Preface ix

SECTION ONE GRAM-POSITIVE COCCI 1

- 1 **β -Haemolytic Streptococci 3**
*Androulla Efstratiou, Shiranee Sriskandan,
Theresa Lamagni and Adrian Whatmore*
- 2 **Oral and Other Non- β -Haemolytic Streptococci 21**
Roderick McNab and Theresa Lamagni
- 3 ***Streptococcus pneumoniae* 41**
Indran Balakrishnan
- 4 ***Enterococcus* spp. 59**
Esteban C. Nannini and Barbara E. Murray
- 5 ***Staphylococcus aureus* 73**
Sharon Peacock
- 6 **Coagulase-Negative Staphylococci 99**
Roger G. Finch

SECTION TWO GRAM-POSITIVE BACILLI 113

- 7 ***Corynebacterium* spp. 115**
Aruni De Zoysa and Androulla Efstratiou
- 8 ***Listeria* and *Erysipelothrix* spp. 129**
Kevin G. Kerr
- 9 ***Bacillus* spp. and Related Genera 139**
Niall A. Logan and Marina Rodríguez-Díaz
- 10 ***Mycobacterium tuberculosis* 159**
Stephen H. Gillespie
- 11 **Non-Tuberculosis Mycobacteria 171**
Stephen H. Gillespie
- 12 **Aerobic Actinomycetes 183**
Stephen H. Gillespie

SECTION THREE GRAM-NEGATIVE ORGANISMS 189

- 13 ***Moraxella catarrhalis* and *Kingella kingae* 191**
Alex van Belkum and Cees M. Verduin
- 14 ***Neisseria meningitidis* 205**
Dlawer A. A. Ala'Aldeen and David P. J. Turner
- 15 ***Neisseria gonorrhoeae* 221**
Catherine A. Ison
- 16 ***Acinetobacter* spp. 231**
Peter Hawkey and Eugenie Bergogne-Berezin
- 17 ***Haemophilus* spp. 245**
Derrick W. Crook and Derek W. Hood
- 18 ***Bordetella* spp. 253**
*Qiushui He, Jussi Mertsola and
Matti K. Viljanen*

- 19 ***Brucella* spp. 265**
Edward J. Young
- 20 ***Actinobacillus actinomycetemcomitans* 273**
Brian Henderson and Derren Ready
- 21 ***Francisella tularensis* 281**
Petra C. F. Oyston
- 22 ***Rickettsia* spp. 285**
*James G. Olson, Franca R. Jones
and Patrick J. Blair*
- 23 ***Bartonella* spp. 295**
J. M. Rolain and D. Raoult
- 24 ***Mycoplasma* spp. 305**
*Christiane Bébéar, Sabine Pereyre and
Cécile M. Bébéar*
- 25 ***Chlamydia* spp. and Related Organisms 317**
S. J. Furrows and G. L. Ridgway
- 26 ***Tropheryma whipplei* 329**
F. Fenollar and D. Raoult
- 27 **Identification of Enterobacteriaceae 341**
Peter M. Hawkey
- 28 ***Escherichia coli* and *Shigella* spp. 347**
*Christopher L. Baylis, Charles W. Penn,
Nathan M. Thielman, Richard L. Guerrant,
Claire Jenkins and Stephen H. Gillespie*
- 29 ***Salmonella* spp. 367**
Claire Jenkins and Stephen H. Gillespie
- 30 ***Klebsiella*, *Citrobacter*,
Enterobacter and *Serratia* spp. 377**
C. Anthony Hart
- 31 **Donovanosis and *Klebsiella* spp. 387**
John Richens
- 32 ***Proteus*, *Providencia* and *Morganella* spp. 391**
Peter M. Hawkey
- 33 ***Yersinia* spp. 397**
M. B. Prentice
- 34 ***Vibrio* spp. 407**
Tom Cheasty
- 35 ***Aeromonas* and *Plesiomonas* spp. 419**
Alpana Bose
- 36 ***Pseudomonas* and *Burkholderia* spp. 427**
Tyrone L. Pitt and Andrew J. H. Simpson
- 37 ***Legionella* spp. 445**
T. G. Harrison
- 38 ***Coxiella burnetii* 457**
*James G. Olson, Franca R. Jones and
Patrick J. Blair*

