessive commitment of resources. They are significant pathogens, however, and certain species either show greater virulence than most of their group (e.g. *B. fragilis*) or are associated with particular types of infections (e.g. *F. necrophorum*, *P. gingivalis* and *P. asaccharolytica*). It is important that primary diagnostic laboratories can at least determine the presence of the main pathogens and identify other significant isolates at least to genus level, for more detailed study in a reference or research laboratory when appropriate.

Preliminary allocation of isolates to the main genera can be made by a relatively simple set of tests based upon colonial and microscopic morphology, growth in the presence of bile (20% in broth or agar medium) or sodium taurocholate (disc tolerance test), disc resistance tests with antibiotics (neomycin 1 mg, kanamycin 1 mg, penicillin 1 or 2 units, rifampicin 15 µg, colistin 10 µg and vancomycin 5 µg) catalase and urease production (Table 45.4), supported by GLC if available.

More detailed identification depends upon sets of biochemical tests with carbohydrate and other substrates and detection of particular enzyme activities. Some of these can be performed with commercial kits (especially the enzymes tests), and these can be useful for the identification of the more common species isolated from clinical specimens. However, most of these systems suffer from the attempt by most manufacturers to produce a single kit for the whole range of anaerobes – Gram-positive and Gram-negative, cocci and bacilli. Tables 45.5–45.9 summarize the sets of tests that enable the identification of most clinically significant Gram-negative anaerobes. The

media and methods for performing these tests are varied, and details may be found in manuals or monographs devoted specifically to anaerobic microbiology – the Wadsworth Anaerobic Bacteriology Manual sixth edition (Jouseimies-Somer *et al.*, 2002), the Virginia Polytechnic Institute Anaerobe Laboratory Manual (Moore and Moore, 1977) or Anaerobes in Human Disease (Wren, 1991). Baron and Citron (1997) provide an outline of a cost-effective protocol.

Non-Culture Detection Methods

The ability to identify reliably obligately anaerobic bacteria directly in clinical samples without the need for culture is particularly attractive. Despite the best efforts of clinical bacteriologists to ensure the handling and transit of samples under anaerobic conditions, a high proportion of infections may be missed as a result of loss of viability (Patrick *et al.*, 1995).

Techniques have been developed in some research laboratories for the direct detection of specific pathogenic anaerobes (*B. fragilis*, *P. asaccharolytica*, *P. gingivalis*, *Pr. intermedia* and *Bil. wadsworthia*) by DNA probes and by polymerase chain reaction (PCR) technology, but as yet, there are no non-culture detection methods for anaerobes in general use in clinical diagnostic laboratories. PCR finger printing identification (e.g. amplified ribosomal DNA restriction analysis) of pure culture isolates has resulted in good identification and differentiation of *Bacteroides*, *Prevotella* and *Porphyromonas* spp. of the *fragilis* group, as has a multiplex PCR assay based on 16S rRNA, the 16S–23S rRNA intergenic spacer region and part of the 23S rRNA gene (Liu *et al.*, 2003). PCR-based assays for the detection of enterotoxigenic *B. fragilis* have also proved reliable. Microarrays enabling the simultaneous detection of multiple genes and therefore multiple bacterial species have been applied to studies of the faecal microbiota. Fluorescence *in situ* hybridisation of 16S rRNA is possible with pure cultures of *B. fragilis*; however, such techniques must be approached with caution if they are to be applied directly to clinical samples, as the penetration of the probe into the bacterial cell is dependent on the nature of encapsulating surface structures.

It is likely, however, that accurate and specific multiplex and quantitative (real-time) PCR diagnostic tests or microarray-based technologies will ultimately become part of routine diagnosis once inherent problems of sensitivity in clinical specimens and potential for contamination from exogenous DNA are resolved.

Antibiotic Susceptibility of Gram-Negative Anaerobes

Approaches to susceptibility testing of Gram-negative anaerobes have been debated amongst microbiologists and infectious disease physicians

for many years. A major consideration is whether susceptibility testing should be, as for most aerobes, concentrated in the primary laboratories doing individual susceptibility tests on clinical isolates from their patients or whether strains should be collected for batch testing in recognised specialist centres while individual clinical treatment is based upon accumulated data generated by that batch testing. For aerobes, laboratories test their significant isolates and clinicians expect prompt susceptibility data on their own patients' organisms. This has not been the case with anaerobes because of three perceptions: 1. anaerobic investigations are slower – initial culture may take several days and susceptibility tests at least 2 days more, so that individual results are irrelevant to patient management; 2. methods for susceptibility testing of anaerobes are unreliable, especially when performed on an individual basis, and batch testing in specialist centre gives more reliable results; and 3. the susceptibility of anaerobes is predictable so that clinical treatment can be based upon the batch data with confidence.

These premises were the basis for susceptibility testing of anaerobes having been neglected in primary laboratories and concentrated in specialist centres that receive clinical isolates from a wide range of sources. However, there is an increasing view from clinicians and microbiologists that the same standard of laboratory data is required in anaerobic infections as in aerobic infections. Testing of individual isolates is supported by four changed perceptions: 1. antibiotic susceptibility in anaerobes is variable and patterns differ in different places and at different times; 2. modern laboratory methodology should enable the prompt isolation of the more common anaerobic pathogens; 3. methods for susceptibility testing of anaerobes are available that can be used in primary laboratories; and 4. the most important reason, patients managed with access to accurate and specific laboratory data on their own anaerobic isolates recover more rapidly with fewer complications.

Both approaches are necessary. Primary laboratories need to develop adequate susceptibility tests on anaerobes for first-choice agents while reference laboratories should enhance their activities in collecting strains from a wide range of sources and batch testing to provide the best general advice for clinicians in choosing empirical therapy and devising antibiotic policies.

Methods

The selection of methods for susceptibility testing of anaerobes has been a major difficulty. The two basic methodologies for rapidly growing, relatively non-fastidious aerobes – disc susceptibility tests on solid media and breakpoint determination in liquid or solid media – are not readily adaptable to anaerobic work, are difficult to standardise and do not give reliably reproducible results with anaerobes. Anaerobes tend to grow more slowly than many common aerobes, and the balance between antimicrobial effect, bacterial growth and antibiotic degradation varies much more, affecting disc susceptibility methods in particular. Many anaerobes need more enriched media than are used for susceptibility testing of aerobes; they are more difficult to standardise, and there are interactions between media components and the antibiotics. The presence of fermentable nutrients often results in a very significant drop in pH in the test medium which can have a major impact of the results obtained with pH-sensitive antibiotics. Similarly, many anaerobes require CO₂ for growth and all

Propionate from lactate	-	+	+	-	-	-	-	-	-
threonine	+	+	+	-	-	+	+	+	+

standard anaerobic gas mixtures contain CO₂ which again lowers the pH (Watt and Brown, 1985). Many anaerobes do not grow well from small inocula, and semi-confluent growth is difficult to achieve. A further practical difficulty arises because the MICs of several agents for anaerobes cluster near the recommended breakpoints for the agents, so that minor variations in method and inevitable margins of error in any technique can give variable results in terms of clinical interpretation and recommendations. Therefore, disc susceptibility tests for anaerobes have been regarded as unreliable for other than the fast-growing anaerobes. Recommended methods in the past have been based upon agar dilution with multi-point inoculation or broth micro-dilution or macro-dilution methods. Some of these have not been entirely satisfactory and are not appropriate for testing individual clinical isolates, hence the methodology has exerted pressure in favour of batch testing in reference laboratories. The E test (AB Biodisc, Denmark) provides reliable susceptibility testing with MIC determination for individual isolates. A plastic strip coated with an antibiotic gradient on one side and with an MIC interpretation scale on the other is placed on a seeded plate as in disc susceptibility testing. After incubation, the edge of the zone of inhibition reaches the scale at a point equivalent to the MIC. This shares some of the disadvantages of disc methods, but experience has shown it to be generally reliable for a wide range of anaerobes (Wexler, 1993; Duerden, 1995; Jouseimies-Somer *et al.*, 2002).

It is likely that molecular detection methods for antibiotic resistance genes will be incorporated into molecular identification protocols. A PCR-restriction fragment length polymorphism analysis identification method for *Bacteroides* spp. that incorporates *nim* gene detection has proved to be rapid and accurate (Stubbs *et al.*, 2000).

Antibiotic Susceptibility

The susceptibility of Gram-negative anaerobes varies considerably both between and within the major genera. Metronidazole has been the mainstay of therapy and prophylaxis for 20 years, and it is re-assuring that resistance amongst Gram-negative anaerobes has remained relatively low (Dubreuil, 1996; Snyderman *et al.*, 1996), so that it remains the drug of choice for many of these infections. Its use has, however, been extended to the treatment of peptic ulcer disease with the recognition of the involvement of *Helicobacter pylori* (Freeman *et al.*, 1997). Whether this wider use of metronidazole is leading to the development of increased resistance in *Bacteroides* of the normal microbiota is not proven, but metronidazole resistance has become more widely recognised in *Bacteroides* spp. in the last 5 years. Of the eight metronidazole resistance genes described (*nimA-G*), all but one (*nimB*) can be found on potentially mobile genetic elements in *Bacteroides* spp. Within the United Kingdom, referral of isolates to the Anaerobe Reference Laboratory has shown the incidence of metronidazole resistance in *Bacteroides* spp. increasing to around 7% since 1995 (Brazier, Stubbs and Duerden, 1999).

A number of different types of mobile genetic elements, including self-transmissible large conjugative transposons and plasmids as well as mobilisable plasmids and transposons, have been identified in the Gram-negative anaerobes (Sebald, 1994; Smith, Tribble and Bayley, 1998). There is evidence of horizontal transfer of antibiotic resistance genes via these mobile elements and the potential transfer of these to facultative species (Vedantam and Hecht, 2003). In the case of the large conjugative transposons that carry a tetracycline resistance gene, exposure to tetracycline, even at sub-inhibitory concentrations, increases the frequency of conjugation (Patrick, 2002). The normal microbiota may therefore represent a potential reservoir of transmissible antibiotic resistance genes.

Bacteroides spp. isolates of *B. fragilis* and other *Bacteroides* spp. are resistant to benzylpenicillin and ampicillin/amoxicillin due to the production of an amp-C type β -lactamase (Wang, Fast and

Benkovic, 1999); in almost all cases this resistance is overcome by the use of a combination of ampicillin/amoxicillin with the β -lactamase inhibitors clavulanate or tazobactam. *Bacteroides* spp. are also resistant to many other β -lactam agents. Cefoxitin has been widely used in the United States for anaerobic infections because it has greater activity against *Bacteroides* spp. than most β -lactam agents, but results of susceptibility tests are variable with up to 40% of isolates giving MIC values around or above the recommended breakpoint of 32 mg/l. Most isolates in the United Kingdom remain susceptible to imipenem, but resistance due to the production of a metallo- β -lactamase, not affected by clavulanate or tazobactam, and encoded by the *cfiA* (*ccrA*) gene does occur and may become a more significant problem in the future. With the inhibitors of protein synthesis, many strains are resistant to erythromycin and tetracycline but most are susceptible to clindamycin. Like the *Bacteroides* spp., *Bil. wadsworthia* produces a β -lactamase and is resistant to most β -lactam agents.

Porphyromonas and *Prevotella*

Although the genera are generally more susceptible to antimicrobial agents than the *Bacteroides* spp., results are still unpredictable. In the past, they were considered to be generally penicillin sensitive, but one-third or more of clinical isolates, especially of *Prevotella* spp., are resistant due to β -lactamase production. Thus, they are susceptible to amoxicillin/ampicillin and clavulanate combinations. Most are susceptible to cefoxitin and highly susceptible to imipenem. They are generally susceptible to erythromycin and clindamycin, but up to half of clinical isolates are resistant to tetracycline and up to 15% are resistant to ciprofloxacin and clindamycin.

Fusobacterium

Most *Fusobacterium* spp. isolates are highly susceptible to a wide range of agents including penicillin and all the β -lactam agents, but resistance mediated by β -lactamase production is increasing. Ceftiozime, ciprofloxacin and erythromycin are poorly active and up to 30% of strains may be resistant to clindamycin and tetracycline (Finegold and Jouseimies-Somer, 1997).

MANAGEMENT OF ANAEROBIC INFECTIONS

Because of the multi-factorial nature of infection with Gram-negative anaerobes (p. 537–539 Clinical features of anaerobic infections) – mixed infections, tissue necrosis, inadequate blood supply/oxygenation, patient already compromised by underlying disease – the management of these infections requires a combination of approaches. Antibiotic treatment is important but is rarely effective if used alone. The choice is generally between metronidazole, a β -lactam agent such as amoxicillin-clavulanate or imipenem, and clindamycin. The recognition of the presence of aerobic or facultative organisms may also need to be addressed either by adding an agent effective against, e.g. *E. coli* to the metronidazole, or by choosing an agent effective against both (e.g. imipenem).

It is axiomatic in medical microbiology that antibiotics alone are ineffective, as treatment for abscesses and many of the anaerobic infections have a component of tissue necrosis and abscess formation. Debridement of necrotic tissue and drainage of pus are essential to the effective management of these infections. An interesting exception is disseminated *F. necrophorum* infection with metastatic abscess formation; this responds well to treatment with penicillin or other antibiotics alone.

Many of the patients who develop anaerobic infections are seriously ill, e.g. peritonitis following major abdominal surgery, and may be developing sepsis syndrome due to the anaerobes or other components

of the mixed infection. These patients clearly need intensive supportive therapy for respiratory and circulatory functions.

PREVENTION AND CONTROL

As most infections with Gram-negative anaerobes are endogenous, cross infection is not a significant problem with these patients, although isolation may be appropriate because of the severity of the infection and, on some occasions, because of the intense malodour created by the anaerobes which can be embarrassing and distressing to the patient and unpleasant and disturbing for others.

Prevention of these infections depends upon prophylactic measures that can be taken to avoid creating the conditions that allow anaerobes to become established. Most of these measures relate to surgical practice in abdominal, gynaecological or oral-facial surgery – i.e. in areas where anaerobes predominate in the normal microbiota. Prevention of post-operative anaerobic infection in these situations depends upon good surgical practice, reduction in the bacterial challenge and the use of appropriate prophylactic antibiotics. Surgical skill goes a long way towards preventing anaerobic infections by not leaving non-viable tissue or foreign bodies at the operation site, ensuring adequate perfusion and oxygenation of the tissues that are left, preventing leakage from the viscus or the accumulation of fluid and closing off any potential spaces where infection can develop. Thus, the 'soil' is not conducive to anaerobic infection. The bacterial challenge can be reduced in part by physical removal of the normal microbiota. This is particularly important in the use of laxatives, enemas or even colonic irrigation to reduce the volume of faeces in the colon before abdominal surgery. A further important prophylactic measure is the use of prophylactic antibiotics pre-operatively. These have made a major impact in reducing the incidence of post-operative infection during the last three decades. Since the advent of specific prophylaxis encompassing anaerobic organisms, the incidence of post-operative infection in abdominal and gynaecological surgery has fallen dramatically, e.g. from 35 to 5–10% for major colonic surgery, 20 to <5% for appendectomy, 25 to 5% for hysterectomy (Willis and Fiddian, 1983). The aim of prophylaxis is to have high levels of appropriate antibiotics in the tissues at the time of the operation to prevent any implanted organisms becoming established. Prophylaxis in this way is not designed to destroy the bacteria in their normal habitat, e.g. in the gastrointestinal lumen. The choice of agent must include effective anti-anaerobe activity – usually by including metronidazole or amoxicillin/clavulanate – plus activity against other organisms likely to be present. Thus, in abdominal surgery, an aminoglycoside (e.g. gentamicin) or a cephalosporin (e.g. cefuroxime or cefotaxime) may be added to the metronidazole. In some circumstances, amoxicillin/clavulanate may fulfil both functions. For effective prophylaxis and to avoid disturbing the normal microbiota or selecting resistant strains before surgery, the antimicrobial agents should be given by intravenous injection at the induction of anaesthesia. For most operations, a single dose at this stage is sufficient to give good protection. In some regimens, a second dose after 4 h or at the completion of the operation has been recommended in more complex and longer operations. In any case, the whole period of prophylaxis should not exceed 24 h. If infection is already present at operation and more prolonged use of antibiotics is clinically necessary, this becomes a therapeutic course for established infection and not a prophylactic measure (Willis, 1991; Keighley, 1992).

Mobiluncus

The genus *Mobiluncus* represents a group of slender, curved, rapidly motile, Gram-variable anaerobic rods found in the vagina and associated with *Gardnerella vaginalis* and *Prevotella* spp. in bacterial (anaerobic) vaginosis (Duerden, 1991). It is a member of the Actinomycetaceae and the phylum of high mol% G+C Gram-positive bacteria, the Actinobacteria, and has a G+C content of 52–56 mol%.

Two morphologically distinct types of *Mobiluncus* are recognised and represent two separate species (Tiveljung, Forsum and Monstein, 1996). *Mobiluncus curtisii* strains have short Gram-positive or Gram-variable cells and are much more active in biochemical tests – they hydrolyse arginine and hippurate, reduce nitrate and produce β -galactosidase. *Mobiluncus mulieris* gives negative reactions in these tests and has much longer cells that appear Gram negative. However, both have a cell wall that is essentially of Gram-positive structure, but the peptidoglycan layer is thin, probably resulting in the variable staining pattern. Both species grow well anaerobically but will grow in 5% O₂ and growth is enhanced by CO₂. Although they may be present in large numbers in vaginosis and were described in vaginal discharge by Curtis in 1915, their role in disease is not clear. PCR detection indicates that, whereas *M. curtisii* is frequently associated with bacterial vaginosis, *M. mulieris* may also be detected in apparently healthy women (Schwebke and Lawing, 2001). *Mobiluncus* spp. are always present along with other potential pathogens such as *G. vaginalis* and *B. fragilis* in vaginosis and may have a synergic role (Spiegel, 1987). Treatment with metronidazole removes the anaerobes from the synergic mixture, and vaginosis usually responds well to short-course treatment with agents active against anaerobes, such as metronidazole to which *Mobiluncus* spp. are often resistant (Jones *et al.*, 1985). In addition, as there is a relationship with the deposition of semen in the vagina, the use of a condom will prevent the development of vaginosis (Duerden, 1991).

Clostridium difficile

Mark H. Wilcox

Department of Microbiology, Leeds General Infirmary & University of Leeds, Old Medical School, Leeds, UK

INTRODUCTION

Antibiotic overprescription is associated with the development of resistance. During the last two decades, another major drawback of antibiotic administration, namely *Clostridium difficile* infection, has emerged. Following *C. difficile* acquisition, the bacterium may simply be excreted by the host or asymptomatic colonisation of gut, diarrhoea, colitis, pseudomembranous colitis (PMC) and/or death may occur. These conditions may blur, and it is often unclear which is the exact clinical diagnosis in a symptomatic patient. PMC is a specific term that should be reserved for the severe end of the spectrum of *C. difficile* infection. Sigmoidoscopy with biopsy for histology is required for an accurate diagnosis.

HISTORICAL ASPECTS

Hall and O'Toole (1935) first described a Gram-positive, sporing, obligate anaerobe isolated from the faeces of neonates and named it *Bacillus difficile*, considering the problems they endured with the organism. Snyder (1937) noted that the lethal effects of broth culture filtrates of the organism could be prevented by an antiserum to *B. difficile*. It was postulated that the toxins of the organism might be involved in life-threatening infections in the newborn. The link between antibiotics and PMC has been apparent since the 1950s, but *Staphylococcus aureus* was presumed to be the infective agent. However, increasing numbers of reports implicating clindamycin and PMC began to appear in the 1970s (Tedesco, Barton and Alpers, 1974), and an alternative pathogen was implied, given the excellent activity of clindamycin against *S. aureus*. PMC was shown to have an infective aetiology by experiments cross-infecting hamsters with caecal contents. A toxin produced by a clostridial-like organism was shown to induce PMC, and disease was prevented by *Clostridium sordellii* antitoxin (Rifkin, Fekety and Silva, 1977; Bartlett *et al.*, 1978). However, it was *C. difficile* as opposed to *C. sordellii* that was recovered from the caeca of diseased animals, and Larson *et al.* (1978) provided evidence linking *C. difficile* with histologically proven PMC in both humans and hamsters.

DESCRIPTION OF THE ORGANISM

Clostridium difficile is a Gram-positive, sporing, obligate anaerobe. Colonial morphology can be variable, depending on media and length of incubation and, hence to the inexperienced, is not a good marker. Distinctive colonies of *C. difficile* growing on the selective medium cycloserine-cefoxitin fructose agar (CCFA) are approximately 4 mm

in diameter, yellow and ground glass-like and have a slightly filamentous edge. However, the odour associated with colonies is very distinctive and is typically referred to as like elephant or horse manure. *Clostridium difficile* colonies fluoresce yellow-green under long-wave (365 nm) ultraviolet illumination (when grown on blood-based selective media), but this property is medium dependent and is not unique to *C. difficile*. As older colony cultures sporulate, they tend to become whiter and the fluorescence fades. Also, colonial fluorescence cannot be screened for on original formulations of CCFA as the neutral red pH indicator autofluoresces. Agar formulations using an egg yolk agar base have a theoretical advantage over blood agar-based media, as *C. difficile* produces neither lecithinase nor lipase, whereas other clostridia commonly present in the gut such as *Clostridium perfringens* and *Clostridium bifementans/C. sordellii* (and which occasionally grow on the selective medium) produce lecithinase and thus can easily be recognised.