SECTION FOUR SPIRAL BACTERIA 461**39 *Leptospira* spp. 463***P. N. Levett***40 *Helicobacter* spp. and Related Organisms 473***Peter J. Jenks***41 *Campylobacter* and *Arcobacter* spp. 485***Diane E. Taylor and Monika Keelan***42 Treponemes 503***Andrew J. L. Turner***43 *Borrelia* spp. 511***Sudha Pabbatireddy and Benjamin J. Luft***SECTION FIVE OBLIGATE ANAEROBIC BACTERIA 527****44 Anaerobic Cocci 529***D. A. Murdoch***45 Non-Sporing Gram-Negative Anaerobes 541***Sheila Patrick and Brian I. Duerden***46 *Clostridium difficile* 557***Mark H. Wilcox***47 Other *Clostridium* spp. 567***Ian R. Poxton***48 Anaerobic Actinomycetes and Related Organisms 575***Val Hall***Index 587**

Preface

Change is inevitable and nowhere more than in the world of bacteriology. Since the publication of the first edition of this book in 1997 the speed of change has accelerated. We have seen the publication of whole genome sequences of bacteria. The first example, *Mycoplasma genitalium*, was heralded as a breakthrough, but this was only the first in a flood of sequences. Now a wide range of human, animal and environmental bacterial species sequences are available. For many important organisms, multiple genome sequences are available, allowing comparative genomics to be performed. This has given us a tremendous insight into the evolution of bacterial pathogens, although this is only a part of the impact of molecular biological methods on bacteriology. Tools have been harnessed to improve our understanding of the pathogenesis of bacterial infection, and methods have been developed and introduced into routine practice for diagnosis. Typing techniques have been developed that have begun unravelling the routes of transmission

in human populations in real time. New pathogens have been described, and some species thought to have been pathogenic have been demonstrated only to be commensals. Improved classification, often driven by molecular methods, has increased our ability to study the behaviour of bacteria in their interaction with the human host. New treatments have become available, and in other instances, resistance has developed, making infections with some species more difficult to manage.

In this revision the authors and editors have endeavoured to provide up-to-date and comprehensive information that incorporates this new knowledge, while remaining relevant to the practice of clinical bacteriology. We hope that you find it helpful in your daily practice.

Gram-Positive Cocci

β-Haemolytic Streptococci

Androulla Efstratiou¹, Shiranee Sriskandan², Theresa Lamagni¹ and Adrian Whatmore³

¹Health Protection Agency, Centre for Infections, London; ²Department of Infectious Diseases, Imperial College School of Medicine, London; and ³Veterinary Laboratory Agency, Addlestone, Surrey, UK

GENERAL INTRODUCTION

Streptococcal diseases such as scarlet fever, erysipelas and puerperal fever were recognised as major problems for centuries before characterisation of the causative organisms. The first attempts to differentiate streptococci were probably made by Schottmüller in 1903, who used haemolysis to distinguish them. The β-haemolytic streptococci, characterised by the production of clear zones of haemolysis around colonies following overnight incubation on blood agar, turned out to contain some of the most ubiquitous bacterial colonisers of humans. Although there are now numerous additional approaches for differentiating streptococci, both haemolytic activity and another early approach, Lancefield typing (based on group-specific carbohydrate antigens), remain useful for differentiating them in the modern clinical microbiology laboratory. Table 1.1 lists the major β-haemolytic streptococci currently recognised. Interestingly, the accumulation of molecular data in recent years has revealed that the β-haemolytic streptococci do largely correspond to a phylogenetic grouping. All the species listed in Table 1.1 fall within the pyogenic grouping recognised by Kawamura *et al.* (1995) on the basis of 16S rRNA sequence, although this grouping also contains non-β-haemolytic streptococci. Moreover, many other streptococci, particularly *anginosus* species, could on occasion show β-haemolytic activity. However, these are not considered primarily β-haemolytic organisms and are discussed by Roderick McNab and Theresa Lamagni in Chapter 2, under nonhaemolytic streptococci.

The most important β-haemolytic streptococci are *Streptococcus pyogenes* and *Streptococcus agalactiae*. *Streptococcus pyogenes*, also known as the group A streptococcus (GAS) – considered the most

pathogenic of the genus – appears to be essentially confined to humans and is associated with a wide spectrum of diseases. These range from mild, superficial and extremely common diseases such as pharyngitis (strep throat) and impetigo to severe invasive disease from which the organism has gained public notoriety as the flesh-eating bacterium and immune-mediated sequelae such as rheumatic fever (RF) and poststreptococcal glomerulonephritis. Although well adapted to asymptomatic colonisation of adults, *S. agalactiae*, or the group B streptococcus (GBS), is a major cause of neonatal sepsis and an increasingly common pathogen of the elderly and immunocompromised as well as an important cause of mastitis in cattle. *Streptococcus dysgalactiae* subsp. *equisimilis* is considered a less pathogenic species than GAS but is a relatively common cause of similar superficial disease and may also be associated with invasive disease of the elderly or immunocompromised. A further four members of the β-haemolytic streptococci are considered to be primarily non-human pathogens, although they have occasionally been associated with zoonotic human infection and will be discussed only briefly in this chapter. *Streptococcus equi* subsp. *zooepidemicus* infections are generally associated with the consumption of unpasteurised dairy products and may induce a broad disease spectrum. *Streptococcus equi* subsp. *zooepidemicus* has been associated with outbreaks of nephritis (Francis *et al.* 1993). There have been some reports (although rare) of the isolation of *Streptococcus canis* from human blood cultures (the microbiological identification of the species does remain questionable). *Streptococcus iniae* has been associated with invasive disease in fish-handlers, and *Streptococcus porcinus* has been occasionally isolated from the human genitourinary tract, although the pathogenic potential of these isolates is unclear. A further three β-haemolytic streptococcal species have not been reported as having been isolated from humans (*Streptococcus equi* subsp. *equi*, *Streptococcus didelphis* and *Streptococcus phoacae*) – *S. phoacae* and *S. didelphis* have been isolated from seals and opossums. *Streptococcus iniae* is also primarily animal pathogen, classically associated with infections amongst freshwater dolphins. The review by Facklam (2002) provides a more detailed description of these streptococci.

Table 1.1 Features of β-haemolytic streptococci

Species	Common Lancefield group(s)	Major host(s)
<i>S. pyogenes</i>	A	Human
<i>S. agalactiae</i>	B	Human, bovine
<i>S. dysgalactiae</i> subsp. <i>equisimilis</i>	C, G	Human, animals
<i>S. equi</i> subsp. <i>equi</i>	C	Animals
<i>S. equi</i> subsp. <i>zooepidemicus</i>	C	Animals (human ^a)
<i>S. canis</i>	G	Dog (human ^a)
<i>S. porcinus</i>	E, P, U and V	Swine (human ^a)
<i>S. iniae</i>	None	Marine life (human ^a)
<i>S. phoacae</i>	C and F	Seal
<i>S. didelphis</i>	None	Opossum

^a Rare causes of human infection.

PATHOGENESIS AND VIRULENCE FACTORS

GAS Pathogenesis

The status of GAS as one of the most versatile of human pathogens is reflected in the astonishing array of putative virulence determinants associated with this organism. Lack of space and the remit of this chapter permit only a cursory discussion of the extensive and ever-expanding

Table 1.2 Putative virulence factors of group A streptococcus (GAS)

Cell-surface molecules	Major function(s)/role
M-protein family (Emm, Mrp, Enn)	Resistance to phagocytosis Multiple ligand-binding capacities Adhesion, invasion?
Fibronectin-binding proteins (multiple)	Inhibits leukocyte recruitment
C5a peptidase	Resistance to phagocytosis
Hyaluronic acid capsule	Adherence?
Excreted molecules	Probable function/role
Streptolysin O/streptolysin S	Haemolytic toxins
Streptokinase	Lysis of blood clots and tissue spread
Superantigens (multiple)	Nonspecific immune stimulation
Protein Sic	Inhibitor of complement
SpeB (cysteine protease)	Generates biologically active molecules Inflammation, shock and tissue damage

literature in this area. For a more encompassing view, readers are referred to the many excellent reviews covering the role of putative virulence factors identified in GAS (Cunningham 2000; Nizet 2002; Bisno, Brito and Collins 2003; Collin and Olsén 2003). Throughout the ensuing section the reader should bear in mind that the repertoire of putative virulence factors is now known to vary between strains and that even when the same factors are present there may be extensive genotypic and phenotypic diversity. It is thus increasingly apparent that GAS pathogenesis involves a complex and interacting array of molecules and that the fine details may vary between different strains. The best-studied virulence factors are listed in Table 1.2, though this table is far from exhaustive as there are numerous less-well-characterised molecules that could be involved in pathogenesis.