Gas-liquid chromatographic methods to detect volatile metabolites indicative of *C. difficile* such as isovaleric acid, isocaproic acid or *p*-cresol in the faeces have been investigated, but the complexity of this approach means that it is unsuitable for use in routine laboratories. Clostridial spores are relatively resistant to heat, solvents and alcohols, enzymes, detergents, disinfectants and ultraviolet and ionising radiation. Control of sporulation is poorly understood in *C. difficile* compared with that seen in *Bacillus subtilis*, although sporulation genes are relatively conserved in *Clostridium* spp. and *Bacillus* spp. *sigK* genes encode an RNA polymerase sigma factor that is essential for sporulation. Notably, *C. difficile* does not readily sporulate on agars containing selective agents, and therefore, colonies will become non-viable if plates are left in air for prolonged periods. In contrast, colonies usually sporulate heavily after incubation for 72 h on non-selective agars and hence will survive prolonged exposure to air. The spore-bearing properties of *C. difficile* can be used to select for the organism before culture, e.g. by alcohol shock (Bartley and Dowell, 1991). Also, addition of bile salts, such as sodium cholate or pure grade taurocholate (Buggy, Wilson and Fekety, 1983), or lysozyme (Wilcox, Fawley and Parnell, 2000) to media enhances the recovery of spores by inducing spore germination from environmental samples or from faeces, after alcohol shock.

Diarrhoea-associated isolates produce usually both toxin A (conventionally called an enterotoxin because of its activity in a rabbit ileal loop assay) and toxin B (classically known as a cytotoxin). Some isolates (not associated with diarrhoeal disease) are non-toxicogenic, and a small but ill-defined proportion produce toxin B but not toxin A (A-B+). A recent report described a *C. difficile* strain that produces toxin A and an aberrant toxin B (Mehlig *et al.*, 2001).

PATHOGENICITY

Aetiology of Antibiotic-Associated Infective Diarrhoea

For *C. difficile* to colonise the gut of a normal individual, the resident flora, which are usually inhibitory to its establishment, must be altered qualitatively and quantitatively (Borriello and Barclay, 1986; Borriello, 1998). Anaerobic gut bacteria are believed to be crucial to colonisation resistance, but the precise components involved have not been defined. There is *in vitro* evidence that the faecal flora of elderly patients are less inhibitory to the growth of *C. difficile* (Borriello and Barclay, 1986). Most commonly, gut flora are disrupted following exposure to antibiotics. Occasionally, colonisation resistance may also be impaired by antineoplastic chemotherapy, which may have additional deleterious effects on the gut mucosa.

Clostridium difficile toxin can be found in faecal samples from almost all patients with PMC. In contrast, toxin is present in 30% of patients with antibiotic-associated colitis and usually less than 5% of patients with antibiotic-associated diarrhoea (AAD). Corresponding figures for *C. difficile* culture-positive faeces are 95%, 60% and 20–40% (Wilcox and Spencer, 1992). Hence, a *C. difficile* culture-positive result is a less specific finding than the presence of toxin. Also, it is very likely that *C. difficile* is not the only pathogen that causes AAD (see *Epidemiology*).

***Clostridium difficile* Toxins**

Clostridium difficile usually produces two toxins, in 1:1 molar ratios, classically called toxin A and toxin B. These are often called an enterotoxin and cytotoxin, respectively, although both are detected in the standard diagnostic cytotoxin assay. Opinions differ on the contribution of each of these toxins to the disease state. It is likely that both have a role in the gut mucosal inflammation that typifies *C. difficile* infection (Borriello, 1998). It is currently unclear how toxin A–B+ isolates cause disease if no functional toxin A is produced. It is possible that the toxin B produced by such strains has a broader specificity and is more active than that present in fully functional strains (Wilkins and Lyerly, 2003).

Clostridia produce various toxins that cause alterations in the actin cytoskeleton. The toxins have been classified into at least three groups. Two of them, the C3-like toxins and the binary toxins, are ADP ribosyltransferases. The large clostridial toxins (toxins A and B) are glucosyltransferases and are the best-studied *C. difficile* virulence determinants, causing cell death by disrupting the actin cytoskeleton, inducing the production of inflammatory mediators and disrupting epithelial cell tight-junction proteins (Nusrat *et al.*, 2001). The genes coding for *C. difficile* toxins A and B and minor toxins C–E are sited in a chromosomal pathogenicity locus. This locus was highly stable in 50 toxigenic *C. difficile* strains, whereas non-toxigenic isolates lacked the unit (Cohen, Tang and Silva, 2000). Also, isolates with a defective pathogenicity locus were still able to cause clinical disease.

Clostridium difficile strains that produce toxin B but not toxin A (toxin A–B+) have been reported from many countries. In the United Kingdom, approximately 3% of isolates are *C. difficile* toxin A–B+ (Brazier, Stubbs and Duerden, 1999). There is now good evidence that *C. difficile* toxin A–B+ strains are virulent. Several reports have shown that *C. difficile* toxin A–B+ strains can cause symptomatic disease and even endoscopically confirmed severe PMC (Limaye *et al.*, 2000). Furthermore, in a Canadian hospital, 31% of 91 cases of *C. difficile* infection occurring in a 12-month period (including two deaths) were caused by a toxin A–B+ strain (Alfa *et al.*, 2000). In view of these observations, toxin A detection alone is insufficient for the laboratory diagnosis of *C. difficile* infection. Toxin A–B+ isolates have a truncated *toxA* gene that contains a stop codon, which means that functional toxin A is not produced. The truncated gene also does not code for the immunodominant repeating units (i.e. the binding

portion) recognised by antibodies used in toxin A-specific enzyme immunoassays (EIAs) (Kato *et al.*, 1999; Moncrief *et al.*, 2000).

A binary toxin (an actin-specific ADP ribosyltransferase) similar to *C. perfringens* i-toxin (which is an enterotoxin) has also been described in *C. difficile*. The virulence potential of *C. difficile* binary toxin is unknown, and to date, it appears to be limited to strains that have altered toxin A and B genes. Approximately 6% of toxigenic isolates of *C. difficile* referred to the Anaerobe Reference Unit from UK hospitals have binary toxin genes (*cdtA* and *cdtB*) genes (Stubbs *et al.*, 2000). However, although binary toxin-positive isolates are widespread, the common UK hospital-associated *C. difficile* ribotypes do not possess binary toxin, implying that it does not play a major role in the aetiology of *C. difficile* diarrhoea. Other potential virulence determinants in *C. difficile* are reviewed elsewhere (Borriello, 1998).

Epidemic *C. difficile* Strains

Some *C. difficile* strains are clearly more virulent than others, and there is emerging evidence for the presence of several epidemic *C. difficile* strains. Brazier and colleagues originally identified 116 *C. difficile* polymerase chain reaction (PCR) ribotypes but noted that the prevalence of ribotype I in hospitalised patients was much higher than from individuals in the community (Stubbs *et al.*, 1999). PCR ribotype I is known to be widely distributed and accounts for 58% of strains submitted to the Anaerobe Reference Unit from UK hospitals (Brazier, 2001). It is now apparent that there are subtypes of PCR ribotype I, as determined by random amplified polymorphic DNA (RAPD) fingerprinting (Fawley, Freeman and Wilcox, 2003). There is no good evidence that differences in virulence between strains correlate with the amount of toxin(s) produced. However, the persistence of one or a few strain types within many institutions implies either that some strains survive (sporulate) and spread more effectively between patients or that other virulence characteristics make them more successful at colonisation and/or causing infection. Notably, PCR ribotype I has been shown to sporulate more than other *C. difficile* strains (Wilcox and Fawley, 2000).

Other virulence determinants in *C. difficile* remain poorly characterised. It is unclear whether *C. difficile* flagellae or other putative adhesins mediate bacterial adherence to eukaryotic cells. The significance of an outer cell coat (S-layer) is similarly uncertain.

Immune Response to *C. difficile*

Following acquisition of *C. difficile* in the hospital setting, only about half of patients develop diarrhoea (Kyne *et al.*, 2000). Furthermore, a proportion of these will experience multiple symptomatic episodes. It has proven difficult to delineate the influence of host factors in *C. difficile* infection, given the frailty and medical complexity of typically affected patients. It is now clear, however, that host immune response to *C. difficile* plays a critical role in determining disease occurrence and recurrence. *Clostridium difficile* toxins A and B share 63% amino acid sequence homology but very little antigenic similarity. Population prevalence studies have detected antibodies against toxins A and B in the serum of approximately 70% of individuals (Johnson, 1997), as might be expected from an organism that is widely distributed in the environment. Early studies found no correlation between antibody titre and toxin-neutralising ability. There is some evidence that the capacity of sera to neutralise toxin decreases with age, despite higher levels of antibody (Viscidi *et al.*, 1983; Warny *et al.*, 1994).

Two key recent studies have significantly advanced knowledge about host humoral response in *C. difficile* infection. In the first of these, serial antibody levels were measured in hospitalised patients who were receiving antibiotics (Kyne *et al.*, 2000). Fourteen per cent of the patients were colonised with *C. difficile* on admission, and a further 17% had nosocomial acquisition. Notably, almost half (44%) of all the patients colonised with *C. difficile* remained asymptomatic

carriers, and yet antibody levels at baseline were similar in those who did and did not later become colonised. The explanation for this observation was that after colonisation those patients who became asymptomatic carriers had significantly greater increases in serum immunoglobulin G (IgG) anti-toxin A than did those who had *C. difficile* diarrhoea. This also explains why patients who are already colonised when admitted to hospital are significantly less likely to develop symptomatic infection (Shim *et al.*, 1998). The second study on humoral immunity to *C. difficile* diarrhoea found that patients who had only one as opposed to multiple episodes of *C. difficile* diarrhoea had significantly higher levels of both serum IgM and IgG anti-toxin A (Kyne *et al.*, 2001). Hence, patients who can mount a serum IgG response to toxin A have relative protection both against a first episode of *C. difficile* disease and recurrent symptoms. It is unknown why individuals can or cannot mount a protective humoral response against *C. difficile*. Furthermore, the relative importance of initiating antibiotic, gut flora disturbance, strain type and host antibody response in determining the risk of *C. difficile* infection has not been elucidated.

EPIDEMIOLOGY

Clostridium difficile is found as part of normal large-bowel flora in approximately 2–4% of normal young adults. This percentage rises with age, and the elderly have colonisation rates of 10–20%, depending on recent antibiotic exposure and the time spent in an institution, i.e. the likelihood of exposure to *C. difficile* (Viscidi, Willey and Bartlett, 1981). It is still not known whether the carriage rate of *C. difficile*, particularly in the asymptomatic elderly, is increasing. Vegetative forms of *C. difficile* die rapidly on exposure to air, but spores are produced when the bacterium encounters unfavourable conditions. Clostridial spores can survive for many months and possibly years and are the most likely infective mode by which *C. difficile* is spread. Interestingly, rates of colonisation in neonates, who have a less complex gut flora, may be very high (up to 70%, depending on the degree of spread of the bacterium within individual units), although babies are very seldom symptomatic. Carriage rates in children approximate to those of adults by the age of 2–3 years. *Clostridium difficile* has also been isolated from farmyard and domestic animals such as horses, cows, pigs, dogs and cats, but there is no evidence that *C. difficile* infection is a zoonosis.

The incidence of *C. difficile* diarrhoea has increased since the 1980s, and now there are approximately 44 000 laboratory reports of *C. difficile* per year in England and Wales. This figure compares with approximately 13 000 and 42 000 reports of salmonella and campylobacter in 2004. Recent reports suggest the emergence of a new epidemic virulent *C. difficile* strain (type 027) in Canada, USA and, most recently, the UK. A recent US study found that between 1989 and 2000, the incidence of *C. difficile* infection increased from 0.68% to 1.2% of hospitalised patients, with a corresponding doubling increase (1.6–3.2%) in the subset who developed life-threatening symptoms (Dallal *et al.*, 2002). It is unclear what is the true distribution of clinical disease represented by laboratory reports of *C. difficile* detection, and some undoubtedly represent asymptotically colonised individuals. Conversely, given the variability of testing protocols, underdiagnosis also appears to be commonplace. Over 80% of *C. difficile* infection cases occur in hospitalised patients aged over 65 years, and the frail elderly are more prone to severe *C. difficile* infection. Although *C. difficile* diarrhoea is more common in older patients, increasing age itself appears not to be a risk factor for the severity of *C. difficile* infection (Kyne *et al.*, 1999). Significant risk factors for severe *C. difficile* diarrhoea included functional disability, cognitive impairment, recent endoscopy and, possibly, enteral tube feeding. *Clostridium difficile* infection appears to be a marker, but not a cause per se, of increased risk of dying (Wilcox *et al.*, 1996; Kyne *et al.*, 2002).

Clostridium difficile infection is generally underdiagnosed in the community setting. A Swedish study found that 42% of cases of *C. difficile* infection presented in the community, and half of these did not have a

history of hospitalisation within the previous month (Karlstrom *et al.*, 1998). The Intestinal Infectious Disease survey in England identified *C. difficile* as the third most common cause of intestinal infectious disease (IID) in patients aged greater than 75 years seen by general practitioners (Tompkins *et al.*, 1999). Clearly, the distinction between nosocomial and community-acquired *C. difficile* diarrhoea is increasingly blurred by the overlap between primary and secondary healthcare provision.

It has been recently estimated that *C. difficile* infection accounts for more than \$1.1 billion in healthcare costs in the United States per annum (Kyne *et al.*, 2002). A UK case-control study found that *C. difficile* diarrhoea occurred approximately 14 days before routine discharge and was associated with a high (37%) clinical failure rate of treatment. Although many remain non-quantifiable, estimated costs (in 1996) attributable to *C. difficile* infection were approximately £4000 per case, 94% of which were due to an increased duration of hospital stay by an average of 3 weeks per patient (Wilcox *et al.*, 1996).

Clostridium difficile in the Hospital Environment

Cross-infection with *C. difficile* is believed to be common and is compounded by widespread environmental contamination (20–70% of sampled sites), which is especially pronounced if a patient has explosive diarrhoea. An infected patient excretes more than 10^5 *C. difficile* per gram of faeces, and spores may survive on contaminated surfaces for months (Mulligan *et al.*, 1979; Fekety *et al.*, 1981). In one study, one-third of environmental samples taken from hospital rooms occupied by patients with PMC were culture positive for *C. difficile*, compared with 1.3% of samples from control rooms. Environmental contamination with *C. difficile* spores has been demonstrated in 34–58% of sites in hospital wards (Samore *et al.*, 1996; Fawley and Wilcox, 2001), including after detergent-based cleaning (Verity *et al.*, 2001). Commodes, bed frames, sluice rooms and toilet floors are the most frequently contaminated sites. Other potential sources of *C. difficile* contamination include nurses' uniforms, blood pressure cuffs and thermometers. Spores are easily carried on the hands of healthcare workers, facilitating spread, and are relatively resistant to many disinfectants, including alcohol-based products. As the prevalence of *C. difficile* in the environment increases, so does the contamination rate on the hands of staff working there (Samore *et al.*, 1996; Fawley and Wilcox, 2001). There may also be an association between the level of environmental contamination and the number of cases of *C. difficile* infection, but it remains unknown whether this is a cause or consequence of diarrhoea. DNA fingerprinting studies identified an endemic strain that caused a cluster of six cases of diarrhoea, but this was only isolated in the environment after the sixth symptomatic patient (Fawley and Wilcox, 2001). This implies that patient-to-patient or staff-to-patient spread predominates.

Other Causes of AAD

Clostridium difficile is the most commonly identified pathogen causing hospital-acquired infective AAD. Most AAD cases are, however, *C. difficile* toxin/culture negative, and the cause(s) of these remains unclear. Enterotoxigenic *C. perfringens* may be pathogenic in some cases of AAD (Borriello *et al.*, 1985; Modi and Wilcox, 2001). In hospitalised patients with suspected AAD, 8% of faecal samples were positive for *C. perfringens* enterotoxin, 16% positive for *C. difficile* cytotoxin and 2% positive for both *C. perfringens* and *C. difficile* toxins (Asha and Wilcox, 2002). Culture and PCR results confirmed most enzyme-linked immunosorbent assay (ELISA) results. Approximately 5% of *C. perfringens* type A isolates carry the *cpe* gene that encodes the *C. perfringens* enterotoxin. It is intriguing that *C. perfringens* isolates from cases of AAD differ from food-poisoning isolates in the location of the enterotoxin gene (*cpe*). *cpe* is found in extrachromosomal DNA in isolates from AAD cases but is chromosomal in those causing food poisoning (Collie and McClane,

1998). This difference may be because AAD isolates acquire *cpe* from resident *C. perfringens*.

Staphylococcus aureus was considered as a prime cause of post-antibiotic diarrhoea, until the link was described between *C. difficile* and AAD in the late 1970s. However, a 2-year prospective study reexamined the role of *S. aureus* as a possible cause of AAD (Gravet *et al.*, 1999). One case of *S. aureus* AAD was found for every five cases of *C. difficile* AAD. Ninety-two per cent of implicated *S. aureus* isolates were methicillin resistant, and of the 47 cases described, 9 developed bacteraemia. Blood culture and stool isolates were indistinguishable by DNA fingerprinting. Significantly more cases than controls received a fluoroquinolone, and significantly fewer received amoxicillin. Also, significantly more AAD *S. aureus* isolates produced specific leucotoxins and staphylococcal enterotoxin A than did random *S. aureus* strains. This relatively high prevalence of *S. aureus* AAD could not be confirmed in a recent UK study of over 4000 faecal samples from patients with nosocomial diarrhoea (unpublished data).

CLINICAL FEATURES

Clinical Presentation

Clostridium difficile infection is typified by diarrhoea starting usually within a few days of starting antibiotics, but antimicrobial therapy taken 1–2 months ago can still predispose to infection. Very occasional cases occur where no recent antibiotic consumption can be identified, and it is possible that antimicrobial substances in food are responsible. Diarrhoeal faeces usually have a foul odour and, in the absence of PMC, are rarely bloody. Depending on the extent of colitis, abdominal pain with or without a pyrexia may occur. It is not uncommon for diarrhoea, particularly in the elderly, to cause electrolyte disturbances, hypoalbuminaemia and/or paralytic ileus. If pancolitis develops, this may lead to toxic megacolon, perforation and secondary endotoxic shock. Patients with *C. difficile* infection often have raised peripheral white blood cell (WBC) counts. Wanahita, Goldsmith and Musher (2002) found that of 400 inpatients with WBC counts $\geq 15 \times 10^9/L$, infection was documented in 207 (53%) and 16% of these had confirmed *C. difficile* infection. When patients with haematological malignancy were excluded, a quarter of patients with WBC counts $\geq 30 \times 10^9/L$ had *C. difficile* infection. *Clostridium difficile* has been reported to cause very occasional extraintestinal infections typically in patients with bowel disease.

Multiple recurrences of diarrhoea following treatment of *C. difficile* infection are common, and subsequent treatment poses a therapeutic dilemma. Recurrence is a clinical definition (associated with toxin-positive faeces), i.e. a symptom-free period followed by diarrhoea with or without other symptoms. It should be noted that recurrence is sometimes overdiagnosed, notably in studies that included patients who were symptom free for only 1 day.

Patients with PMC tend to have more marked systemic symptoms. If pancolitis develops, this may lead to toxic megacolon, perforation and secondary endotoxic shock. There is a high mortality associated with these complications. In some cases, e.g. toxic megacolon, reduced diarrhoea may occur. Clinicians must be alert to this possibility and to the potential need for urgent surgical intervention in a patient with worsening abdominal and/or systemic signs. Patients with *C. difficile* infection often have raised peripheral WBC counts.

Antimicrobials Predisposing to *C. difficile* Infection

Simplistically, broad-spectrum, particularly anti-anaerobic, agents should be those most associated with *C. difficile* infection, according to colonisation resistance theory. However, *in vivo* antimicrobial activity, and therefore probably the risk of *C. difficile* infection, can be markedly influenced by factors such as drug penetration into the large

gut lumen, specific and non-specific antibiotic binding and gut pH and redox potential. It is extremely difficult to determine accurately the risk of developing *C. difficile* infection associated with specific antibiotics. Most studies in this area to date are flawed because of the use of incorrect control groups, bias and inadequate control of confounding and/or small sample sizes (Wilcox, 2001; Thomas, Stevenson and Riley, 2003). Many factors may affect colonisation resistance and therefore potentially distort the risk associated with particular antibiotics. Also, affected patients are frequently exposed to multiple antibiotics and indeed often receive combinations of antimicrobial agents. Importantly, an antibiotic may be assumed to have a high *C. difficile* risk because it was used during an outbreak of *C. difficile* infection.