Cell-Associated Molecules

The M protein has long been considered the major cell-surface protein of GAS. M protein was originally defined as an antiphagocytic protein that determines the serotype of a strain and evokes serotype-specific antibody that promotes phagocytosis by neutrophils in fresh human blood. Despite extensive antigenic variation all M proteins have an α -helical coiled-coil conformation and possess an array of properties that may be important in their antiphagocytic role. The best-characterised activities are binding of factor H, a regulatory component of complement control system, and binding of fibrinogen that diminishes alternate complement pathway-mediated binding of C3b to bacterial cells, thus impeding recognition by polymorpholeukocytes (PMLs). The M-protein-encoding gene (*emm*) is now known to belong to a family of so-called M-like genes linked in a cluster that appear to have evolved by gene duplication and intergenic recombination (Whatmore and Kehoe 1994). A variety of genomic arrangements of this family has been identified, the simplest of which consists of only an *emm* gene flanked by a regulatory gene *mga* (multiple gene activator) and *scpA* (see *Virulence Gene Regulators*). However, many isolates contain an upstream gene (usually designated *mrp*) and/or a downstream gene (usually designated *enn*), and several members of the M-like gene family have been found to bind a whole array of moieties including various immunoglobulin A (IgA) and IgG subclasses, albumin, plasminogen and the factor H-like protein C4bBP. In recent years it has become clear that resistance to phagocytosis is not solely dependent on the M protein itself. For example, inactivation of *emm49* has little impact on resistance to phagocytosis, with *mrp49*, *emm49* and *enn49* all appearing to be required (Podbielski *et al.* 1996; Ji *et al.* 1998).

The capacity of some strains (notably M18) to resist phagocytosis is virtually entirely dependent on the extracellular nonantigenic hyaluronic acid capsule (Wessels and Bronze 1994). Many clinical isolates, particularly those epidemiologically associated with severe disease or RF, produce large mucoid capsules. These may act to mask streptococcal antigens or may act as a physical barrier preventing access of phagocytes to opsonic complement proteins at the bacterial cell surface, as well as being involved in adherence.

In addition to the antiphagocytic molecules described above many other cellular components have postulated roles in pathogenesis. All GAS harbour *scpA* mentioned above that encodes a C5a peptidase. This protein destroys C5a complement protein that is a chemotactic signal that initially attracts neutrophils to sites of infection. GAS have been shown to possess an array of fibronectin-binding proteins, indicating the importance of interactions with this molecule. Fibronectin is a Principal glycoprotein in plasma, body fluids and the extracellular matrix. Perhaps the best-characterised GAS fibronectin-binding protein is protein F (SfbI) that has roles in adherence and invasion (see *Adherence, Colonisation and Internalisation*). However, an ever-expanding array of other molecules has been shown to possess this activity, including proteins such as SfbII, SOF, proteinF2, M3, SDH, FBP-51, PFBP, Fba and glyceraldehyde-3-phosphate dehydrogenase.

With the recent completion of genome sequencing projects many novel cell-surface proteins have been identified. Most remain to be fully characterised, but their surface location facilitates potential roles in host interaction. Examples include Slr, a leucine-rich repeat protein, isogenic mutants of which are less virulent in an intraperitoneal mouse model and more susceptible to phagocytosis by human PMLs (Reid *et al.* 2003). Two novel collagen-like proteins, SclA and SclB, have also been identified. Their function is unclear, but they may be important in adherence and are of potential interest in the pathogenesis of autoimmune sequelae (Lukowski *et al.* 2000; Rasmussen, Eden and Bjorck 2000; Whatmore 2001). A further potential virulence factor identified from the genome sequence is protein GRAB, present in most GAS and possessing high-affinity binding capacity for the dominant proteinase inhibitor of human plasma α 2-macroglobulin. Again, mutants are attenuated in mice and it has been suggested that α 2-macroglobulin bound to the bacterial surface via protein GRAB entraps and inhibits the activity of GAS and host proteinases, thereby protecting other virulence determinants from proteolytic degradation (Rasmussen, Muller and Bjorck 1999).

Excreted Products

Most GAS produce two distinct haemolysins, streptolysin O (SLO) and streptolysin S (SLS). SLO is an oxygen-labile member of the cholesterol-binding thiol-activated toxin family that elicits antibodies useful for documenting recent exposure and is toxic to a variety of cells. SLS belongs to the bacteriocin family of microbial toxins and is not immunogenic in natural infection but shares similar toxic activities to SLO. Streptokinase facilitates the spread of organisms by promoting the lysis of blood clots. Streptokinase binds to mammalian plasminogen, and this complex then converts other plasminogen molecules to the serum protease plasmin that subsequently acts on a variety of proteins including fibrin. GAS have cell-surface receptors capable of binding plasminogen, which following conversion to plasmin in the presence of streptokinase may generate cell-associated proteolytic enzyme capable of causing tissue destruction.