Accepting the inadequacies of many studies, some antibiotics and antibiotic classes have been consistently associated with increased risks of *C. difficile* infection, whereas others are conspicuous by the absence of reports linking them to *C. difficile* diarrhoea (Table 46.1). The main predisposing factor for *C. difficile* diarrhoea is antibiotic therapy, notably with cephalosporins (in particular third-generation cephalosporins such as cefotaxime and ceftriaxone), clindamycin and broad-spectrum penicillins. Golledge, McKenzie and Riley (1989) found that over a 1-year period, 5% of patients treated with extended-spectrum cephalosporins developed *C. difficile* diarrhoea. A similar study by de Lalla *et al.* (1989) showed that although all cephalosporins were statistically more likely to induce *C. difficile* infection, there was a significantly higher risk of diarrhoea with third-generation as opposed to first-generation cephalosporins. Aronsson, Möllkby and Nord (1985) found that cephalosporins were implicated in *C. difficile* infection 40 times more often than narrow-spectrum penicillins. Duration of antimicrobial therapy is an important factor in assessing the risk of *C. difficile* infection. A large prospective study of patients in five Swedish hospitals demonstrated that patients treated for fewer than 3 days had a significantly lower incidence of *C. difficile* infection than those receiving longer courses of antibiotic therapy (Wistrom *et al.*, 2001). Macrolides, especially clarithromycin, have been cited as a risk factor for *C. difficile* infection, although confounding factors are difficult to exclude, particularly as hospitalised patients often these agents with other antibiotics.

Anti-pseudomonal penicillins such as piperacillin and ticarcillin (with or without β -lactamase inhibitors) appear to have a low propensity to induce *C. difficile* infection, which is interesting given their deleterious effects on endogenous aerobic and anaerobic gut flora. Anand *et al.* (1994) found that 51 cases of *C. difficile* infection were associated with 40 000 doses of third-generation cephalosporins, and yet none were seen following 62 000 doses of ticarcillin–clavulanate ($P=0.0001$). In a prospective, geriatric ward crossover study, there was a highly significant difference in the rates of colonisation and

Table 46.1 Antibiotic-related risk of *C. difficile* infection

<i>High risk</i>
Cephalosporins
Clindamycin
<i>Medium risk</i>
Ampicillin/amoxicillin
Co-trimoxazole
Macrolides

<i>Low risk</i>
Aminoglycosides
Metronidazole
Anti-pseudomonal penicillins \pm β -lactamase inhibitor
Fluoroquinolones
Rifampicin
Vancomycin

These subdivisions may be biased because of the relative frequency of use of agents and the complexity of interaction between antibiotic exposure, *C. difficile* and other factors.

C. difficile diarrhoea in cefotaxime as opposed to piperacillin–tazobactam-treated patients (relative risk of diarrhoea 7.4, 95% CI=1.7–33) (Settle *et al.*, 1998). The reasons why anti-pseudomonal penicillins rarely appear to induce *C. difficile* infection compared with cephalosporins are uncertain but possibly relate to lower-than-expected faecal concentrations of antibiotic and lack of induction of toxin production.

Aminoglycosides have reduced propensity to induce *C. difficile* infection, probably due to their lack of effect on the endogenous anaerobic gut bacteria. So far, there has been little evidence linking fluoroquinolones with *C. difficile* infection. Older fluoroquinolones (including ciprofloxacin) have poor anti-anaerobic activity, whereas new agents such as moxifloxacin and gatifloxacin have significantly increased activity. In a retrospective case–control study of 27 patients, prior exposure to cephalosporins and use of ciprofloxacin were found to be significant risk factors for *C. difficile* infection in a multivariate analysis (Yip *et al.*, 2001). However, a much larger prospective study showed that the incidence of *C. difficile* diarrhoea was significantly lower in patients treated with levofloxacin compared with those treated with cefuroxime (2.2% vs. 9.2%, $P < 0.0001$) and was similar to those receiving amoxicillin (1.8%, $P = 0.7$) (Gopal Rao, Mahankali Rao and Starke, 2003). Other antibiotics considered to have a low risk of inducing *C. difficile* infection include penicillin, trimethoprim, rifampicin, fusidic acid and nitrofurantoin. There are also very few published reports associating co-amoxiclav with *C. difficile* infection, despite widespread usage of this combination antimicrobial agent.

Although *C. difficile* infection is most commonly associated with antibiotic treatment, studies have shown that short-term perioperative prophylaxis with antimicrobial agents can also predispose to *C. difficile* diarrhoea. In a retrospective case–control study, significantly fewer patients who developed *C. difficile* diarrhoea than controls received antibiotic prophylaxis for an appropriate duration (i.e. ≤ 24 h). Length of hospital stay was also significantly longer in the toxin-positive group (16.5 days vs. 10.2 days, $P < 0.05$), suggesting that overlong antibiotic prophylaxis was detrimental in terms of both diarrhoea and patient stay (Kreisel *et al.*, 1995).

LABORATORY DIAGNOSIS

Many diseases and drugs are associated with the symptom of diarrhoea, and indeed, antibiotics can cause diarrhoea by means that do not involve *C. difficile*, e.g. erythromycin-induced stimulation of gut peristalsis. It is therefore necessary to use the microbiology laboratory to confirm a suspected diagnosis of *C. difficile* infection. There is a great variability both in the criteria used by microbiology laboratories to decide which faecal specimens to test and in the methods employed to detect *C. difficile*. At one extreme, some only test for *C. difficile* if it is specifically requested. At the other extreme, others look for the bacterium/toxins on all specimens received. Both approaches have their merits, but unless some degree of selectivity is operated, there is a real risk of overdiagnosing the infection, given the existence of asymptomatic carriers. In the hospital setting, some laboratories operate a 3-day rule whereby all faecal samples from patients admitted at least 3 days previously are examined for *C. difficile* but not for other enteropathogens such as salmonellae and shigellae (Wood, 2001).

Clostridium difficile Culture

There are two main alternatives for the laboratory diagnosis of *C. difficile* infection. Firstly, detection of the bacterium by culture, which is relatively slow (taking up to 5 days) and is less specific than toxin testing, particularly given the existence of asymptomatic carriage, especially in the elderly, and occasional non-toxigenic (and therefore non-pathogenic) strains. Most laboratories now detect *C. difficile* by toxin testing, and the proportion of centres using culture continues to decline. For those laboratories performing both approaches, there is no consensus on how to interpret the occasional specimen that yields a

toxin-negative result and yet is culture positive. Culture is, however, required if typing is to be performed to establish the epidemiology of strains present in a ward or hospital.

Agar formulations using an egg yolk agar base (CCEY) have a theoretical advantage over blood agar-based media, as *C. difficile* produces neither lecithinase nor lipase, while other clostridia commonly present in the gut such as *C. perfringens* and *C. bifermens/C. sordellii* (and which occasionally grow on the selective medium) produce lecithinase and thus can easily be recognised. Commercially available formulations of CCEY are available, and these are optimised for *C. difficile* isolation and recognition. Putative *C. difficile* colonies can be identified by the characteristics noted above and by using antigen (e.g. Microgen, UK) or enzyme detection kits.

Clostridium difficile Toxin Detection

Detection of one or both of the toxins of *C. difficile* remains the gold standard test with which other diagnostic tests are compared in evaluations of sensitivity and specificity. The presence of cytotoxin usually causes a rounding-up cytopathic effect (CPE), depending on the cell line used. Both toxins A and B can cause a CPE, although the latter is approximately 1000-fold more potent in this assay. Assay for *C. difficile* cytotoxins can be performed using many different commonly used cell lines, including Vero, HEp2, monkey kidney, HeLa, fibroblast and Chinese hamster ovary cell lines. It is disputed which cell line(s) is the most sensitive, but Vero cell lines are probably most commonly used in Europe. A centrifuged, filtered faecal filtrate is inoculated onto the cell monolayer, which is examined after overnight incubation and again after 48 h. Non-specific CPEs are detected by using a control cell monolayer containing either *C. difficile* or *C. sordellii* antitoxin that neutralises *C. difficile* cytotoxic activity. Disadvantages of the cytotoxin technique include a lack of method standardisation, a need to maintain a cell-culture line and the relative slowness of the test (24–48 h) compared with EIA (1–2 h). However, this delay may be beneficial in avoiding treatment of cases of *C. difficile* diarrhoea that resolve spontaneously. It is also possible to detect 75% of cytotoxin-positive results after incubation for only 6 h (Settle and Wilcox, 1996).

Many kit-based methods (primarily EIAs) to detect toxins A ± B are available. These are quicker and simpler to perform than the cytotoxin technique but tend to suffer from reduced sensitivity. Numerous studies have compared the performance of different kits with each other and with other methods, but no meta-analysis has been performed to determine with confidence the superiority of any particular test (Brazier, 1998). A recent study comparing six different rapid methods with the cytotoxin technique on over 1000 faecal samples (Turgeon *et al.*, 2003) confirmed earlier findings that such kits are about 80–90% sensitive and 90–99% specific. Assays that target both toxins tend to perform better and have the advantage of being able to detect the toxin A–B+ strains. Triage[®] is a membrane immunoassay for the simultaneous but distinct detection of toxin A and glutamate dehydrogenase. Triage[®] has been shown to have a high negative predictive value, suggesting that it might be a useful screening test (Barbut *et al.*, 2000; Turgeon *et al.*, 2003). In general, nucleic acid amplification techniques have not offered any significant benefit to date compared with the above approaches for the diagnosis of *C. difficile* diarrhoea, primarily because of the high clinical accuracy associated with direct toxin detection methods.

Histopathology

The histological appearances of large-bowel tissue obtained via sigmoidoscopy remain the optimum way of distinguishing between the different pathological conditions associated with *C. difficile*, although in about 10% of patients evidence of colitis is found only in the caecum or transverse colon (Fekety, 1994). In approximately 25% of individuals,

stools may continue to be culture and toxin positive for some time after symptoms have resolved (Bartlett, 1984; Fekety *et al.*, 1984), and follow-up stools from asymptomatic patients should not be sent for toxin assay.

Clostridium difficile Typing

Numerous typing schemes have been proposed for *C. difficile* (Brazier, 2001; Cohen, Tang and Silva, 2001). These differ markedly in ease of use and interpretation and, importantly, in their discriminatory power (Table 46.2). The three most extensively studied are serogrouping (used predominantly in France and Belgium; Delmée, Homel and Wauters, 1985), restriction endonuclease analysis (REA) (used in United States; Kuijper *et al.*, 1987) and ribotyping (used in United Kingdom; Stubbs *et al.*, 1999). Serogrouping is simple to perform and has moderate discriminatory power but is limited by availability of sera. REA has good discriminatory power but produces highly complicated DNA banding patterns that can be difficult to interpret. Ribotyping requires molecular biology expertise but is highly discriminatory and produces simple banding patterns. RAPD and pulsed-field gel electrophoresis (PFGE) have shown potentially very high discriminatory power but have problems associated with reproducibility and demanding methodology, respectively (Fawley, Freeman and Wilcox, 2003). Some strains, such as *C. difficile* serogroup G isolates (PCR ribotype I), have proved to be difficult to type by PFGE, presumably due to high endonuclease activity, although a modified method appears to have overcome the DNA degradation (Fawley and Wilcox, 2002). In general, standardisation and simplification of *C. difficile* typing nomenclature schemes is needed.

MANAGEMENT OF INFECTION

Treatment

There are few proven therapeutic regimens for *C. difficile* infection. First-line treatment should, where possible, involve discontinuation of the precipitating antibiotic(s), although in many patients this is not possible. Specific treatment is indicated when the patient has a systemic illness with evidence of colonic inflammation, PMC or persistent symptoms, despite stopping the precipitating antibiotic. Spontaneous symptomatic resolution may occur in approximately a quarter of cases of *C. difficile* infection. In reality, most patients are commenced on either metronidazole or vancomycin when the infection is diagnosed and before precipitating antibiotic(s) is ceased. Precipitating antibiotic(s) can be substituted with lower-risk agents, but this approach is of unproven benefit. *Clostridium difficile*

infection is treated preferably with oral metronidazole (400 mg or 500 mg three times daily) for 7–10 days. Oral vancomycin (125 mg four times daily) is a more expensive alternative and risks selecting for glycopeptide-resistant enterococci. There is no statistically proven difference between metronidazole and vancomycin when overall response or recurrence rates are examined (Teasley *et al.*, 1983; Wilcox and Spencer, 1992). The mean duration of symptoms is marginally shorter (mean 1.6 days) following vancomycin compared with metronidazole administration (Wilcox and Howe, 1995). Either antibiotic can be administered via the nasogastric route if they cannot be tolerated orally. For intravenous treatment, both antibiotics should be administered together because of the unpredictable colonic concentrations of each agent. Reports of reduced susceptibility of *C. difficile* to metronidazole and vancomycin are very uncommon, but both intermediate (8–16 mg/L) and high-level resistance (>64 mg/L) to metronidazole have been described (Pelaez *et al.*, 2002). Disturbingly high rates of intermediate resistance to metronidazole (6.3%) and vancomycin (3.1%) were reported in Spain in 2002 (Pelaez *et al.*, 2002), but only one metronidazole-resistant isolate has been reported in the United Kingdom (Brazier *et al.*, 2001).

Recurrence

Symptomatic recurrences following treatment of *C. difficile* infection are common (up to 37% of cases), and subsequent treatment poses a therapeutic dilemma (Wilcox *et al.*, 1996). DNA fingerprinting studies have shown that relapses are often re-infections with different strains (O'Neill, Beaman and Riley, 1991; Wilcox *et al.*, 1998). Hence, the common practice of switching metronidazole to vancomycin and vice versa in patients with symptomatic recurrences is illogical, and a first recurrence should be re-treated with oral metronidazole. Courses of 4–6 weeks with tapering and pulsed doses of vancomycin have been used in theory to first kill the vegetative bacteria, to allow spores to germinate and later to kill them (Tedesco, Gordon and Fortson, 1985). Controlled studies of this approach have not been performed. Success of this approach may be due to the prolonged antibiotic course, preventing reacquisition of *C. difficile*, while colonisation resistance by bowel flora remains ineffectual against opportunistic bacterial colonisation. Use of anion exchange resins to bind *C. difficile* toxins is not a practical option because it is cumbersome to use and vancomycin can bind to these agents *in vitro* (Taylor and Bartlett, 1980).

Biotherapy

There is much interest in the biotherapeutic and immunological approaches for the management of *C. difficile* infection. *Saccharomyces*

Table 46.2 Comparison of techniques used to type *C. difficile*

Typing method	Typeability	Reproducibility	Discriminatory power	Interpretation	Performance (number of types/groups)
Antimicrobial susceptibility	All	Fair	Poor	Easy	Easy
Serotyping	Most	Good	Fair (19)	Easy	Easy
Phage/bacteriocin	Few	Fair	Poor	Easy	Easy
Sodium dodecyl sulphate polyacrylamide gel electrophoresis	All	Good	Good (17)	Easy	Moderate
Immunoblot	All	Good	Good	Easy	Moderate
Plasmid profile	Few	Fair	Poor	Moderate	Moderate
Toxinotype	All	Good	Poor (11)	Easy	Moderate
Pyrolysis mass spectrometry	All	Fair	Excellent	Easy	Difficult
Restriction endonuclease analysis	All	Good	Good (55)	Difficult	Moderate
Restriction fragment length polymorphism	All	Good	Poor	Moderate	Moderate

Modified from Cohen, Tang and Silva (2001).

boulardii in particular, which prevents binding of toxin A in a rat ileal model (Pothoulakis *et al.*, 1993), has been extensively examined and is commercially available as a freeze-dried preparation. There have been several placebo-controlled, double-blind trials examining the role of *S. boulardii* in preventing or treating AAD. Early prophylaxis studies investigated the effect of *S. boulardii* given to patients receiving antibiotics. There was a reduced incidence of diarrhoea within 2 weeks of cessation of antibiotic therapy, but diarrhoea was not significantly reduced in the group of patients with *C. difficile*, and neither acquisition of *C. difficile* nor production of toxin was reduced (Adam, Barret and Barrett-Bellet, 1977; Surawicz, Elmer and Speelman, 1989). In a large, double-blind, placebo-controlled study of *S. boulardii* for the treatment of *C. difficile* infection, *S. boulardii* did not reduce subsequent recurrences in patients with a first episode of *C. difficile* diarrhoea. In patients experiencing recurrent diarrhoea, there was a significant decrease in recurrences in those receiving *S. boulardii* compared with placebo (McFarland *et al.*, 1994). The reason for such a discrepancy in response is unclear.

An area of potential concern with biotherapy is the risks associated with the administration of live micro-organisms, particularly to frail elderly patients with inflamed gut mucosae. Cases of fungaemia have been reported in both immunocompromised and immunocompetent patients following administration of *S. boulardii*, highlighting the potential virulence of this yeast in humans (Fredenucci *et al.*, 1998; Niauxt *et al.*, 1999). Furthermore, *S. boulardii* isolates obtained from varied commercial sources were shown to differ in their virulence in murine models of systemic infection, suggesting a lack of uniformity of yeast strains in such preparations (McCullough *et al.*, 1998). Also, commercially available *S. boulardii* strains had moderate virulence compared with *Saccharomyces cerevisiae* (baker's yeast) in these models.

Biotherapy studies in AAD have been usually open and contained few subjects, and thus, the true efficacy of most, if not all of the, regimens described to date is uncertain. Small series of patients have been treated for, or received prophylaxis against, AAD with biotherapy, including *Lactobacillus acidophilus*, *Lactobacillus GG*, *Enterococcus faecium* SF 68, non-toxicogenic *C. difficile*, yoghurt or Brewer's yeast. Trials evaluating the role of *Lactobacillus GG* in acute diarrhoea have reported conflicting results (Gorbach, Chang and Goldin, 1987; Siitonen *et al.*, 1990; Thomas *et al.*, 2001). Notably, a recent large, randomised, double-blind, placebo-controlled trial found neither a decrease in the rate of diarrhoea nor a decrease in the rate of *C. difficile* infection in patients receiving *Lactobacillus GG* (Thomas *et al.*, 2001). Rectal biotherapy and rectal infusion of faeces have been used occasionally in *C. difficile* infection to circumvent gastric acid-mediated degradation of potential probiotics. However, this route of administration is often impractical and unpleasant to administer.

Toxin-Binding Polymer

A high-molecular-weight toxin-binding polymer, GT160-246, is undergoing investigation for treatment of *C. difficile* diarrhoea. It has no direct antimicrobial activity but binds toxins A and B. It has been shown to protect *C. difficile*-infected hamsters from mortality, although not from initial development of colitis (Kurtz *et al.*, 2001). The treatment has been shown to be well tolerated in phase I trials and may offer a promising alternative to the current limited choice of proven therapies.

PREVENTION AND CONTROL

Antibacterial Prophylaxis Against *C. difficile* Infection

Antibacterial prophylaxis against *C. difficile* infection is not a practical option as oral antibiotics can adversely affect the normal gut

flora and increase the potential period of susceptibility to colonisation by *C. difficile*. A study of prophylaxis with oral metronidazole or vancomycin against *C. difficile* infection concluded that neither was effective at preventing asymptomatic faecal excretion of *C. difficile* (Johnson *et al.*, 1992). Two studies have claimed evidence that metronidazole, given as surgical prophylaxis to surgical patients, may reduce the risk of postoperative *C. difficile* infection (Gerding *et al.*, 1990; Cleary *et al.*, 1998). However, in one of these, the comparator group with more cases of *C. difficile* infection received clindamycin (a high-risk antibiotic) instead of metronidazole as anti-anaerobic cover (Gerding *et al.*, 1990). In the other study, a non-significant difference was seen in the incidence of *C. difficile* colonisation in patients receiving a non-standard prophylaxis regimen (Cleary *et al.*, 1998). Thus, there is no sound evidence of a benefit of using metronidazole to prevent *C. difficile* infection.

Immunotherapy

In the mid 1990s, *C. difficile* toxin-neutralising antibodies were found to be present in nine batches from three commercial (United States) Ig suppliers (Salcedo *et al.*, 1997). There have been several case reports of patients with *C. difficile* infection unresponsive to standard antimicrobial therapy who were successfully treated with intravenous Ig, but no comparative studies of Ig have been performed. Diarrhoea was prevented in clindamycin-treated, *C. difficile*-exposed hamsters when given prophylaxis with bovine colostrum Ig concentrate (Lyerly *et al.*, 1991). Bovine Ig concentrate has been reported to inhibit the cytotoxicity and enterotoxicity of *C. difficile* toxin (Kelly *et al.*, 1996), and human faeces were shown to contain neutralising antitoxin activity after oral administration of this preparation (Kelly *et al.*, 1997). However, current concerns about bovine spongiform encephalopathy are likely to undermine further progress with this preparation in humans.

Vaccination

Vaccines preventing *C. difficile* infection in the elderly could potentially revolutionise current therapeutic options. A vaccine containing both *C. difficile* A and B toxoids has been shown to be safe and immunogenic in healthy volunteers, producing increased serum IgG and faecal IgA anti-toxin levels in excess of those associated with protection in clinical studies (Kotloff *et al.*, 2001; Aboudola *et al.*, 2003). It remains unclear, however, whether this approach will be effective in the main target population, particularly since infection in the elderly may be attributable to a compromised immune response.