GAS produce an array of superantigens. These protein exotoxins have the ability to trigger excessive and aberrant activation of T cells by bypassing conventional major histocompatibility complex (MHC)-restricted antigen processing (Llewelyn and Cohen 2002). Subsequent excessive and uncoordinated release of inflammatory cytokines such as tumour necrosis factor- α (TNF- α), interleukin-2 (IL-2) and interferon- γ (IFN- γ) results in many of the symptoms consistent with toxic shock

syndrome. Over a dozen distinct superantigens have now been recognised in GAS, and many appear to be located on mobile genetic elements. Different isolates possess distinct arrays of superantigens with subtly different specificities and activities. SpeB was initially thought to be a superantigen, but it is now thought that its disease contribution is related to protease activity. SpeB is a chromosomally encoded cysteine proteinase that acts on many targets including various Ig classes and generates biologically active molecules by activities that include cleaving IL-1 β precursor to an active form and releasing bradykinin from a precursor form. These activities generate reactive molecules with roles in inflammation, shock and tissue destruction.

A further proposed secreted virulence factor is the streptococcal inhibitor of complement (Sic) protein found predominantly in M1 strains which binds to components of the complement membrane attack complex (C5b-C9) and thus inhibits complement-mediated lysis *in vitro*. The *in vivo* function of Sic is not clear, but it appears to be rapidly internalised by human epithelial cells and PMLs where specific interactions result in the paralysis of the actin cytoskeleton and significantly decreased opsonophagocytosis and killing of GAS. Sic is one of the most variable bacterial proteins known, and variants arise rapidly *in vivo* (Matsumoto *et al.* 2003), suggesting an important role for this molecule in M1 isolates.

Adherence, Colonisation and Internalisation

The GAS infectious process entails several steps proceeding from initial adherence to mucosal cells to subsequent invasion of deeper tissue, leading to occasional penetration of the bloodstream. The strategies by which GAS adhere and invade are multiple and complex and vary between strains and between host cell types, with the potential involvement of multiple adhesins and invasins. An astonishing array of putative adhesins has been described (reviewed by Courtney, Hasty and Dale 2002), although only the roles of lipoteichoic acid (LTA), M protein and some fibronectin-binding proteins have been studied in any great detail.

LTA adheres to fibronectin on buccal epithelial cells, an interaction that is blocked by excess LTA or anti-LTA antibody, and this serves as a first step in adhesion with secondary adhesins, thus facilitating stronger and more specific binding. Many studies have implicated M protein in adhesion, although observations vary greatly from strain to strain and depend on the *in vitro* model and tissue type studied. However, there is evidence that M protein mediates adherence to skin keratinocytes via CD46. There is substantial evidence that fibronectin-binding proteins such as SfbI and related proteins are important in adhesion. SfbI mediates adherence to respiratory epithelial cells and cutaneous Langerhans cells. Expression is environmentally regulated, being enhanced in oxygen-rich atmospheres, in contrast to that of M protein.

Following adhesion GAS must maintain itself on the pharynx. The capsule may be important at this stage as encapsulation facilitates more persistent colonisation and leads to higher mortality in animal models than is seen in isogenic acapsular mutants. Although not generally considered intracellular pathogens, GAS have been shown to penetrate and, in some cases, multiply within a variety of epithelial cell lines *in vitro*. Both M protein and SfbI are implicated in internalisation because of their fibronectin-binding capacities that bridge GAS to integrin receptors, promoting actin rearrangement by independent mechanisms and leading to invasion. The biological significance of these interactions is unclear, but they may facilitate deep-tissue invasion or be important in the persistence of GAS in the face of host defences or therapy.

Virulence Gene Regulators

In recent years it has become clear that complex regulatory circuits control virulence factor expression in GAS, allowing it to respond to environmental signals and adapt to various niches (reviewed by