Hospital Infection Control

The fundamental principle in the control of *C. difficile* infection is the control of antimicrobial prescribing, and there are numerous examples of restrictive antibiotic policies associated with reduction in rates of *C. difficile*-associated diarrhoea (CDAD) (Pear *et al.*, 1994; Ludlam *et al.*, 1999). Despite the recognition of *C. difficile* infection and its well-known link with antibiotic use, incidence of infection may still increase, and constant feedback to prescribers may be required (Stone *et al.*, 2000).

Nosocomial transmission of *C. difficile* is believed to occur primarily via the contaminated hands of healthcare workers or via environmental (including healthcare equipment) contamination and, less commonly, by direct patient-to-patient spread. Symptomatic patients should be isolated or cohort nursed, and hand hygiene is a key intervention to prevent nosocomial spread of *C. difficile* infection. Much of the evidence, however, is observational, although some studies have demonstrated the effectiveness of gloves (Johnson *et al.*, 1990), anti-septic soaps and alcohol-based hand-rub solutions (Bettin *et al.*, 1994;

Lucet *et al.*, 2002). Contamination of healthcare workers' hands can lead to and result from contamination of the environment. Thus, the prevalence of healthcare worker hand contamination with *C. difficile* correlates with the level of environmental contamination (Samore *et al.*, 1996; Wilcox *et al.*, 2003). However, proof that reducing environmental *C. difficile* can decrease the incidence of infection is lacking.

The optimum method for decontaminating hospital environments contaminated with *C. difficile* remains controversial. Hypochlorite was found to be more effective than a quaternary ammonium solution in a bone marrow transplant (BMT) unit, but not in an ITU or a general medical ward (Mayfield *et al.*, 2000). The same workers reported a reduction in *C. difficile* diarrhoea rates in the BMT unit after use of the hypochlorite solution, but no reduction on the other wards studied. When the use of ammonium solution was restarted, rates of *C. difficile* diarrhoea rose, suggesting that hypochlorite solution is effective at reducing the risk of infection in high-risk clinical areas. However, environmental *C. difficile* prevalence was not measured and antibiotic use was altered during the study period. An outbreak of *C. difficile* infection ended following introduction of disinfection with unbuffered hypochlorite (500 ppm available chlorine), and surface contamination with *C. difficile* decreased to 21% of initial levels (Kaatz *et al.*, 1988). Phosphate-buffered hypochlorite (1600 ppm available chlorine, pH 7.6) was found to be more effective at reducing environmental *C. difficile* levels (98% reduction in surface contamination). Wilcox and Fawley (2000) found that some non-chlorine-based hospital cleaning agents, but not chlorine-based cleaning products, caused increased sporulation of *C. difficile in vitro*. Hence, the choice of environmental cleaning agents may in fact increase the persistence of organisms and lead to increased risk of infection. In a recent crossover study on elderly medicine wards, hypochlorite-based cleaning was associated with a reduction in both *C. difficile* environmental prevalence and *C. difficile* infection incidence in one of the two study wards (Wilcox *et al.*, 2003).

Other *Clostridium* spp.

Ian R. Poxton

Medical Microbiology, University of Edinburgh Medical School, Edinburgh, UK

INTRODUCTION

The Gram-positive, anaerobic, spore-forming rod-shaped bacteria – the clostridia – are ubiquitous. They are found throughout nature – in soils, fresh water and marine sediments, decaying vegetation and animal matter, sewage and the gastrointestinal (GI) tract of vertebrates and invertebrates. Saprophytic forms have a major role in recycling organic matter, while other forms inhabit the GI tract of animals in commensal associations. A few infamous species are well recognised as significant opportunist pathogens causing severe wound infections and GI disease.

DESCRIPTION OF THE GENUS *CLOSTRIDIUM*

Almost 100 different clostridial species are currently recognised. Table 47.1 summarises the phenotypic characteristics of the more commonly encountered species. All form oval or spherical spores that often distend the cell, but spores in some species –, e.g. *C. perfringens* – are difficult to demonstrate in the laboratory. Cell shape is straight or sometimes slightly curved rods of variable length and width. They all have typical Gram-positive cell envelope morphology and most stain Gram positive. However, some only show this characteristic in young cultures, with a few species tending always to appear Gram negative. Most species are obligate anaerobes, but there is a degree of oxygen

tolerance, with some species, most notably *C. tertium*, being able to grow in air. Those that can grow in air do not sporulate under aerobic conditions, and their growth is not as profuse as in oxygen-free conditions. There are non-motile and motile species, the latter usually with peritrichous flagella. The %G+C of the DNA of clostridia varies considerably, ranging from 22 to 55%. However, there are two main clusters with %G+C of 22–34 and 40–55, and it was once proposed to separate these into two different genera (Sneath, 1986). A recent discussion paper by Finegold, Song and Liu (2002) highlights many of the current problems and anomalies in the classification of clostridia. As in most, if not all, other groups of bacteria, the naming and classification of the clostridia must be a compromise between that based on the most accurate and modern polyphasic taxonomy and the need to communicate names that can be remembered and mean something to clinicians.

The optimum growth conditions of clostridia reflect their diverse habitats, with optimum temperatures between 15 and 69 °C. Energy production is usually by fermentation of carbohydrates or peptides with end products of metabolism being a mixture of alcohols and volatile and non-volatile fatty acids. These are often used in identification by gas chromatography and typically are responsible for the noxious smells produced by cultures (or wounds) in which clostridia are growing. Those species pathogenic for human and other mammals typically produce one or more potent exotoxins.

Table 47.1 *Clostridium* spp. that may be commonly encountered in the diagnostic laboratory – a brief guide to their phenotype

Species	Growth in air	Position/shape of spore	Pathogen/normal flora/saprophyte	Haemolysis	Lecithinase production	Lipase production
<i>C. bifermentans</i>	N	C/ST O	NF/S	y	Y	N
<i>C. butyricum</i>	N	C/ST O	S/NF	N	N	N
<i>C. botulinum</i>						
Types A, B and F	N	ST O b	P/S	Y	N	Y
Types C and D	N	C/ST O	P/S	Y	y	Y
<i>C. chauvoei</i>	N	ST/C O B	P (animal)	Y	N	N
<i>C. difficile</i>	N	ST/T O	P/NF	N	N	N
<i>C. novyi</i>	N	ST/C O	P	Yd	Y	Y
<i>C. perfringens</i>	N	ST/C O	P/NF	YD	Y	N
<i>C. septicum</i>	N	ST/C O B	P/NF	Y	N	N
<i>C. sordellii</i>	N	C O	NF	y	Y	N
<i>C. sporogenes</i>	N	ST O b	NF	y	y	Y
<i>C. tertium</i>	G	T O	S/NF	y	N	N
<i>C. tetani</i>	N	T/ST S	P/NF/S	Y	N	N

Notes: N, no growth; G, growth; T, terminal; ST, subterminal; C, central; O, oval; S, spherical; B, bulging; P, pathogen; NF, normal flora; S, saprophyte; Y, yes; D, double zone; N, no; Y, yes; N, no; Y, yes; N, no. Upper case: always/nearly always, lower case sometimes.

Overview of the Structure of Clostridia and their Virulence Factors

Clostridia are typically Gram positive in structure, with a cell envelope consisting of a cytoplasmic membrane and a peptidoglycan-containing cell wall with *meso*-diaminopimelic acid as the diamino acid of the peptidoglycan side chain. Many species are capsulate, but this character is not of major importance either as a virulence factor or in classification, although capsular antigens were once used to serotype strains of *C. perfringens*. The resistant exospores that members of the genus invariably produce are crucial for survival in hostile environments. All soils and dusts throughout the world are likely to contain spores of clostridia. The various exotoxins and extracellular enzymes produced by clostridia are the main virulence factors of clostridia. Traditionally the toxins are referred to by Greek letters such as alpha and beta. However, it should be stressed that the alpha-toxin of one species may be very different from the alpha-toxin of another species.

The Pathogenic Clostridia

Of the 100 or so species only a handful are commonly found causing infections in human and domestic animal, with a further 10 or so found rarely. Many of the infections arise from contamination of wounds with soil or faeces, and it is sometimes difficult to know if an isolate from a polymicrobial infection is playing a pathogenic role or if it is simply a contaminant.

PATHOGENICITY

The pathogenic mechanisms of clostridia are invariably associated with the exotoxins that they produce. In the past the first test to see whether a clostridial isolate was pathogenic was to inoculate some culture supernatant into a mouse to see if it was lethal. Clostridial exotoxins can be categorised according to several different criteria, such as the effects they have on the whole animal, the cell or at the biochemical level. Many have enzymatic effects, while others have immunomodulating effects, some may be superantigens, while others have an unknown action. Table 47.2 summarises the main groups of

Table 47.2 Some of the better characterised clostridial exotoxins

Exotoxin type	Effect	Examples
Phospholipase C	Breakdown of cell membranes and tissue destruction	<i>C. perfringens</i> alpha-toxin
Neurotoxins	Cleavage of peptides involved in neurotransmission	Botulinum and tetanus toxins
Enterotoxin	Diarrhoea. Apoptosis or necrosis of villus cells and induction of proinflammatory cytokines	<i>C. perfringens</i> enterotoxin
Perfringolysin	Binds to cholesterol in membranes and causes cell lysis	<i>C. perfringens</i> theta-toxin (perfringolysin O)
Affecting cytoskeleton:		
(i) Glycosylation of proteins from the Rho family that regulate actin polymerisation	Dissociation of the actin filaments in the cytoskeleton inducing cell rounding, cell dysfunctions, changes in cell permeability and disruption of intercellular junction	(i) The large clostridial toxins from <i>C. difficile</i> (toxins A and B), <i>C. sordellii</i> and <i>C. novyi</i>
(ii) ADP-ribosylation of actin monomers		(ii) The clostridial binary toxins: <i>C. perfringens</i> iota, <i>C. botulinum</i> C2 and <i>C. difficile</i> binary

toxins and their effects. Details of pathogenesis will be described more fully for each species in later sections. Toxins often work in concert, and the tissue destruction characteristic of so many clostridial wound infections is a result of one or more exotoxins and perhaps some extracellular enzymes produced by the bacteria. It is often difficult to differentiate between what are exotoxins and extracellular enzymes. A possible way of defining them is that a toxin if injected in pure form is capable of producing pathology, while the extracellular enzymes cannot, and are dependent on true toxins to initiate the pathology. In practice of course this does not matter as it is the result that is important.

Table 47.3 lists the common pathogenic species and the exotoxins that they produce and summarises their role in infection. With the exception of *C. difficile*, which is covered in detail in Chapter 46, the major clostridial pathogens will be described in some detail later.

Table 47.3 The pathogenic clostridia, their clinical spectrum and major toxins

Species	Major toxins	Infections they cause
<i>C. perfringens</i>	Alpha (phospholipase-C), beta, epsilon iota. Enterotoxin	Gas gangrene, food poisoning and other GI infections: pigbel, enteritis necroticans, antibiotic associated diarrhoea
<i>C. tetani</i> <i>C. botulinum</i>	Tetanospasmin (TeNT) Botulinum neurotoxins (BoNT) A, B, C1, D, E and F and C2 exotoxin	Tetanus Botulism (classical food-borne) Infant botulism Wound botulism Equine dysautonomia
<i>C. novyi</i>	Type A: alpha (lethal, necrotising), gamma (phospholipase C) and epsilon (lipase). Type B: alpha-toxin, beta toxin (lecithinase)	Gas gangrene – in mixed infections with <i>C. perfringens</i> and <i>C. septicum</i> . Other oedematous wound infections – previously in war wounds, but more recently a cause of death in injecting drug users
<i>C. difficile</i>	Toxin A, toxin B, ADP-ribosylating toxin	Pseudomembranous (antibiotic associated) colitis and antibiotic associated diarrhoea
<i>C. septicum</i>	Lethal, haemolytic and necrotising alpha-toxin	Gas gangrene – in mixed infections with <i>C. perfringens</i> and <i>C. novyi</i> . A lethal disseminating disease: ‘malignant oedema’ in cattle and ‘braxy’ in sheep. Similar diseases in other domestic and wild animals
<i>C. sordellii</i>	Lethal toxin – immunologically cross-reactive with <i>C. difficile</i> toxin B	Various soft-tissue infections in human and other animals
<i>C. chauvoei</i>	Beta toxin (deoxyribonuclease) Gamma toxin (hyaluronidase)	Blackleg in cattle and sheep not a pathogen of human
<i>C. barati</i> <i>C. carnis</i> <i>C. fallax</i> <i>C. haemolyticum</i> <i>C. histolyticum</i> <i>C. limosum</i> <i>C. ramosum</i> <i>C. sporogenes</i> <i>C. tertium</i>	Poorly characterised or unknown	Isolated infrequently from soft-tissue infections with other bacteria – primary role in pathogenesis or contaminant uncertain in most cases

GENERAL METHODS FOR THE ISOLATION OF CLOSTRIDIUM SPECIES

Most isolation procedures make use of the fact that clostridia produce heat- and alcohol-resistant spores. Treatment of 70–80 °C for 10 min or addition of an equal volume of 95% or absolute ethanol to a specimen for a few minutes prior to culturing is often used. Many different enrichment and selective media exist for clostridia. Reinforced clostridial agar is one of the most commonly used general plate media. Many clostridia, including *C. perfringens*, *C. novyi*, *C. sordellii*, *C. bifermentans* and some *C. botulinum* are identified by their production of lipases and/or lecithinases. Egg yolk, a rich source of lecithin, is often incorporated into plate media to permit easy identification. A zone of opalescence extending beyond the colony is indicative of lecithinase production, while restricted opalescence under a colony with an associated 'pearly layer' over the colony indicates lipase activity. Proteolytic clostridia produce clear zones in egg-yolk-containing agar. The media of Lowbury and Lilly and Willis and Hobbs are examples of egg-yolk agars. Full details of recipes, including instruction for making egg-yolk suspensions (which is also available commercially), are in Collee, Brown and Poxton (1996).

Spore formation, a diagnostic feature of clostridia, is a very variable characteristic in laboratory cultures. Many species sporulate readily in broth or on plates, and spore numbers usually increase with the age of the culture. However, one species in particular, *C. perfringens*, is notoriously difficult to make sporulate in the laboratory. Several media, including those of Ellner, Duncan and Strong, Phillip, and an alkaline egg-yolk agar (all detailed in Collee, Brown and Poxton 1996), have been developed to encourage sporulation in *C. perfringens*, but none is absolutely effective. In nature, *C. perfringens* readily sporulates as it passes into the small intestine – an event associated with the production of the enterotoxin, the crucial stage in the pathogenesis of perfringens food poisoning (see p. 560).

CLOSTRIDIUM PERFRINGENS

Clostridium perfringens is a relatively large Gram-positive, rod-shaped bacterium (4–6 × 1 µm). In usual laboratory culture it rarely forms spores (see above for special media). There are five types of *C. perfringens* recognised and are classified as types A–E based on the different combinations of lethal toxins they produce (Table 47.4). Food poisoning strains typically produce heat-resistant spores and an enterotoxin that is produced on sporulation. All types of *C. perfringens* produce alpha-toxin, a phospholipase C (lecithinase) that cleaves phosphatidyl choline into phosphoryl choline and an insoluble diglyceride. This results in opalescence in agars containing egg yolk and is the basis for the Nagler reaction where the reaction can be inhibited by

Table 47.4 Classification of types of *C. perfringens* – by patterns of major toxins produced

Type	Where found	Major lethal toxins			
		α	β	ε	ι
A	Gas gangrene Food poisoning	+	–	–	–
B	Lamb dysentery	+	+	+	–
C	Enteritis necroticans in human. Enteritis in other animals	+	+	–	–
D	Enterotoxaemia and pulpy kidney disease in sheep	+	–	+	–
E	Possible pathogen of sheep and cattle	+	–	–	+

specific anti-alpha-toxin (Collee, Brown and Poxton, 1996). Many strains produce a haemolysin that, together with the alpha-toxin, gives rise to a typical double zone of haemolysis: a clear inner zone and an outer zone of incomplete lysis, on blood agar. Colonies are usually large and smooth and cells are often capsulate.

Clostridium perfringens is an anaerobe, but may grow microaerobically. In optimum growth conditions at a temperature of between 37 and 45 °C, it can grow at a high growth rate with a generation times of 15 min or less.

Clostridium perfringens is ubiquitous – found in the soil, dust and the GI tract of human and other animals. In the GI tract it is usually considered a minor component of the normal flora, or in transient passage. It usually numbers about 10^{3–4} organisms per gram of faeces in humans.

As a pathogen, *C. perfringens* is found in two major conditions: in anaerobic wounds it is the key agent causing gas gangrene (often associated with other clostridia or other bacteria), and much more commonly it is responsible for a type of food poisoning.

Clinical Features

Gas Gangrene

Classically this was a consequence of war wounds associated with contamination of complex deep wounds with soil and faeces. It came to real prominence in the trenches of the First World War in France and Belgium – where the organism was encountered commonly in the soil. However, in other theatres of war, such as the desert and Gallipoli, where the organism is uncommon in soil, gangrene was much less common (Willis and Smith, 1990). More typically these days gangrene is an uncommon complication of diabetic ulcers and other wounds associated with poor tissue perfusion.

The crucial events in initiating pathogenesis are tissue destruction such that the environment of the wound is anoxic and contamination with the organism – most likely in the form of spores. Other clostridial species as well as some facultative organisms may also contribute to the pathology. The incubation period ranges from a few hours to a week, depending on injury and soiling. Pain is an early event, with progressive oedema and swelling of the wound with mild-to-moderate fever. A profuse serous exudate often with blood is produced, and this is followed by bubbles of gas appearing in the discharge. The skin is marbled and the tissues become crepitant. Without surgical intervention the patient becomes extremely toxæmic and shocked, and sudden death is usually due to circulatory failure. Once symptoms have commenced the only successful treatment is by radical and extensive surgical excision of all affected tissue. The use of systemic antitoxin is probably not useful, almost certainly because the antibodies are unable to reach the affected tissue. Hyperbaric oxygen treatment remains controversial and the literature abounds with doubts about its use (Wang *et al.*, 2003).

Prevention is through thorough cleansing and debridement of any likely wound with antibiotic treatment – drugs should include anti-anaerobe antibiotics such as metronidazole, an aminoglycoside and a beta-lactam – to cover against the non-clostridial components of what is often a polymicrobial infection.

The alpha-toxin (phospholipase C) and to a lesser extent the theta toxin are primarily responsible for most of the observed pathology (Awad *et al.*, 1995; Rood, 1998). Moreover, the proteases produced by the bacteria are likely to contribute to the spreading pathology.

Diagnosis of gangrene is primarily a clinical one, as clostridia often contaminate wounds. However, isolation and identification of *C. perfringens* and other clostridia, including *C. novyi*, *C. septicum* and *C. histolyticum*, from suspected cases of gangrene is helpful.

Clostridium perfringens Food Poisoning and Other Forms of GI Disease

The symptoms of acute diarrhoea with severe abdominal pain 8–22 h after ingestion of meat stews are likely to indicate food poisoning caused by *C. perfringens*. Type A strains of *C. perfringens*, typically those producing heat-resistant spores, produce an enterotoxin that is responsible for the symptoms. These strains are often poorly haemolytic compared to the strains found in gangrene and are sometimes referred to as type A2. However, other strains are sometimes involved.

A review of over 1500 cases of *C. perfringens* food poisoning in the UK between 1970 and 1996 (Brett and Gilbert, 1997) showed that meat, poultry or their products were implicated in 97% of outbreaks. 'Preparation of food too far in advance; inadequate cooling; storage at ambient temperature and inadequate reheating' were the major contributory factors in outbreaks. Outbreaks are typically large with more than 1000 individuals involved being not uncommon. In the Brett and Gilbert (1997) studies there were 28 associated deaths from more than 36 000 cases. The usual sequence of events begins with warm, bulk-cooked meat stews or casseroles. These may already contain heat-resistant spores that have survived the cooking, or it has become contaminated with spores from dust. The cooked meat (cf. cooked-meat broth – a common medium for culturing anaerobes) provides the ideal environment for the germination of the spores and subsequent growth of *C. perfringens*. Cell division can occur every 10 min. The resultant vegetative bacterial cell culture is then ingested. On entering the small intestine these vegetative cells sporulate and coincidentally release an enterotoxin. This enterotoxin, which appears to be carried on a transposable element (Brynstad, Synstad and Granum, 1997), acts on the villus cells and, depending on the dose, brings about their apoptosis or oncosis (necrosis) (Chakrabarti, Zhou and McClane, 2003). It has been proposed that the enterotoxin has some superantigen properties as it stimulates the production of some proinflammatory cytokines. However, this does not seem to be the case (Wallace *et al.*, 1999). The combined result of cell death and induction of mediators is reduced absorption with some fluid secretion and a painful watery diarrhoea. This form of food poisoning is relatively common and as it is often associated with large outbreaks – due to the bulk cooking of food – it is one of the most commonly reported types, despite its short duration (1–2 days) and relatively trivial symptoms. Treatment is not usually necessary except in the young and very old where dehydration might require correction.

Detection of excessive numbers of *C. perfringens* in faeces can be used in diagnosis: median counts of 8.5×10^6 /g in cases of diarrhoea compared to 1.5×10^4 /g in healthy people (Poxton *et al.*, 1996). Although typing is possible, utilising methods such as pulse-field gel electrophoresis (Maslanka *et al.*, 1999), it is not commonly done. It should also be recognised that more than one type of *C. perfringens* can be in the same sample of faeces or food, and several colonies must be selected from each specimen. Commercial enzyme immunoassays (EIA) are available for the detection of *C. perfringens* enterotoxin, e.g. that produced by Techlab Inc., Blacksburg, Virginia. It appears not as sensitive as the in-house EIA used by the UK Health Protection Agency Food Microbiology Laboratory, but it is specific and recommended for investigation of outbreaks (Forward, Tompkins and Brett, 2003).

Enterotoxin-producing *C. perfringens* can also be responsible for outbreaks of antibiotic associated diarrhoea that appears very similar to that caused by *C. difficile* (Borriello *et al.*, 1985). The enterotoxin EIA kit mentioned above is probably the best method for diagnosing this condition and allowing differentiation from *C. difficile* diarrhoea (Asha and Wilcox, 2002).

Various forms of necrotic enteritis or enteritis necroticans have been reported in human and other animals – including chickens – and is thought to be often caused by type C strains of *C. perfringens*. Necrotising jejunitis or 'Pigbel' was once common in the natives of Papua

New Guinea. This invariably followed feasting on pork and sweet potatoes (which contain protease inhibitors). The pathogenesis appears to be due to the production of high amounts of beta toxin by the *C. perfringens* in the presence of protein-rich pork and protease inhibitors. Normally the toxin would be expected to be destroyed by trypsin, but during the feasting with excessive protein and the protease inhibitor, the trypsin activity is insufficient and pathology occurs. In severely protein-malnourished children in the Developing World a similar condition exists.

CLOSTRIDIUM NOVYI

Cells of *C. novyi* are typically large Gram-positive rods ($5\text{--}8 \times 1 \mu\text{m}$) with oval central or subterminal spores. It is a rare member of faecal flora of human, but may be more common in other animals.

This species is closely related to type *C. botulinum* and phenotypically (biochemically) is indistinguishable – except that it does not produce the C1 botulinum neurotoxin. Instead it produces one of four toxins or 'soluble antigens' that define the types A–D. The most common type A strains produce an alpha-toxin that is encoded by a lysogenic bacteriophage similar to the toxin-encoding phages of *C. botulinum* types C and D. The three toxin types can be interconverted by curing of one bacteriophage and re-infecting with a different one (Eklund and Poysky, 1974; Eklund *et al.*, 1974).

Clostridium novyi strains are extremely strict anaerobes, increasing in strictness from A to D. They are therefore difficult to isolate except in laboratories using exacting anaerobiosis. However, types B, C and D are not usually associated with disease in human.

Clinical Features

Clostridium novyi type A strains are associated with wound and soft-tissue infections. Its former name *C. oedematiens* was descriptive of the oedematous lesions it produced. It was typically found in soiled wounds, classically war wounds, and sometimes in farm animals. In the past 50 years it has been extremely uncommon, rarely being encountered in anaerobic/gangrenous wounds. However, *C. novyi* infections have recently re-emerged from an unexpected source. In Scotland between April and August 2000, 60 injecting drug users (IDUs) presented with severe skin and muscle damage and 23 died of systemic shock and *C. novyi* type A was isolated from several cases. IDUs, especially those with no veins left in which to inject, have been injecting heroin directly into muscle or skin (muscle- or skin-popping). An epidemiological study which explored the outbreak revealed temporally related cases in England and the Republic of Ireland, and the source of the infection appeared to be a batch of purer than normal heroin contaminated with spores of *C. novyi* type A. The higher concentration of heroin necessitated more citric acid to be added to it to help it dissolve. This appears to have caused more tissue destruction than normal allowing a better environment for the germination of spores and growth of the clostridia. A series of papers have been published describing the outbreak in the same issue of the *Journal of Medical Microbiology* (Brazier *et al.*, 2002; Jones *et al.*, 2002; McGuigan *et al.*, 2002; McLauchlin *et al.*, 2002a,b). Other clostridia, including *C. botulinum* and *C. tetani*, have also been associated with injection of heroin (see pp. 562–563).

Clostridium novyi strains produce several toxins, but it is likely that the alpha-toxin is the key virulence determinant. It is one of a family of large clostridial cytotoxins (Von Eichel-Streiber *et al.*, 1996), with a mass of 250 kDa. *In vivo* it is lethal and causes oedema. *In vitro* it is a potent cytotoxin, acting on cells by modifying small GTP-binding proteins. It shares a great deal of sequence homology with toxins A and B of *C. difficile* and the lethal toxin from *C. sordellii*. However, unlike these toxins it uses UDP-*N*-acetylglucosamine as the source of the sugar moiety it transfers to the their protein substrates (Busch *et al.*, 2000).

Laboratory Diagnosis of *C. novyi* Infection, Patient Management and Prevention

Laboratory diagnosis is by observation of typical lipase- and lecithinase-positive colonies on egg-yolk-containing agar – due to the gamma and epsilon toxins, respectively. On horse blood agar, discrete colonies show a double zone of haemolysis – a narrow inner zone of complete haemolysis and an outer zone of partial haemolysis. Older, spreading colonies do not tend to show this effect. As mentioned earlier, *C. novyi* is one of the strictest anaerobes, and good anaerobic technique is an absolute necessity.

Patient management is similar to that for gas gangrene. Radical surgical intervention is always crucial, with appropriate antibiotic therapy. Prevention is through thorough cleansing of contaminated wounds. Vaccines have been developed for some *C. novyi* infections of animals (Willis and Smith, 1990).

NEUROTOXIC CLOSTRIDIA

Clostridium botulinum

Clostridium botulinum is not a single species in the accepted sense – it is more a collection of different phenotypes of anaerobic, Gram-positive, spore-forming bacteria only related to each other by the powerful neurotoxins with similar pharmacological actions which all produce. They are denoted as types A, B, C, D, E and F, with a type G that was renamed *C. argentinense*, and perhaps will be named *C. botulinum* type G again (Finegold, Song and Liu, 2002). Types F and G are rarely encountered, and for most practical purposes types A–E are the only types to be concerned about. The neurotoxins are not antigenically related in that antiserum to one type does not neutralise another type, but they do share some common active sites.

Type A and proteolytic type B strains are lipase positive and lecithinase negative, and closely resemble *C. sporogenes*, both biochemically and antigenically. Non-proteolytic B and E strains share antigens with *C. perfringens* and some other clostridia including *C. chauvoei*, *C. septicum* and *C. tertium*. Types C and D are similar to each other, and almost identical to *C. novyi*: they are lecithinase and lipase positive, and as mentioned above are interconvertible by infection with the appropriate toxin-encoding bacteriophage (Poxton, 1984; Poxton and Byrne, 1984; Hunter and Poxton, 2002). Carrying of genes encoding virulence factors by bacteriophages is not uncommon in bacterial pathogens (e.g. cholera toxin, the shiga toxin of enterohaemorrhagic *E. coli* and diphtheria toxin in *Corynebacterium diphtheriae* are examples and are discussed elsewhere in this book). However, the interconversion of these type III clostridia by curing and reinfection may be unique. Whether this happens in nature is not known.

Types of *C. botulinum* are widely distributed in nature – soils, lake sediments, vegetables, GI tract of mammals, birds and fish, but they are best known for their role in the uncommon, but extremely dangerous form of food poisoning/intoxication botulism. Botulinum toxins are also considered as prime candidates for use as biological weapons. Toxicoinfections with *C. botulinum* cause infant botulism and wound botulism in human and shaker–foal syndrome and equine grass sickness in horses.

The Action of Botulinum Toxins

The mechanism of action of all botulinum toxins is similar pharmacologically, despite them being antigenically different. Their prime action is to block neurotransmitter release at cholinergic nerve terminals. They are bipartite toxins with heavy (H) and light (L) chains. The H chain is the binding part, while the L is the active component and is a zinc-dependent endopeptidase, targeting SNARE proteins, which are involved in the exocytosis of neurotransmitters at

the synapse. Each different toxin acts by proteolysis of specific proteins forming synaptic vesicle docking and fusion complex: e.g. cleavage of synaptobrevin by B, D and F toxins, cleavage of SNAP-25 by C1 and syntaxin by A and E.

Toxins A, B and E are chromosomally encoded, while C1 and D are carried on temperate bacteriophages. This association between toxin-encoding bacteriophage and bacterium in *C. botulinum* types C and D, which permits interconversion as discussed earlier, is sometimes referred to as pseudolysogeny. It appears the association is very unstable and the phage is easily lost. From our recent experience it appears that sporulation results in phage loss. This means that isolation of pure toxin-producing cultures by conventional streak plating from a sporulating culture is difficult.

It may be that in nature there is a ‘parental’ non-toxin-producing bacterium which can be readily infected by a toxin-encoding bacteriophage that confers it with an advantage in its natural environment. However, until we understand the reasons why the toxins are required by these bacteria in their normal habitats we will not be able to understand the pressures selecting them.

Classical Food-Borne Botulism

Classical food-borne botulism results from ingestion of preformed toxin in food, and symptoms are flaccid paralysis. The disease is often fatal unless modern supportive intensive therapy is available. It is not restricted to human, but can be found in domestic animals (where it is known as forage poisoning). Botulinum toxin is the most powerful natural toxin, where less than 1 µg is the lethal dose for a human. Human disease is usually associated with types A, B and E, while the avian form is usually type C or D, the toxins of the latter types being poorly absorbed through the human gut mucosa. Forage poisoning in domestic animals is usually from A, B and sometimes C or D.

Food-borne botulism is generally not common, but in some parts of the world it is much more than others. Outbreaks are usually associated with home-canned or bottled vegetables or meat, with the very rare occasions where commercially canned food is implicated – usually due to a flaw in the can. In Northern and Northwestern Europe it is extremely uncommon with outbreaks occurring only once in a decade or so. In Southern and Eastern Europe it is more common: for example between 1965 and 1990 in Poitiers, France there were 108 cases investigated (Roblot *et al.* 1994). In North America cases occur with some regularity and a recent outbreak in Texas is a typical example (Kalluri *et al.*, 2003). This outbreak affected 15 people out of 38 attending a church supper. Patients presented over a 4-day period with cranial neuropathy and progressive peripheral muscle weakness. Botulinum toxin type A was detected in stool specimens from nine patients. The intoxication was shown to be associated with a chilli dish prepared from frozen chillis that had been stored inadequately eaten 4 days before the first patients presented. Of the 10 patients who received medical care, six had severe neurological impairment and required mechanical ventilation. There were no fatalities.

Toxicoinfectious Botulism

Toxicoinfectious botulism describes the condition where viable bacteria enter the body, either through a wound or into the gut, and if conditions are appropriate, they grow and produce toxin locally. This toxin is absorbed and may produce systemic effects similar to food-borne botulism. Wound botulism, an extremely rare condition, was associated with war wounds. However, similar to the *C. novyi* infections in IDUs, wound botulism has recently been seen to increase in this unexpected patient group.

Prior to 1999 no reports of wound botulism had been notified to the Communicable Diseases Surveillance Centre of the Public Health Laboratory Service of England and Wales (PHLS; now the Health Protection Agency; HPA). Then in 2000 six cases of wound botulism

were reported, followed by four in 2001 and 13 in 2002. All were from IDUs employing the practice of skin or muscle popping.

Infant botulism results in a spectrum of disease from 'floppy baby syndrome' to sudden infant death (cot death). Spores of *C. botulinum* get into the immature infant gut where they germinate and the vegetative cells multiply producing toxin which is absorbed through the gut wall. The symptoms are the result of systemic spread of the toxin to cholinergic nerve terminals. Infant botulism has been reported from many countries of the world; however it is extremely rare in many of them (Arnon, 1986). However, in some locations, where the custom is to supplement milk feeds with food in which botulinum spores may be present, it is more common. This is true in the southwest of the USA where honey has been fed to young babies.

Recently we have identified another form of toxicoinfectious botulism. This is equine dysautonomia or equine grass sickness. Here we hypothesise that toxin is produced by *C. botulinum* type C in the gut of the horse and the enteric neurones are destroyed – possibly by the combined action of BoNT/C (C1 neurotoxin), and C2 cytotoxin (Hunter, Miller and Poxton, 1999) causing the characteristic stasis of the GI tract. Dysautonomias with clinical signs and pathological findings similar to equine grass sickness have been recognised in rabbits and hares, and recently we have hypothesised that feline dysautonomia may have *C. botulinum* as the aetiological agent (Nunn *et al.*, 2004).

Laboratory Diagnosis, Patient Management and Prevention

Traditional laboratory diagnosis is by demonstration of specific toxin by toxin-neutralisation tests in mice. Samples can include faeces, food, vomit, gastric fluid, tissue, serum or an environmental sample. Very few laboratories are able, or have ethical permission, to perform this test. Detailed instructions for the test are in Poxton *et al.* (1996). Some recent developments for detection of the toxin include ELISA, which is of much lower sensitivity, and detection of the specific enzymatic activity of the specific toxin. This latter approach is still experimental, but may eventually prove extremely useful. Methods for detecting the organism range from selective culture (Dezfulian *et al.*, 1981) which only seems to work for types A, B and E, to detection of toxin genes by PCR (Lindstrom *et al.*, 2001). These methods only prove the presence of toxigenic bacteria and do not prove that toxin has been produced. If, based on clinical findings, there is suspicion that botulism is a possibility then detection of genes by PCR must be considered as confirmation, especially if the specimen was food. As previously noted several clostridia are phenotypically very similar to *C. botulinum* strains, and proof of identification can only be based on detection of biologically active toxin or the genes encoding it.

Generally, the types of botulism encountered reflect the predominant types of *C. botulinum* present in the local environment. Type E is often associated with marine environments.

Prevention is largely through adherence to good hygiene during food preparation and storage. A pentavalent toxoid vaccine is available from CDC for at-risk groups such as laboratory workers and the military. Its efficacy is however debated, although several botulinum toxoid vaccines of proven use are available for animals.

Treatment of food-borne botulism involves emergency medical intensive care support. The relatively slow incubation period for the disease (due to time taken for toxin to locate to nerve terminals), and the possibility of outbreaks from a common food source, means that antitoxins are often of potential use. Possibly exposed individuals may be offered antitoxin for prophylaxis. Once the toxin has bound, antitoxin is probably of little use for reversing the systems, but systemic antitoxins do prevent further binding of any remaining free toxin and may shorten the course of the disease. It is only for the most common types of botulism – that caused by A and B – that antitoxins are available, and most are of equine origin. However, infant botulism

is treated in the USA under the recommendations of the California Department of Health Services Infant Botulism Treatment and Prevention Program (IBTPP). Botulism Immune Globulin (BIG) – prepared from vaccinated individuals – was officially licensed by the US Food and Drug Administration on 23 October 2003 for the treatment of infant botulism types A and B under the proprietary name of BabyBIG™. Infant botulism is not usually fatal, but prompt treatment with BabyBIG™ may reduce the length of time for recovery and babies may not need mechanical ventilation. Full details for its use are given on the web site of the American Society of Health-System Pharmacists at: (<http://www.ashp.org/news/ShowArticle.cfm?id=3637>).

CLOSTRIDIUM TETANI

Clostridium tetani has several characteristics in common with *C. botulinum*, but with none of the heterogeneity of the latter species. It is a strictly anaerobic, rod-shaped bacterium (0.5–1×2–5µm), growing singly or in pairs at temperatures between 14 and 43 °C. Cells can sometimes be long and filamentous, and become Gram-negative after about 24h of incubation. Most strains are motile – by means of peritrichous flagella – and spores typically are round and terminal and their diameter can be up to twice that of the vegetative cell giving sporulating cells a 'drumstick' appearance. *Clostridium tetani* grows well on blood agar, and colonies show a fine branching appearance, which after 48–72h of incubation can extend over the whole surface of the plate, reminiscent of shigellae, and may not be apparent when given a cursory examination.

Clostridium tetani is not routinely typed, but there are recognised differences in flagellar types. It produces two toxins, the tetanus neurotoxin (TeNT, tetanospasmin) and the haemolysin tetanolysin.

Tetanus and its Pathogenesis

Classical tetanus results from *C. tetani* spores entering a wound in which the redox potential is low enough for their germination and subsequent growth – typically in a deep puncture wound contaminated with soil or animal faeces. The organism is found in the GI tracts of various animals and is ubiquitous in soils throughout the world where it may have a role as a saprophyte. The TeNT is produced within the wound and from there it enters the systemic circulation and travels to the synapses causing spastic paralysis of the voluntary muscles (see last paragraph of this section). The lethal dose for human is approximately 1 ng/kg, making it second only to botulinum toxin as the most powerful toxin known. Unless treated by modern intensive care it is invariably fatal.

Clinical symptoms usually appear 7 and 10 days after the wound is infected, but can be as short as 3 days and as long as 30 days (Collee, Brown and Poxton, 1996). The first symptoms are often trismus – where the muscles of the jaw are affected – giving rise to its common name 'Lockjaw'. Other early symptoms include pain and stiffness, which develops into muscle rigidity and later becomes generalised. External stimuli such as a sudden noise can trigger spasms. Spasms of the larynx may occur and be life threatening. Autonomic problems occur in more severe cases, and these begin a day or two after the muscle spasms. Clinical signs include pyrexia, sweating, hypertension and cyanosis of the digits. Tetanus might be mistaken for strychnine poisoning, convulsions, brain infections or haemorrhage, psychiatric disorders and even local oral disease. However, clinical diagnosis is relatively straightforward, but there are very few clinicians with experience of tetanus. This is because it is extremely uncommon to encounter this disease in the Developed World as it is so well controlled by active vaccination programmes (see Laboratory Diagnosis, Patient Management and Prevention of Tetanus). However, there are an estimated 400 000 cases throughout the world each year, mainly in neonates – following infection of the umbilicus.

As has already been described for *C. novyi* and *C. botulinum*, *C. tetani* is also causing recent problems in IDUs. Between July and November 2003, seven clinically diagnosed cases of tetanus were

reported in IDUs in England and Wales (CDR, 2003). Sources of *C. tetani* could be contamination of the drugs themselves, or the equipment used, or conceivably the skin.

Despite the symptoms being very different, the pathogenesis of tetanus is very similar to that of botulism and TeNT is very similar to the BoNTs (see p. 561). Both are zinc-dependent endopeptidases that target synaptic members of the SNARE proteins, which are involved in the exocytosis of neurotransmitters at the synapse. Although they have identical intracellular mechanism of action, TeNT is transported retrogradely through motor neurons and inhibits exocytosis in inhibitory interneurons, compared to the BoNTs which block neurotransmitter release at the neuromuscular junction. The resultant primary symptom of tetanus is the characteristic spastic paralysis of the voluntary muscles, compared to the flaccid paralysis of botulism (Verastegui *et al.*, 2002).

Laboratory Diagnosis, Patient Management and Prevention of Tetanus

Laboratory diagnosis is similar to that for other clostridial infections. In addition a Gram-stained smear of wound exudates may show the presence of the typical rods with bulging spores; however, this is not diagnostic. Wound samples are cultured anaerobically on blood agar and in cooked-meat broth. The wound culture usually produces a mixture of anaerobes, but the *C. tetani* can be picked pure by examining the plate through a hand lens and sampling from the spreading edge of growth – utilising the growth characteristics described earlier. Heat selection of spores should be attempted, but it should be noted that some strains produce heat-sensitive spores. Full details of laboratory isolation and identification are given in Collee, Brown and Poxton (1996).

Tetanus is preventable with toxoid vaccine. It is one of the safest and most effective vaccines currently in use. It is usually administered along with diphtheria, with or without pertussis, in babies. Later in life it is usually boosted jointly with diphtheria toxoid, although it can be administered alone. Boosters are recommended every 10 years. If an individual is thought to be at risk of developing tetanus following a soiled wound and because they have not having been previously vaccinated, or have not completed the three-dose primary course, or they are of unknown vaccine status, then postexposure treatment can be given in the form of an immune globulin preparation. These days this is usually of human origin (prepared from vaccinees), but in the past it was from hyperimmunised horses. In a manner similar to botulism, the rationale for passive therapy after symptoms begin is to prevent further binding of toxin. However, in the case of tetanus, antibiotic therapy is also recommended if there is still evidence of an infected wound (metronidazole or benzyl penicillin), along with thorough wound cleansing.

OTHER CLOSTRIDIA

The following clostridia are uncommon causes of disease in human and are only covered briefly.

Clostridium septicum and *C. chauvoei*

These are two closely related species, both of which cause disease in farm animal. It is only *C. septicum* that is considered a pathogen of humans. It is found in polymicrobial infections in gangrene and in systemic infections associated with malignancies or immunosuppression where it has a variable clinical presentation and is associated with a high mortality. Patients with colorectal cancer had septicaemia and ‘vague abdominal symptoms’ (Chew and Lubowski, 2001). There have also been reports of secondary *C. septicum* infections following *Escherichia coli* O157 haemolytic uraemic syndrome – perhaps as a zoonosis (Barnham and Weightman, 1998).

Clostridium sordellii

This is another clostridial species infrequently associated with wound infections and gangrene. *Clostridium sordellii* can also be responsible for a rare and rapidly fatal postpartum endometritis in previously healthy young women (Rorbye, Petersen and Nilas, 2000). Recently there have been reports of *C. sordellii* infection associated with allograft musculoskeletal tissue transplantation using tissues removed from cadavers (Malinin *et al.*, 2003).

GENOMICS OF CLOSTRIDIA

The genomes of several species of *Clostridium* are being, or have been sequenced, some because they are important pathogens and others because they may have important uses in biotechnology. *Clostridium tetani* is an example of the former. The tetanus toxin and a collagenase have been shown to be encoded on a 74 kbp plasmid, while other virulence factors such as surface-layer adhesion proteins have been identified, some of which are unique to *C. tetani* (Bruggemann *et al.*, 2003). The genome of *C. perfringens* (Shimizu *et al.*, 2002) has allowed identification of enzymes for anaerobic fermentation leading to gas production, but none for the tricarboxylic acid cycle or respiratory chain. More than 20 newly identified genes have been proposed as coding for virulence factors as well as providing a method for detecting the two-component VirR/VirS regulon that co-ordinately regulates the pathogenicity of *C. perfringens* (Banu *et al.*, 2000). Genomics is perhaps most useful when the pathogenesis of an organism still has many unknowns. Certainly our understanding of *C. perfringens* has been advanced. However, it is probably the recently sequenced genome of *C. difficile* that will further our knowledge of a *Clostridium* most – but that is covered in its own chapter.

SUMMARY

Clostridia are typically thought of as dangerous, exotoxin-producing pathogens which are rarely encountered in modern medicine. Formerly they were found in dirty war and postoperative wounds in the preantibiotic era where they caused gangrene and tetanus. These conditions have largely disappeared from the Developed World. However, some species such as *C. perfringens* continue to cause food poisoning, while others, despite being rare, do cause life-threatening infections. Since the 1970s there has been increasing awareness of *C. difficile* and its real increasing incidence (covered in Chapter 46). It is probably true to say that *C. difficile* is the only species of *Clostridium* (or even anaerobe) that is a real concern to Public Health in the Developed World. However, over the past decade several clostridial infections have appeared when not expected: the occurrence of botulism, tetanus and *C. novyi* infections was unexpected in IDUs. These together with the possible association of *C. septicum* with malignancies and the potential for botulinum toxins as biological warfare agents indicates that we must keep closely aware of these important pathogens.

Anaerobic Actinomycetes and Related Organisms

Val Hall

Anaerobe Reference Laboratory, National Public Health Service for Wales, Microbiology Cardiff, University Hospital of Wales, Heath Park, Cardiff, UK

INTRODUCTION

Actinomyces species are facultatively anaerobic Gram-positive bacilli, endogenous to mucous membranes of humans and animals. Some members of the genus cause actinomycosis, a chronic, subacute suppurating granulomatous infection. This disease occurs most commonly in the cervicofacial area but may affect organs of the thorax, abdomen or pelvis and, rarely, the central nervous system or limbs. Advanced cases of actinomycosis are uncommon in the developed world but may be severely debilitating, disfiguring and potentially fatal. Aggressive therapy is required. The clinical diagnosis of actinomycosis and laboratory isolation and identification of the causative agents are notoriously problematic.

Actinomyces species also occur in polymicrobial superficial soft-tissue abscesses and may play an important role in the development of dental plaque, periodontal diseases and caries. The clinical significance of their association with intrauterine contraceptive devices has been much debated. Recently, a plethora of novel *Actinomyces* species has been isolated from clinical and veterinary sources. The natural habitats and pathogenic potential of these species have yet to be established.

DESCRIPTION OF THE ORGANISMS

General Description

Actinomyces are facultatively anaerobic, Gram-positive, irregularly staining bacilli that are non-acid-fast, non-sporing and non-motile. Growth is enhanced by the presence of blood or serum and CO₂. Anaerobic conditions are favoured but some species can be cultured aerobically or in air plus 5% CO₂. Members of the genus are fermentative and produce acetic, formic, lactic and succinic acids but not propionic acid as endproducts of glucose metabolism. They are indole negative, catalase negative or positive and rarely (weakly) proteolytic. Cell-wall peptidoglycan contains alanine, glutamic acid and lysine with either aspartic acid or ornithine. Diaminopimelic acid and mycolic acids are absent. Cell-wall carbohydrates include glucose, galactose and rhamnose, but not arabinose. Major cellular fatty acids are myristic (tetradecanoic, 14:0), palmitic (hexadecanoic, 16:0), stearic (octadecanoic, 18:0) and oleic acids (octadecenoic, 18:1*cis*-9). The G + C ratio of DNA is 55–71 mol%. Optimal growth temperature is 35–37°C.

Classification

Current taxonomy is based upon phylogenetic trees constructed from 16S rRNA sequence comparisons and supported by data derived from

biochemical characteristics, whole-cell protein profiles and other diverse methods. The genus *Actinomyces* has been shown to comprise at least three subgroups that may represent separate genera (Schaal *et al.*, 1999). Closely related genera are *Arcanobacterium*, *Actinobaculum*, *Mobiluncus* and the recently described *Varibaculum*. Genetic, serological and phenotypic diversity has been demonstrated within some species. These characteristics are particularly variable within the *Actinomyces naeslundii/A. viscosus* complex, wherein clear species distinctions are difficult to define. Johnson *et al.* (1990) restricted *A. viscosus* to strains of animal origin, formerly designated *A. viscosus* serotype I, and designated two 'Genospecies' of *A. naeslundii*. Genospecies 1 comprises strains of *A. naeslundii* serotype I, while *A. naeslundii* Genospecies 2 includes *A. naeslundii* serotypes II and III plus *A. viscosus* serotype II (human strains). Other strains, closely related to these may form additional Genospecies. The term Genospecies was used because, whilst isolates formed genetically distinct taxa, they could not be reliably differentiated in phenotypic tests.

As of early 2004, the genus *Actinomyces* comprises 31 species, 13 of which have been reported only from animal sources (Tables 48.1 and 48.2). Advances in isolation techniques and molecular detection methods are likely to lead to the valid publication of additional species. The 'classically described' species, associated with actinomycosis, and their principal host-species are listed in Table 48.1. *Propionibacterium propionicum* is included in this table and throughout the chapter as this species also causes actinomycosis and resembles *Actinomyces israelii* both morphologically and phenotypically. Table 48.2 lists species described more

Table 48.1 The 'classically described' *Actinomyces* species and *P. propionicum*

Species	Former name(s)	Principal host species
<i>A. bovis</i>		Cattle
<i>A. israelii</i>	<i>A. israelii</i> serotype I	Humans and animals
<i>A. gerencseriae</i>	<i>A. israelii</i> serotype II	Humans and animals

<i>A. vaccimaxillae</i>	Cattle	Hall <i>et al.</i> (2003a)
<i>A. oricola</i>	Humans	Hall <i>et al.</i> (2003b)
<i>A. nasicola</i>	Humans	Hall <i>et al.</i> (2003c)

recently and of less certain pathogenicity. Early reports of *Actinomyces bovis* from human infections are unverified and probably represent misidentifications. The organisms now classified as *A. viscosus* (formerly *A. viscosus* serotype I) appear to be specific to animals; reports of *A. viscosus* from humans probably represent *A. naeslundii* Genospecies 2. A recent study wherein *Actinomyces* species were identified by a genotypic method (ARDRA) detected five strains that resembled *A. denticolens* in 475 strains isolated from human clinical sources, but failed to detect any of the other animal-associated species (Hall *et al.*, 2001b). This suggests that these species occur rarely or not at all in clinical material and, consequently, they will not be considered further in this chapter. They are *A. howellii*, *A. hordeovulneris*, *A. slackii*, *A. hyovaginalis*, *A. bowdenii*, *A. canis*, *A. marimammalium*, *A. catuli*, *A. suimastitidis*, *A. coleocanis*, *A. vaccimaxillae* and the aforementioned *A. bovis* and *A. viscosus*.

Morphology

Members of the genus demonstrate considerable variation in both cell and colony morphologies. This may lead to difficulties in recognition of putative *Actinomyces* on primary isolation media. However, to the experienced eye, cell and colony appearance can be a useful aid to species-level identifications, increasing confidence in results obtained by biochemical or genotypic tests. Morphologies of *Actinomyces* spp. that occur in human clinical specimens and *P. propionicum* are listed in Table 48.3.

In clinical material, the fine, filamentous, beaded cells of *A. israelii*, *A. gerencseriae*, *A. oricola* and *P. propionicum* may be mistaken for chains of streptococci. On primary isolation, colonies of these species

Table 48.3 Cell and colony morphology of *Actinomyces* spp. from human sources and *P. propionicum*

Species	Cells ^a	Colonies ^b	Comments
<i>A. israelii</i>	Fine, filamentous, beaded, branching	White-to-cream, breadcrumb or molar tooth, gritty, pitting	Slow growing Old colonies may become pink
<i>A. gerencseriae</i>	Fine, filamentous, beaded, branching	Bright white, breadcrumb or molar tooth, pitting and softer than <i>A. israelii</i>	Slow growing
<i>A. naeslundii</i>	Medium rods, may have clubbed ends, some branching	White, cream or pinkish, smooth, convex, entire edged	Occasional rough forms occur
<i>A. odontolyticus</i>	Diphtheroid like, some clubbed ends	Cream-to-red, smooth, convex, entire edged	Old colonies may be dark brown
<i>A. meyeri</i>	Short, fine rods	Small, white, smooth, convex, entire edged	Slow growing
<i>A. denticolens</i> like	Diphtheroid like	White-to-pink, heaped or molar tooth, pitting	
<i>A. georgiae</i>	Diphtheroid like	White or cream, smooth, convex, entire edged	
<i>A. neuii</i> subsp. <i>neuii</i> and <i>anitratus</i>	Diphtheroid like	White or cream, smooth, convex, entire edged	
<i>A. radingae</i>	Cocco-bacilli	Grey-to-white, semitranslucent, smooth, low convex, entire edged	
<i>A. turicensis</i>	Cocco-bacilli	Grey, semitranslucent, smooth, low convex, entire edged	
<i>A. europaeus</i>	Cocco-bacilli	Whitish, semitranslucent, smooth, low convex, entire edged	
<i>A. graevenitzii</i>	Medium length, thick, granular, branched	White, pronounced molar tooth or smooth, convex	Red fluorescence. Rough and smooth forms occur together Old colonies may be dark brown
<i>A. radidentis</i>	Coccoid	Cream-to-pink, smooth, convex, entire edged	Old colonies may become red
<i>A. urogenitalis</i>	Cocco-bacilli	Cream-to-pink, with darker rings, smooth, convex, entire edged	Old colonies may become red
<i>A. funkei</i>	Fine, filamentous, beaded, branching	Grey, semitranslucent, opaque centre (fried-egg), low convex, entire edged	
<i>A. cardiffensis</i>	Fine, filamentous, beaded, branching, ends may be clubbed	Cream-to-pink, smooth, convex, entire edged	
<i>A. nasicola</i>	Diphtheroid like orocco-bacilli may be branched	White or grey, smooth, convex, entire edged	
<i>A. oricola</i>	Diphtheroid to filamentous, some branching	White, breadcrumb, pitting	
<i>P. propionicum</i>	Fine, filamentous, beaded, branching or coccoid	Off-white to buff, breadcrumb, gritty, pitting, or smooth, convex, entire edged	Red fluorescence. Rough and smooth forms occur together

^a Cells of all species are Gram positive or Gram variable.

^b All colonies ≤ 1 mm diameter.

develop very slowly and are obligately anaerobic but, on subculture, organisms usually grow more rapidly and become more aerotolerant. Colonies, particularly those of *A. israelii*, may be very hard and grit like, and it may be necessary to crush them between two microscope slides in order to prepare a film suitable for Gram's staining. This characteristic may cause difficulties in obtaining smooth suspensions for susceptibility testing and for inoculation of identification test substrates. Other organisms that sometimes produce breadcrumb-like colonies and, therefore, may be mistaken for *Actinomyces* spp. include *Bifidobacterium* spp., *Streptococcus mutans* and microaerophilic streptococci.

The red pigmentation of mature *Actinomyces odontolyticus* colonies is a well-known distinguishing characteristic but it must be noted that the recently described species *A. radidentis*, *A. urogenitalis* and *A. graevenitzii* may also produce pink-to-red colonies, particularly in old cultures. Young cultures of the above-named species, and *A. naeslundii*, *A. georgiae*, *A. neuui*, *A. cardiffensis* and *A. nasicola* form smooth, white or cream colonies, may grow more rapidly than *A. israelii* and may grow well in air or in air plus CO₂. Consequently, it is important to differentiate them from *Corynebacterium* spp. The failure of most *Actinomyces* spp. to produce catalase aids identification but *A. neuui*, *A. radidentis* and some strains of *A. naeslundii* are catalase positive. *Actinomyces radidentis* is similar to staphylococci in its cell and colony morphology and catalase production, but can be differentiated in biochemical tests and by endproducts of glucose metabolism.

The grey, semitranslucent colony morphology, growth within 5 days and relative aerotolerance of *A. turicensis* are useful aids to distinguish this species from the phenotypically similar *A. meyeri*, which grows slowly and only anaerobically, producing tiny, opaque, white colonies. *Actinomyces turicensis* and other rapidly growing, aerotolerant species with similar morphology (*A. radingae*, *A. europaeus* and *A. funkei*) may be mistaken for non-haemolytic streptococci, lactobacilli or other commensal organisms.

PATHOGENESIS

Actinomyces spp. appear to be unable to invade intact mucous membranes. Trauma such as dental diseases, infection with other organisms, surgery or penetration of mucosa by a foreign body commonly precede infection, but in some cases the portal of entry is not apparent.

The species that cause actinomycosis characteristically form *in vivo* dense microcolonies of cells with protruding clubbed ends comprising both bacterial and host material and surrounded by neutrophils and foamy macrophages. Clearly, the organisms within these clusters are protected from both host defences and antimicrobial agents. As the organisms slowly multiply, the host mounts a 'foreign-body' response and the characteristic chronic abscesses and sinus tracts of advanced disease develop. Doubtless, the other bacterial species invariably present in such lesions influence pathogenicity and may produce specific toxins or agents active against host cells or against antibiotics. *Actinomyces* spp. are not known to produce specific toxins. Humoral antibody responses to infection are not reliably produced; therefore serological tests for actinomycosis have not been developed.

In the development of dental plaque and intraoral diseases, the abilities of *Actinomyces* spp. to co-aggregate with other bacteria and to adhere to mammalian cells are important factors. Their fermentative properties may also provide essential nutrients for other pathogenic species, e.g. succinate for *Porphyromonas* spp., and may regulate pH.

Epidemiology

The 'classically-described' *Actinomyces* spp. and *P. propionicum* are known to be early colonisers of the mucous membranes, especially specific niches within the oral cavity. They may occur also in the gastrointestinal and genitourinary tracts in smaller numbers.

Little is known of the natural habitats of many recently described species. However, *A. graevenitzii* has been found to be an early coloniser of the mouth and *A. urogenitalis* appears to be aptly named (Sarkonen *et al.*, 2000; Hall *et al.*, 2001b). The many reported isolates of *A. turicensis* associate this species with the genitourinary and gastrointestinal tracts and lipid-rich areas of the skin (Sabbe *et al.*, 1999; Hall *et al.*, 2001b). *Actinomyces radingae*, *A. funkei* and *A. europaeus* appear to occupy similar habitats, and *A. neuui* is probably a commensal of the skin. *Actinomyces cardiffensis* has been isolated from sites similar to those of *A. israelii* but has not been proven to cause actinomycosis (Hall *et al.*, 2002).

Association with Intrauterine Contraceptive Devices (IUCDs)

In 1976, *Actinomyces*-like organisms (ALO) were first reported in Papanicolaou-stained cervical smears of IUCD users and were confirmed as *A. israelii* by direct immunofluorescence (Gupta, Hollander and Frost, 1976). Numerous subsequent studies employing combinations of cytological examination, cultivation and immunofluorescence, have endeavoured to elucidate the prevalence and clinical significance of ALO. All studies confirmed a strong association of ALO with IUCD usage. However, other findings have been highly variable, due in part to differing methodologies, variations in study populations and criteria, types of IUCD and other confounding factors. Accuracy of detection by Papanicolaou smears has been questioned. Confirmation by immunofluorescence has been recommended but specific antisera are not commercially available. Cultivation from urogenital sites has a poor record of recovery, largely due to the heavy concomitant flora.

Reported detection rates for ALO or confirmed *Actinomyces* spp. in IUCD users are 1.6–50%, averaging approximately 20%. Several authors reported increasing prevalence with duration of IUCD use, becoming significant after 2–8 years in different studies. Some noted significantly higher incidence in users of plastic devices over those with copper-containing IUCDs, possibly due to the known bactericidal effect of copper. However, both findings have been disputed and may be biased by the recommendation that copper IUCDs are replaced every 2 years, whilst plastic IUCDs have a longer life span. A study of the new generation of hormone-releasing IUCDs found ALO in 2.9% of users of a levonorgestrel-releasing IUCD and in 20% of users of a copper-containing IUCD (Merki-Feld *et al.*, 2000).

Clinical significance of ALO or confirmed *Actinomyces* spp. in the genital tract, IUCD or endometrium has proved difficult to assess. Indisputably, worldwide, overt pelvic actinomycosis remains extremely rare, whilst vast numbers of IUCDs are in use and perhaps 20% are colonised by ALO. Hence, actinomyces appear to occur as commensals and rare opportunist pathogens. However, IUCD usage is associated with increased incidence of pelvic inflammatory disease and other less severe pelvic symptoms, and the role played by actinomyces in these entities has not been established.

The potential, though remote, risk of serious infection (and perhaps, fears of litigation) led many authors to recommend removal of any ALO-associated IUCD, with or without antimicrobial cover, and replacement of the device after 1–2 months, when follow-up smears demonstrated absence of ALO. Other authors recommended removal only in symptomatic patients. The Clinical and Scientific Committee of the British Faculty of Family Planning and Reproductive Healthcare has produced concise recommendations (Cayley *et al.*, 1998). In summary these are: in symptomatic patients with ALO, remove the IUCD, offer antimicrobial therapy and review symptoms; in asymptomatic women with ALO, counsel regarding risks and symptoms, advise consultation if symptoms occur, arrange 6-monthly follow-up, and either leave the device in place or remove or replace it.

ALO have been associated with other foreign bodies of the genital tract or uterus, including vaginal pessaries and forgotten tampons (Bhagavan and Gupta, 1978). Species isolated from IUCDs are *A. israelii*, *A. gerencseriae*, *A. naeslundii*, *A. odontolyticus*, *A. meyeri*,

A. cardiffensis, *A. europaeus*, *A. funkei*, *A. neuui*, *A. radingae*, *A. turicensis*, *A. urogenitalis*, *P. propionicum* and *A. denticolens*-like strains (various studies and PHLS Anaerobe Reference Unit records).

CLINICAL FEATURES

Actinomycosis

Actinomycosis is a subacute to chronic disease, characterised by abscesses with hard fibrous walls enclosing collections of white or yellow pus that may contain 'sulphur granules' or 'drusen' (microcolonies of the *Actinomyces* spp.). In advanced cases, sinuses develop and discharge at the skin surface or to internal sites. Central suppurative foci regress and cicatrise, producing very disfiguring lesions. Infection is usually endogenous, and concomitant bacteria, frequently other members of the oral microflora, are almost invariably isolated. Acute lesions are usually painful but chronic forms are often painless. The disease progresses over months or years, invading surrounding tissues, regardless of fascia and organ boundaries, and forming multiple indurated abscesses, cavities and fistulae. Osteitis and osteomyelitis occur rarely in human infections, though bone involvement is common in bovine cases. Spontaneous remissions and relapses are characteristic, and the disease may become recalcitrant or eventually fatal if ineffectively treated. Indeed, in the pre-antibiotic era, mortality was high, and 902 deaths were documented in UK for the period 1916–1935 (Cope, 1938). An average of 25 deaths per annum were reported in the USA for the years 1949–1969 (Slack and Gerencser, 1975).

Actinomycosis can affect any part of the body but occurs most often in the cervicofacial region (60% cases). Thoracic and abdominal/pelvic infections account for approximately 15 and 20% of cases, respectively. Rare, exogenous sources of infection are fistfight injuries to the hand (punch actinomycosis), human bites and, possibly, animal bites. Predisposing factors include diabetes, dental diseases and chronic lung diseases. Persons of any age may be affected, and various studies have reported a male to female preponderance of between 2:1 and 4:1. Slack and Gerencser (1975) reviewed the incidence of infection and concluded that 'Actinomycosis occurs throughout the world and that it is neither a rare nor a common disease'. The principal agents of human actinomycosis are *A. israelii* and *A. gerencseriae*. Less frequently, *A. naeslundii*, *A. odontolyticus*, *A. meyeri* or *P. propionicum* are isolated.

Cervicofacial Actinomycosis

Given the oral habitat of the causative organisms, it is not surprising that the majority of actinomycotic lesions occur in the face and neck regions. Infection may be preceded by poor oral hygiene, dental and periodontal diseases, tooth extraction and other dental procedures, jaw fracture, tonsillitis or damage to mucosa by foreign bodies such as fish bones. However, predisposing or causative factors are not always determinable. The principal site of infection is tissue adjacent to the mandible. Other sites include the cheek, chin, maxillary area, neck, mastoid, sinuses, parotid and thyroid glands, tongue, lips, ears and nasal septum. Lesions near the mandibular joint may result in trismus. The primary lesion is often a hard, red and painful 'boil-like' swelling. Untreated, the disease progresses slowly as described above, resulting in characteristic multiple indurated abscesses at various stages of development, discharging sinuses and scarring. Secondary spread to the brain, thorax, other organs or bloodstream may be life threatening.

Thoracic, Abdominal and Pelvic Actinomycosis

The usual source of thoracic actinomycosis is aspirated oral microflora. Consequently, alcoholics are at increased risk of disease. Other predisposing conditions include dentogingival disease, emphysema

and bronchiectasis. Less commonly, the disease may extend directly from cervicofacial or abdominal lesions. Abdominal and some pelvic infections arise from damage to the gastrointestinal mucosa, such as may result from surgery, ruptured appendix or diverticula, neoplasia, ulcerative diseases or accidental trauma. Primary hepatic abscesses may be seeded with gastrointestinal flora via the portal vein. As discussed above, colonisation of IUCDs and other foreign bodies in the uterus and cervix is another source of pelvic infection. Causative organisms are as listed for cervicofacial actinomycosis. However, *A. meyeri* is particularly associated with thoracic infections and has a tendency to disseminate to cerebral, muscular and cutaneous sites.

Thoracic infection commonly develops within the lungs but may spread to the pleura, ribs, intercostal tissue and chest wall. Involvement of the latter results in chronic draining sinuses and stigmata characteristic of actinomycosis. Other thoracic presentations include pericarditis, tracheal, paravertebral and psoas abscesses.

Abdominal/pelvic infection may involve the gut wall, bladder, kidney, liver, spleen, fallopian tubes, ovaries, uterus and anorectal abscesses. In chronic disease, fistulous abdominal wall abscesses may develop. In all the abovementioned sites, early symptoms are frequently vague and non-specific. Differential diagnosis commonly includes carcinoma and tuberculosis, and less commonly, Crohn's disease or other ulcerative conditions of the gastrointestinal tract. Correct diagnosis is often made only at a late stage when sinuses are apparent, obstruction of major organs occurs or surgery for suspected neoplasm is performed. By this stage, there may be extensive tissue damage, the disease is difficult to treat, and may become life threatening.

The published literature abounds with cases of thoracic, abdominal and pelvic actinomycosis that mimicked neoplasia, correct diagnosis being made only peri- or postoperatively, or at postmortem examination. Weese and Smith (1975) reported on 57 cases of which only four were diagnosed as actinomycosis upon admission. Misdiagnoses included carcinoma and tuberculosis. In 181 cases of actinomycosis in military personnel studied by Brown (1973), only nineteen were diagnosed correctly by the attending physician, and five of eight cases with pulmonary involvement were thought to have tuberculosis. Other diagnoses included histoplasmosis, nocardiosis, maduramycosis, sporotrichosis and carcinoma. Shannon, Wightman and Carey (1995) described pulmonary actinomycosis as 'a master of disguise' and reported three cases with initial diagnoses of malignant neoplasia. In each case correct diagnoses were made histologically, subsequent to lobectomy or pneumonectomy. Similarly, Williams, Lamb and Lewis-Jones (1990) described actinomycosis of the abdomen and pelvis as 'the great imitator' and warned 'beware the IUCD'. They reported two cases of pelvic actinomycosis, in patients with IUCDs. Both had experienced low-grade symptoms followed by acute exacerbations. One was diagnosed as pelvic malignancy, the other as spastic colon. Both required colostomies, and one suffered relapse after several months. In this patient, actinomycosis was diagnosed only when *A. israelii* was isolated from a metastatic groin abscess. The authors stressed the need to consider actinomycosis when pelvic neoplasia or inflammatory disease is suspected in patients with IUCDs. They concluded that radiology, particularly computed tomography (CT), may be important both in diagnosis and monitoring of treatment efficacy (Williams, Lamb and Lewis-Jones, 1990). CT-guided core needle biopsy may be a valuable aid to diagnosis and may obviate surgical intervention in some cases (Lee *et al.*, 2000). Fine-needle aspiration cytology has been used to confirm diagnosis early in cervicofacial disease, and to collect material for microbiological examination (Nespolon and Moore, 1994).

Infections of the CNS, Bones and Soft tissues

Actinomycotic infections of the central nervous system (CNS), bones and skin are rare. CNS infections arise from direct extension of infection of the head, neck, thorax or abdomen, or by haematogenous spread.

The most common form of CNS involvement is cerebral abscess (75%), predominantly in the temporal or frontal lobes. Infections may be polymicrobial, commonly involving members of the oral microflora. Chronic low-grade meningitis is another presentation and may be misdiagnosed as tuberculous meningitis. Abscesses of the spinal cord, vertebrae or paravertebral regions may follow surgery. *Actinomyces meyeri* appears to be associated most often with such cases.

Osseous involvement results in periostitis, osteomyelitis and bone destruction. Infection usually arises by direct extension from soft tissues; hence the mandible, ribs and spine are the most frequent sites involved. However, infection of the long bones occurs occasionally. Two case reports indicate the potential severity of this manifestation and difficulties in treatment (Macfarlane, Tucker and Kemp, 1993; Vandeveld, Jenkins and Hardy, 1995). In both patients (female, 19 and male, 22 years), infection originated from penetrating injuries to the foot, sustained on farms. Chronic infection of bone, joint and soft tissues occurred over 41 and 11 years, respectively, and after numerous courses of prolonged therapy and minor surgical interventions, both underwent below-knee amputations. In the latter case, where the causative organism was *A. naeslundii*, this apparently resulted in a cure. However, in the former case, disease progressed to eventually involve the femur, hip joint, spine, psoas muscle, perirenal space, pelvis and abdominal wall. At the time of reporting, significant improvement in symptoms had been achieved by prolonged ciprofloxacin therapy (Macfarlane, Tucker and Kemp, 1993). In this patient, the causative organism was not identified to species level. Notably, in both these severe cases, the source of the infecting organisms may have been exogenous, and from a farm environment. Wust *et al.* (2000) reported infection of a hip prosthesis with *A. naeslundii*. This patient responded well to appropriate antimicrobial therapy.

Cutaneous actinomycosis presents as subcutaneous or muscular abscesses and usually occurs by dissemination from 'classic' sites of infection such as the lung. However, cases with no apparent primary focus have been recorded. Cultures are often unsuccessful, but *A. meyeri* has a strong association with disseminated disease.

Lacrimal Canaliculitis

In lacrimal canaliculitis, the tear duct becomes obstructed by concretions of *Actinomyces* spp. or *P. propionicum* and concomitant oral or nasal microflora. Purulent exudate from the puncta and chronic conjunctivitis may occur. Infection may be undiagnosed for months or years and may respond poorly to topical antimicrobial therapy alone. Surgical evacuation of concretions, or manipulation of these through the puncta is usually necessary and these are valuable specimens for laboratory confirmation of causative organisms. The disease occurs mainly in females over 40 years of age, and *P. propionicum* is strongly associated (Brazier and Hall, 1993).

Bacteraemia

Bacteraemia and subacute endocarditis are rarely caused by actinomycetes. Cases due to *A. naeslundii*, *A. viscosus* (presumably *A. naeslundii* Genospecies 2), *A. meyeri*, *A. odontolyticus*, *A. israelii*, *A. turicensis* and *A. funkei* have been reported. Some of these have occurred in injecting drug users and possible sources of infection include skin or oral flora. Transient *Actinomyces* bacteraemia following tooth-brushing and endodontic therapy has been demonstrated (Silver, Martin and McBride, 1979; Debelian, Olsen and Tronstad, 1995).

Superficial Soft-Tissue Infections

Actinomyces spp. have been isolated from a variety of superficial soft-tissue infections, usually in conjunction with other bacteria. Their clinical significance in these polymicrobial infections is often

difficult to establish. Several of the recently described *Actinomyces* spp. have been isolated from such sources, but have not been implicated in 'classic' actinomycosis. Some species appear to be associated with specific sites or disease entities. Notably, *A. turicensis* has been isolated frequently from pilonidal sinuses, perianal and decubital abscesses, balanitis, omphalitis and ear, nose and throat infections (Wust *et al.*, 1995; Vandamme *et al.*, 1998; Sabbe *et al.*, 1999; Hall *et al.*, 2001b). *Actinomyces radingae* and *A. europaeus* have been isolated from various soft-tissue infections, though numbers of isolates studied are small. Likewise, *A. neuui* is frequently isolated from abscesses, including breast abscesses, in association with mixed anaerobic flora. A catalase-negative isolate of *A. neuui* subsp. *neuui* has been reported in an infected mammary prosthesis (Brunner *et al.*, 2000).

Dental Caries and Periodontal Diseases

As the development and progression of dental caries and periodontal diseases involves complex interactions of numerous member species of the oral microflora, the precise roles played by individual species are difficult to ascertain. *Actinomyces* spp. are numerically significant components of plaque and were formerly thought to be associated with dental caries, but later research indicated that mutans streptococci and lactobacilli were more significant (Marsh and Martin, 1992). Demineralisation of tooth enamel by acids produced from carbohydrate metabolism may initiate caries. Whether genespecies of *A. naeslundii* have a disease-causing or protective role continues to be debated (Bowden *et al.*, 1999; Morou-Bermudez and Burne, 2000), and the presence of *A. odontolyticus* may affect the progression of lesions. Periapical actinomycosis is considered to be extremely rare, but a review of the literature suggests this occurs more frequently than previously thought (Sakellariou, 1996). Diagnosis was aided by histological examination of periapical lesions. The recently described species *A. radidentis* has been isolated in pure culture and, to date exclusively, from infected root canals (Collins *et al.*, 2000).

The organisms associated with periodontal diseases are principally Gram-negative obligate anaerobes, including *Porphyromonas gingivalis*, *Prevotella intermedia* and *Actinobacillus actinomycetemcomitans*. The latter is named for its frequent association with actinomycetes. Human strains of *A. naeslundii* have been shown to cause destructive periodontal disease in animal models. Conversely, later research indicated that *Actinomyces* spp. were more frequently isolated from healthy or non-progressive sites than from sites with active periodontal disease (Moore *et al.*, 1987; Dzink, Socransky and Haffajee, 1988), and a beneficial role was suggested. However, more recent studies have shown associations of *A. naeslundii* with active periodontal sites (Tanner *et al.*, 1998) and *A. meyeri* with destructive periodontitis (Moore and Moore, 1994). Thus, evidence of pathogenicity remains contradictory, but *Actinomyces* spp. appear to play an important ancillary role by maintaining a favourable environment for causative agents of caries and periodontal diseases. Furthermore, the adhesive and co-aggregative properties of *Actinomyces* spp. are important in the development of dental plaque, where filamentous organisms form the basis of 'corn-cob' structures of bacteria. Adherence to buccal epithelia is facilitated by binding to host galactosyl ligands, and fimbriae of *A. naeslundii* mediate binding of cells to host surfaces and bacteria via acidic proline-rich proteins and statherin (Marsh and Martin, 1992; Hallberg *et al.*, 1998). *Actinomyces odontolyticus* has tongue-specific binding properties (Hallberg *et al.*, 1998).

LABORATORY DIAGNOSIS

Appropriate Specimens

Clinical awareness, appropriate specimens and laboratory expertise are important in confirming a diagnosis of actinomycosis. Where neoplasia is suspected, entire perioperative specimens are often placed

in formalin and are, therefore, unsuitable for microbiological investigations. Whilst histological examination is valuable, it is non-specific and cannot predict antimicrobial susceptibilities; specific confirmation rests currently upon microbiological evidence. However, in cases where symptoms are non-specific, or other infectious processes are suspected, the patient may have received multiple courses of antibiotics prior to surgery, biopsy or aspiration of clinical material, and culture-failure may result. Clearly, late or misdiagnosis of actinomycosis can have catastrophic consequences for the patient, whereas early detection and appropriate antimicrobial therapy may effect a complete cure and may prevent much suffering, disfigurement, drastic surgery, infertility, recrudescence or death.

For confirmation of clinical actinomycosis, optimal specimens are pus or sinus exudate. These may be examined for sulphur granules, and by microbiological staining and culture. During specimen collection, care should be taken to minimise contamination of material with skin or oral flora. Other appropriate specimens include biopsy material, bronchial secretions obtained by transtracheal aspiration and concretions from lacrimal canaliculi. The latter may be placed directly onto suitable agar media and microscope slides at the bedside, but these must be transferred to the laboratory immediately. For microbiological investigations, biopsy material should be placed in sterile saline.

Swabs are less successful for isolation of *Actinomyces* spp. but may be the only option in cases where frank pus cannot be collected, and from superficial soft-tissue infections. Dry swabs are unsuitable, particularly for maintenance of fastidious concomitant organisms. Rather, swabs in transport media, based on formulations of Stewart or Amies, should be used.

IUCDs and vaginal pessaries may be cultured, but isolation of *Actinomyces* spp. from these devices and associated material is not necessarily indicative of clinical infection. Furthermore, removal of the device via the genital tract may introduce organisms from the local flora. Similarly, data obtained from intraoral sites must be interpreted with caution as isolates may represent endogenous flora. Also for this reason, expectorated sputum is unsuitable for diagnosis of pulmonary infection.

For investigation of endocarditis, several sets of anaerobic blood cultures should be collected and processed in line with local laboratory policies for such cases, including prolonged incubation and terminal subculture.

Ideally, specimens should be collected prior to commencement of antimicrobial therapy. All specimens should be transported to the laboratory without delay, and be examined promptly. Accompanying documentation should request specific examination for actinomyces as extended incubation on specifically selective media is necessary for isolation of the causative organisms.

Detection of Sulphur Granules

Sulphur granules or 'drusen' are yellowish, irregular, gritty particles that are sometimes present in pus or sinus exudate from human and bovine cases of actinomycosis. The granules may be very sparse, or so numerous as to give exudate the appearance of semolina. They are composed of central masses of bacterial filaments, radiating peripherally, and with hyaline, clubbed ends. Clubs are composed of a polysaccharide and protein complex, presumed to be derived from the bacteria, and a variety of salts and polypeptides, thought to result from interaction with host cells (Slack and Gerencser, 1975). There is no evidence that they contain sulphur.

Sulphur granules are valuable aids to diagnosis of actinomycosis. However, they must be differentiated from similar particles that may result from aggregations of other bacteria or host material. The latter are usually soft and easily emulsified on a microscope slide. Conversely, actinomycotic granules are usually hard and impossible to emulsify with a bacteriological loop. They may be crushed between two slides and stained by Gram's and modified Ziehl-Neelsen methods. If available, specific fluorescent antibody techniques may be

applied. Granules may be seen in fixed tissue sections and may be similarly stained.

Sulphur granules are virtually pure concentrations of *Actinomyces* spp. and organisms within may be protected from effects of antimicrobial therapy and host defences. Hence, culture of washed granules greatly enhances isolation of the causative organism from polymicrobial infections. A thin layer of pus or exudate should be examined in a sterile Petri dish, and any granules teased out and washed free of cellular debris in sterile saline. The granules should sink and remain intact. These may be aspirated with a sterile Pasteur pipette for culture on appropriate media. Appropriate safety precautions should be taken for examination of potentially hazardous specimens, such as those where differential diagnosis includes tuberculosis. Pseudosulphur granules, composed of synthetic material may be found in association with IUCDs.

Direct Microscopy

Gram's staining of sulphur granules reveals characteristic masses of Gram-positive beaded, branched filaments. Unlike aggregates of *Nocardia* spp., *Actinomyces* spp. are non-acid-fast when stained by modified Ziehl-Neelsen (Kinyoun) method.

In fixed tissue sections, haematoxylin-eosin staining may reveal granules composed of eosinophilic clubs surrounding basophilic filaments, and the whole usually surrounded by proliferations of polymorphonuclear leucocytes and foamy macrophages. Confirmation of aetiology is obtained by Grocott's methenamine silver stain and Gram's stain (Brown-Brenn modification).

In Gram-stained smears prepared from pus, mucosal secretions, blood cultures or swabs, *Actinomyces* spp. may appear as individual Gram-positive beaded and branched filaments, loose aggregations or spider-like microcolonies, or as short diphtheroidal rods. Other bacteria are often present, and the actinomycetes may be very sparse, even in overt actinomycosis. Therefore, the finding of characteristic filaments in a clinical specimen should arouse suspicion of actinomycosis, but is not pathognomic, but their absence does not rule out infection.

Culture Media

Actinomyces spp. may be grown on various nutrient-rich solid or fluid media. Addition of serum or whole blood (rabbit, sheep or horse blood 5%) enhances growth. Columbia blood agar (Oxoid, UK) can be used, but fastidious anaerobe agar (BioConnections, UK) or anaerobe basal agar (Oxoid) are superior for the cultivation of fastidious anaerobes and *Actinomyces* spp.

Frequently, in clinical material, large numbers of concomitant bacteria are present with *Actinomyces* spp. Broth cultures are rarely advantageous, as less-demanding organisms usually proliferate rapidly, to the detriment of actinomycetes. A fluid medium sufficiently selective to overcome this problem has yet to be discovered. However, pure isolates may be cultivated in thioglycollate broth or fastidious anaerobe broth (BioConnections), with or without cooked meat granules. Light inoculation of broth media with organisms that form gritty colonies (e.g. *A. israelii*) may result in growth of discrete 'cloud-like' colonies, whilst the surrounding broth remains clear and apparently sterile. This phenomenon has technical implications for subsequent manipulations such as subculture and susceptibility testing and may be a reason for culture-failure of enrichment broths of clinical material.

Isolation of slow-growing actinomycetes from polymicrobial infections demands selective media. However, *Actinomyces* spp. are susceptible to a wide range of antimicrobial agents and may fail to grow on media containing neomycin, kanamycin or gentamicin, commonly used for isolation of obligate anaerobes. Several media incorporating cadmium sulphate (15–20 mg/l) have been developed specifically for isolation of *A. naeslundii* from dental plaque.

However, other species of *Actinomyces*, including *A. israelii*, may be inhibited by these media and they have not been evaluated for the isolation of recently described species.

For isolation of *Actinomyces* spp. from clinical specimens, inherent resistance to metronidazole has been exploited. Traynor *et al.* (1981) described a medium incorporating metronidazole (2.5 mg/l) in Columbia base with horse blood (10%). Lewis *et al.* (1995) reduced the horse blood to 5% in their MMBA medium and improved the selectivity of Traynor's formula by addition of mupiricin (128 mg/l). Brazier and Hall (1997) recommended metronidazole (10 mg/l), nalidixic acid (30 mg/l) and horse blood (7%) in fastidious anaerobe agar. Subsequently, however, this concentration of nalidixic acid has been found to inhibit some strains of *Actinomyces* and 15 mg/l nalidixic acid is now preferred. These media are semiselective, inhibiting obligate anaerobes and most Gram-negative bacteria but unable to suppress growth of other Gram-positive non-sporing bacilli and, except MMBA, staphylococci, streptococci and enterococci. However, reduction of the overall bacterial load, combined with good spreading technique, improves the chances of successful isolation of *Actinomyces*.

Application of commercial antimicrobial discs to agar plates may enhance selectivity when special media are not readily available, and may be useful in obtaining pure cultures. This procedure is cheap, simple and flexible, as inhibitory agents such as colistin sulphate, nalidixic acid and/or metronidazole can be chosen to best suppress the flora of the individual specimen. Ciprofloxacin (1 mg/l) discs may be used to inhibit staphylococci (personal observation), but higher concentrations of this agent may inhibit *Actinomyces* spp. Efficacy of selective media for isolation of recently described *Actinomyces* spp. has not been established.

Isolation Techniques

Clinical material should be cultured on an actinomyces selective agar and on a range of media suitable for isolation of other expected pathogens, choice depending upon source of material. *Actinomyces* spp. vary considerably in oxygen tolerance, but growth of most isolates is enhanced by CO₂ and all grow under anaerobic conditions. *Actinomyces naeslundii*, *A. viscosus* and *A. odontolyticus* may grow rapidly and equally well under aerobic or anaerobic conditions. Other species, particularly *A. israelii*, *A. gerencseriae*, *A. meyeri*, *A. cardiffensis* and *A. oricola* grow only anaerobically and very slowly on primary isolation. Aerotolerance and speed of growth may both increase upon repeated subculture. However, primary plates should be incubated anaerobically for 10–14 days, under conditions that avoid desiccation of media and examined at 2–3, 7 and 10–14 days. Anaerobic chambers or jars or the pyrogallol–sodium carbonate method may be used. A major advantage of using anaerobic chambers is that interim examination of cultures can be performed without exposure to air. Subcultures and other manipulations of colonies may be performed on the open bench provided that cultures are returned to anaerobic conditions promptly.

Gram's stain should be performed on colonies consistent with *Actinomyces* spp. or *P. propionicum* (Table 48.3). A hand-lens or stereo microscope are valuable aids for examination and for selection of single colonies from mixed cultures. Blood-containing plates may be examined under long wave (365 nm) ultraviolet light for the bright red fluorescence of *P. propionicum*, *A. graevenitzii* and some *Bifidobacterium* spp. Colonies of other *Actinomyces* spp. occasionally fluoresce weakly (personal observations). This simple test is a useful adjunct but is not specific as many other anaerobic bacteria demonstrate red (or green) fluorescence.

Suspicious colonies should be subcultured to three non-selective plates; one incubated anaerobically to obtain a pure culture; and the others in air and air plus CO₂ 5%, to assess atmospheric requirements. A pure culture is essential for confirmation of identity and for susceptibility testing.

Direct Detection by Specific Probes

For pathogens that are slow growing or difficult to isolate, direct detection in clinical material is clearly advantageous. For the 'classic' *Actinomyces* spp. and *P. propionicum*, direct or indirect immunofluorescence and, more recently, DNA probes have been applied for this purpose.

Fluorescent antibody techniques, originally developed for serological grouping of *Actinomyces* spp., have been applied successfully to fresh clinical material, formalin-fixed tissue, histological sections, primary microbiological cultures and pure isolates (Slack and Gerencser, 1975). These authors used serotype-specific antibodies, raised in rabbits, conjugated with fluorescein isothiocyanate and, where necessary, absorbed with cross-reacting antigens. They claimed this procedure to be the most rapid and reliable means of identifying *Actinomyces* and *P. propionicum*, but recommended that, where possible, conventional isolation and identification are also performed.

Similar methods, using species-specific antibodies, became popular in the 1970s to early 1990s, particularly for confirmation of identity of ALO seen in cervical smears and associated with IUCDs (Gupta, Erozan and Frost, 1978; Leslie and Garland, 1991). However, several problems are associated with the technique and it remains a research tool. Antisera have not been produced commercially and antibody production is non-standardised, laborious, complex and involves laboratory animals. The process is further complicated by the well-documented occurrence of cross-reactions, commonly between serotypes and between species, and occasionally between genera (Slack and Gerencser, 1975). Furthermore, in the light of current knowledge regarding antigenic heterogeneity within species, particularly in *A. naeslundii* and *A. viscosus*, it is possible that antisera raised from single or few strains may demonstrate strain or subspecies specificity, rather than species specificity.

Given the complexity of current taxonomy of the genus, it is clear that large numbers of antisera would be necessary to detect all species of *Actinomyces* now known to occur in clinical material, and the method would be impractical for routine use. Efficacy for detection of recently described species has not been reported.

DNA probes species specific for the 'classic' *Actinomyces* spp. have been applied to supra- and subgingival plaque samples (Ximénez-Fyvie, Haffajee and Socransky, 2000) and to infected root canals (Tang *et al.*, 2003). DNA cloning and sequencing, combined with checkerboard DNA hybridisation for some species has been applied to various intraoral niches to elucidate bacterial species associated with caries and in health (Paster *et al.*, 2001; Kazor *et al.*, 2003).

Multiplex fluorescent *in situ* hybridisation (FISH) successfully detected *A. naeslundii* and other five bacteria in a simulated oral biofilm (Thurnheer, Gmür and Guggenheim, 2004). This technique appears promising for the direct detection of *Actinomyces* spp. from clinical material. However, many species-specific probes would be required and, given the intraspecies genetic diversity within this genus, specificity and sensitivity may be problematic. The complexities of these techniques render them suitable only for research purposes at present. However, rapid advances in new technologies, including DNA microarrays, may bring such techniques into routine clinical use in the future.

Identification Procedures

Gas-Liquid Chromatography (GLC) for Products of Glucose Metabolism

The volatile and non-volatile fatty acids formed as endproducts of glucose metabolism are a stable characteristic of obligate and facultative anaerobes. The presence and approximate amounts (major or minor) of specific acids differentiate many anaerobic non-sporing Gram-positive bacilli to genus level. *Actinomyces* produce minor-to-moderate amounts

of acetic acid and major amounts of lactic and succinic acids, but no propionic acid. Members of *Actinobaculum*, *Arcanobacterium* and *Corynebacterium* produce similar endproducts, with or without lactic acid. *Propionibacterium* spp. produce major amounts of acetic and propionic acids and may produce isovaleric, lactic and succinic acids. Bifidobacteria produce acetic and lactic acids as major products, but no succinic acid. Lactobacilli produce only lactic acid (major). *Eubacterium* spp., the related *Eggerthella* and *Slackia*, produce various volatile acids, or none at all, and may produce lactic acid but not succinic. Susceptibility of these genera and clostridia to metronidazole (5 µg disc) differentiates them from other non-sporing Gram-positive bacilli.

Volatile and non-volatile fatty acids may be detected in broth cultures by the GLC methods described in the Anaerobe Laboratory Manual (Holdeman, Cato and Moore, 1977), or a modification thereof. Background levels of acids in uninoculated broth should be determined for comparison.

Conventional Biochemical Tests

Identification of *Actinomyces* to species level is traditionally based on differentiation in carbohydrate fermentation tests, hydrolysis of aesculin, urea and starch, and supplementary reactions including production of indole, catalase and nitrate reductase. Tests have been performed in various formats including broths, agar slopes and stabs, and in various basal media. Prolonged anaerobic incubation may be necessary and, in order to obtain adequate growth, serum is commonly added to broth or sloped media.

The agar plate method of Phillips (1976) was developed specifically for testing of fastidious anaerobes. A series of blood agar plates, each containing a single carbohydrate source, is inoculated and incubated anaerobically until good growth is visible. Acids formed by fermentation are demonstrated by addition of a pH indicator to an agar plug of culture. This method, though time-consuming, is sensitive, well controlled, and practical for testing small batches

of isolates and is, therefore, recommended for testing of *Actinomyces* spp.

Rapid results may be obtained with commercially available tablets (Rosco Diagnostic tablets, BioConnections, UK) that detect carbohydrate fermentation or preformed proteolytic enzymes by chromogenic changes after 4 h of aerobic incubation in suspensions of test organisms. This method is cheap, simple and flexible as the range of tests performed can be tailored to individual needs. However, a heavy inoculum of a fresh (<48 h) culture is essential. A scheme for presumptive identification of *Actinomyces* spp. and related genera using such tests has been developed (Sarkonen *et al.*, 2001).

Despite the widespread use of conventional biochemical tests, identification of *Actinomyces* spp. by these methods is notoriously problematic. Variation in results may occur due to varying methodologies, in particular the choice of basal medium and, possibly, atmospheric conditions. Technical problems include slow growth, obtaining smooth suspensions of colonies and differing results upon repeat testing of individual strains. Interpretation of results is also problematic. For some species, conventional tests differentiate poorly. This may be due, in part, to the heterogeneous nature of some species as previously described, and some anomalies may be clarified by recent or future taxonomic changes. An example is the differentiation of *A. israelii* and *A. gerencseriae* by failure of the latter to ferment arabinose; obsolete identification schemes would list fermentation of arabinose by *A. israelii* (including *A. gerencseriae*) as variable. Differentiating reactions listed in schemes by various authors are not always in agreement, possibly due to differing methodologies used, or the different strains from which data were obtained. Furthermore, most published schemes are now obsolete in respect of current taxonomy. Table 48.4 lists biochemical reactions that may aid the identification to species level of *Actinomyces* spp. from human sources. However, the abovementioned limitations must be heeded, and interpretation should be based on a consensus of reactions together with consistent cell and colony morphology. Recent descriptions of species should be consulted (see references listed in Table 48.2).

Commercial Identification Kits

Commercial kit-form systems (e.g. API rapid ID32A, bioMérieux, France; RapID ANA II, Innovative Diagnostic systems, USA) for identification of anaerobes are used widely in UK clinical laboratories. In these systems, a suspension of fresh culture is added to a panel of freeze-dried substrates and, after aerobic incubation for 4 h, preformed enzymes involved in carbohydrate fermentation or proteolysis are detected by chromogenic reactions. Tests are scored numerically and the resulting code is compared with those in the manufacturer's database. Advantages of kits are ease of use, standardisation of substrates, long shelf-life and rapid results. Disadvantages, for anaerobes in general, include difficulties in interpretation of weak reactions, omission from databases of some clinically relevant species and variable results dependent on culture medium from which the isolate is taken. Furthermore, for aerobic organisms, various kits are available, with tests appropriate to a specific genus, or related genera, e.g. *Streptococcus*, Enterobacteriaceae. However, single kits are marketed for identification of all anaerobes and consequently, for some genera, only a limited number of tests in the panel is relevant. Problems specific to *Actinomyces* spp. include obtaining a smooth suspension for inoculation, lack of specificity of results and inadequate databases. Four commercial systems were recently evaluated specifically for identification of *Actinomyces* spp. and closely related species, and performance was found to be universally poor, particularly for recently described species (Santala *et al.*, 2004).

Despite the limitations listed above, combinations of API-ZYM, API rapid ID32Strep and API CORYNE kits (bioMérieux, France) have proved useful in classification and identification of recently described *Actinomyces* spp. Results may be interpreted with reference to the most recent species descriptions. Sabbe *et al.* (1999) recommend the API CORYNE kit for clear discrimination of *A. turicensis* from other *Actinomyces* spp.

Specific Antibody Techniques

Fluorescent antibody techniques, including immunodiffusion using antisera raised against whole cells or soluble antigens and cell-wall agglutination tests have been applied to mixed cultures and pure isolates of *Actinomyces* spp. In each of these techniques, unavailability of sera, lack of standardisation, cross-reactions and non-specificity have been problematic. Therefore, these methods have not been widely used for identification of *Actinomyces* spp.

Chemotaxonomic Approaches

Combinations of chemotaxonomic and molecular methods are valuable tools in classification of *Actinomyces* spp. However, the specialist expertise and equipment required for performance of tests and analysis of data have ensured that these methods have not gained favour for routine identification. Methods commonly employed for classification are whole-cell protein profiling by sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS-PAGE) and analysis of cell-wall constituents such as amino acids, sugars, fatty acids, phospholipids and menaquinones. In each of these methods, findings may vary with culture conditions, particularly media composition. Therefore, results for individual isolates can only be compared with those for strains grown under similar conditions, and standardisation of procedures is important.

Molecular Methods

In recent years, identification methods based on detection of variations at the genetic level have become increasingly practical and, for genera such as *Actinomyces* that are difficult to speciate in conventional tests, have greatly improved the accuracy of identification. In general, the

16S rRNA gene is a popular target for genetic probes because it is mostly highly conserved but contains several, often species-specific, variable regions and occurs in high-copy numbers in each cell. Also, as nucleotide sequence variations within this gene form the mainstay of modern taxonomy, identification methods based on detection of such variations are directly linked to current classification.

Prior to the widespread use of PCR, Barsotti *et al.* (1994) digested total genomic DNA with the endonuclease *BstEII* to detect restriction fragment length polymorphisms (RFLP) and were able to differentiate *A. bovis*, *A. gerencseriae*, *A. israelii*, *A. meyeri*, *A. odontolyticus* and *Arcanobacterium pyogenes* to species. However, *A. naeslundii* and *A. viscosus* were not clearly distinguishable.

Methodology has been refined and simplified by PCR amplification of specific DNA prior to enzymatic digestion. The technique, known as PCR-RFLP or amplified ribosomal DNA restriction analysis (ARDRA), has been adapted to differentiate species of many genera. In brief, DNA extracted from a pure cultured isolate is used as the template for PCR amplification with specific primers (commonly targeting the almost complete 16S rRNA gene). The amplicon is digested by one or more endonucleases, selected for their ability to cleave the DNA at species-specific variable regions. Resulting DNA fragments are separated by gel electrophoresis, alongside molecular size markers, and are visualised by ethidium bromide staining. Banding patterns are compared with those of reference strains, either visually or by computer software.

For human oral *Actinomyces* spp., two small studies found PCR-RFLP with the endonuclease *MnII* to be discriminatory (Sato *et al.*, 1998; Ruby *et al.*, 2002). However, in studies of over 600 human clinical and veterinary strains, banding patterns produced from separate digestions with endonucleases *HaeIII* and *HpaII* were analysed. This method discriminates to species or subspecies level, all currently recognised species of *Actinomyces*, *Arcanobacterium*, *Actinobaculum*, *Varibaculum*, *Mobiluncus*, *Gardnerella*, *Propionibacterium* and many species of *Bifidobacterium*, *Lactobacillus* and other non-sporing Gram-positive bacilli (Hall, Lewis-Evans and Duerden, 2001a; Hall *et al.*, 2001b). The method is practical and cost-effective and is now in routine use for the identification of these organisms at the PHLS Anaerobe Reference Unit.

Antimicrobial Susceptibility Testing

Disc Diffusion Tests

In the United Kingdom, the antimicrobial susceptibilities of clinically significant bacteria are commonly determined by disc diffusion tests, but this method was developed for the testing of rapid-growing aerobic organisms. Where organisms have a longer than average lag phase of growth, the antibiotic diffuses further into the agar before active growth begins and, hence, produces exceptionally large zones of inhibition. Furthermore, there are few recommended anaerobic control organisms, and these do not adequately represent all clinically significant genera. Consequently, disc diffusion methods are not well suited to testing of slow-growing and fastidious organisms such as *Actinomyces* spp. but nevertheless, for reasons of economy and convenience, are commonly used methods. The special methodological problems pertaining to the testing of Actinomycetes, including difficulties in obtaining a uniform inoculum, have been discussed by Schaal and Pape (1980). It is recommended that, if disc diffusion methods are used for fastidious organisms, a maximum of four discs are placed on a standard Petri dish, and any unusual resistance is confirmed by other methods.

Determination of MICs

Determination of minimum inhibitory concentrations (MICs) of antimicrobial agents by agar dilution is the 'gold standard' method for

fastidious anaerobes. This method is suitable for the testing of large numbers of isolates, but the labour-intensity of agar preparation renders it impractical for testing of occasional isolates. In the USA, the National Committee for Clinical Laboratory Standards guidelines recommend the use of Brucella agar supplemented with vitamin K and haemin for testing of anaerobes. It should be noted that Wilkins–Chalgren agar does not support good growth of some anaerobes and interpretation of endpoints can be problematic, particularly where hazy trailing endpoints occur.

Broth dilution methods for determination of MICs are not recommended for fastidious organisms, and the granular or ‘microcolony’ growth of some *Actinomyces* spp. in broth cultures is a further contraindication for use of this method with these organisms.

Conversely, the Etest method (AB-Biodisk, Sweden) is easy to use, accurate and practical for susceptibility testing of individual clinical isolates, including fastidious and slow-growing organisms, though relatively expensive in comparison with disc diffusion testing. The formation of an immediate and stable antimicrobial gradient overcomes problems encountered with slow-growing organisms in the disc diffusion method, and the Etest appears to be less sensitive to variations in inoculum concentration. However, results are still subject to variations in media constituents, quality of growth and incubation time, and to excess moisture on agar surfaces. Clear endpoints are usually readable after incubation for 20–48 h. In an evaluation of 50 strains of *Actinomyces* and closely related genera, results obtained by Etest correlated well with those obtained in the agar dilution method (Hall and Talbot, 1997).

Surveillance-Based Therapy

Alternatively, treatment regimens may be based on surveillance of representative clinical isolates or on reported clinical responses rather than the testing of individual strains. This approach is attractive and is commonly used in cases of actinomycosis, where diagnosis is often clinical or histological, the causative agent is frequently not isolated, and antimicrobial susceptibility patterns are stable and highly predictable. However, for data to retain relevance, it is important to monitor adequate numbers of fresh representative isolates and/or clinical outcomes periodically, and to establish efficacy of new antimicrobial agents and combination therapies.

Monitoring of MICs by Etest at the PHLS Anaerobe Reference Unit confirms that the long-established *Actinomyces* spp. and *P. propionicum* remain exquisitely sensitive to commonly used antimicrobial agents. Typical ranges of MICs were: benzyl penicillin <0.004–0.094 mg/l, amoxycillin <0.016–0.064 mg/l, tetracycline 0.125–2.0 mg/l, erythromycin <0.016–0.25 mg/l, cefuroxime <0.016–0.5 mg/l, clindamycin <0.016–0.5 mg/l and imipenem <0.002–0.064 mg/l. However, for *A. odontolyticus* MICs were generally higher though still within the therapeutic range, e.g. penicillin 0.032–0.5 mg/l, amoxycillin 0.064–1.0 mg/l, imipenem 0.064–0.5 mg/l, and one strain, isolated from a pleural fluid, was resistant to erythromycin with an MIC of >256 mg/l.

For recently described species, few data have been reported to date. Monitoring at the PHLS Anaerobe Reference Unit indicates that most isolates are susceptible to penicillin, erythromycin and tetracycline, but some exceptions occur and empirical data cannot be relied upon. Notably, 13 of 42 *A. turicensis* strains and one of 10 *A. funkei* strains were resistant to tetracycline, some strains having MICs of >256 mg/l. Five strains of *A. turicensis* showed reduced susceptibility or resistance to erythromycin. Also, high-level resistance to erythromycin (MIC > 256 mg/l) occurred in three of seven strains of *A. europaeus* and two of five strains of *A. radingae* examined. The eight strains of *A. urogenitalis* tested were all clinically susceptible to penicillin, but their MICs of 0.5–1.0 mg/l were considerably higher than those of ‘classic’ *Actinomyces* spp. In many cases, the pathogenicity and, therefore, clinical relevance of antimicrobial resistance in these

species is questionable. However, one isolate of *A. turicensis* with MICs of 0.19 mg/l for penicillin, 3.0 mg/l for erythromycin and 48 mg/l for tetracycline was isolated from a blood culture of a 31-year-old intravenous drug abuser with an injection-site abscess and pneumonia.

TREATMENT

Aggressive antimicrobial therapy is essential for treatment of actinomycosis. Additionally, depending upon the site and severity of disease, surgical intervention, ranging from drainage of pus to excision of organs may be required. Historically, prognosis was poor, even when radical surgery was performed. However, treatment options greatly improved with the availability of penicillin and, to a lesser extent, sulphonamides. As reported above, *Actinomyces* spp. and *P. propionicum* are usually susceptible to a wide range of antimicrobial agents, including penicillins, cephalosporins, chloramphenicol, tetracyclines, erythromycin, clindamycin and imipenem. Conversely, fluoroquinolones, aztreonam, aminoglycosides and metronidazole have poor activity.

Although *Actinomyces* are exquisitely sensitive *in vitro* to many agents, bacteria within microcolonies (sulphur granules) and indurated abscesses are protected from their action. Therefore, high-dosage and long-term therapy is often necessary, and the pharmacological properties of penicillin make it the agent of choice in most cases. Alternatives for penicillin-allergic patients include tetracycline, erythromycin, clindamycin or cephalosporins. Therapy aimed at concomitant bacteria may be necessary, particularly where *Actinobacillus actinomycetemcomitans* or β -lactamase producers are present. Schaal (1998) recommends amoxycillin/clavulanic acid for cervicofacial and thoracic cases, and amoxycillin/clavulanic acid with metronidazole and an aminoglycoside or imipenem for abdominal cases. However, Smego and Foglia (1998) claim, controversially, that regimens targeting only *Actinomyces* sp. are usually curative, and cover against secondary organisms is unnecessary.

Typical regimens for straightforward cervicofacial infection are: oral penicillin V or doxycycline, 100 mg twice daily for 2 months, without surgical intervention (Smego and Foglia, 1998); or amoxycillin (2 g)/clavulanic acid (0.2 g) three times daily for 1 week, followed by 1 week at half this dose (Schaal, 1998). For more complicated infections, Martin (1984) recommends parenteral penicillin G, 10–20 million units daily for 4–6 weeks, followed by oral penicillin V 2–4 g daily for 6–12 months. For pelvic actinomycosis, without perforation, Hamid *et al.* (2000) suggest high-dose intravenous penicillin and metronidazole until biological parameters are within normal limits, then oral therapy for 1 month prior to surgery to excise residual abscess and relieve any urinary or bowel compression. Surgical procedures would usually entail bilateral salpingectomy or bilateral salpingoophorectomy and total hysterectomy.

Clinical response to prolonged ciprofloxacin therapy (750 mg twice daily for 6 months, 375 mg for 4 years) in a severe and very long-standing case of abdominal/pelvic infection has been reported (Macfarlane, Tucker and Kemp, 1993). However, *in vitro* activity of this agent is poor.

In all presentations of actinomycosis, early diagnosis greatly improves prognosis and, despite the armamentarium of modern medicine, inadequate treatment or late diagnosis may lead to years of suffering or even death from the disease or associated complications. Recurrence or secondary foci of disease are not uncommon; therefore all patients should be followed for long periods. IUCD users should be assessed regularly and managed as recommended by the British Faculty of Family Planning and Reproductive Healthcare (Cayley *et al.*, 1998).

After dental surgery, prophylaxis is advised for those at risk of cardiac infection, and early treatment of postsurgical inflammation may prevent development of cervicofacial actinomycosis.