Kreikemeyer, McIver and Podbielski 2003). The multiple gene regulator Mga is located upstream of the *emm* gene cassette and is thought to form part of a classic two-component regulatory signal transduction system, though the sensor remains unidentified. It controls transcription of itself and a variety of other genes including those encoding M and M-like proteins, C5a peptidase, SclA and Sic. Mga positively regulates itself and binds to a consensus sequence upstream of the gene it regulates, increasing expression in response to increased carbon dioxide concentrations, increased temperature and iron limitation. A further two-component system known as CsrRS (capsule synthesis regulator) or CovRS (control of virulence genes) has also been identified. This system represses the synthesis of capsule and several other virulence factors including streptokinase, SpeB and SLO and the CovRS operon itself. Recent microarray studies have indicated that this system may influence transcription directly or indirectly of as many as 15% of GAS genes (Graham *et al.* 2002). A further regulator, RofA, was first identified in an M6 strain as a positive regulator of SfbI in response to reduced oxygen, but it also negatively regulates SLS, SpeB and Mga. Nra, identified in an M49 strain shares 62% identity with RofA and shares many of its activities. A global regulator Rgg or RopB homologous to transcriptional regulators in other Gram-positive organisms has been identified and appears to affect the transcription of multiple virulence genes genome-wide through modulation of existing regulatory networks (Chaussee *et al.* 2003). Studies carried out to date have highlighted the complexity and interdependence of GAS regulatory circuits. The understanding of these is clearly in its infancy, and it will be crucial for a fuller understanding of GAS pathogenesis.

Host Immune Response to Infection

Protective immunity against GAS correlates with the presence of opsonising antibody against type-specific M protein. However, the paucity of infection in adults relative to children suggests that other mechanisms help to protect against infection. Secretory IgA against nonserotype-specific regions of M protein plays a role in host protection by preventing adhesion to mucosal surfaces. In addition, it is likely that immune responses to other streptococcal molecules have roles in protection. Thus, for example, a novel antigen generating opsonising protective antibody (Dale *et al.* 1999) has been reported in an M18 isolate, and surface molecules such as the C5a peptidase, SOF and the group A carbohydrate induce protective immune responses. Furthermore, antibodies against the GAS superantigens may be important in neutralising the toxic activity of these molecules.

Pathogenesis of Sequelae

Although a close link between GAS and rheumatic fever (RF) has been established for many years, the exact mechanism by which GAS evokes RF remains elusive. Molecular mimicry is assumed to be the reason for RF, and antigenic similarity between various GAS components, notably M protein, and components of human tissues such as heart, synovium, and the basal ganglia of brain could theoretically account for most manifestations of RF (Ayoub, Kotb and Cunningham 2000). Only certain strains of GAS appear capable of initiating the immune-mediated inflammatory reaction, related either to cross-reacting antibodies generated against streptococcal components or to the stimulation of cell-mediated immunity that leads to disease in susceptible hosts.

Like RF, acute poststreptococcal glomerulonephritis (APSGN) is associated with only some GAS strains and certain susceptible hosts. Again, the precise causative mechanisms are not clear. Renal injury associated with APSGN appears to be immunologically mediated, and antigenic similarities between human kidney and various streptococcal constituents (particularly M protein and fragments of the streptococcal cell membrane) that could generate cross-reactive antibodies have been investigated. However, other nonmutually exclusive mechanisms

such as immune complex deposition, interactions of streptococcal constituents such as SpeB and streptokinase with glomerular tissues and direct complement activation following the deposition of streptococcal antigens in glomeruli have also been proposed.

GBS Pathogenesis

Despite GBS being the predominant cause of invasive bacterial disease in the neonatal period, little is known about the molecular events that lead to invasive disease. The capsule is considered the most important virulence factor, and most isolates from invasive disease are encapsulated. The capsular polysaccharide inhibits the binding of the activated complement factor C3b to the bacterial surface, preventing the activation of the alternative complement pathway (Marques *et al.* 1992). GBS also produce a haemolysin (cytolysin) (Nizet 2002), and a surface protein, the C protein, has been extensively characterised. C protein is a complex of independently expressed antigens α and β , both of which elicit protective immunity in animal models. The function of the C protein remains unclear, although the β component binds nonspecifically to IgA and is presumed to interfere with opsonophagocytosis. Like GAS, *S. agalactiae* also harbours a C5a peptidase that interferes with leukocyte recruitment to sites of infection and hyaluronidase, protease and nuclease activities, though the roles, if any, of these molecules in pathogenesis are unclear. Recently completed GBS genome sequences have revealed an array of uncharacterised cell-wall-linked proteins and lipoproteins, many of which may be important in host interaction and pathogenesis.

Pathogenesis of Other β-Haemolytic Streptococci

Infection of humans with *S. dysgalactiae* subsp. *equisimilis* [human group G streptococcus (GGS)/group C streptococcus (GCS)] causes a spectrum of disease similar to that resulting from GAS infection. These organisms have been found to share many virulence determinants such as streptokinase, SLO, SLS, several superantigens, C5a peptidase, fibronectin-binding proteins, M proteins and hyaluronidase. An emerging theme in the field is the occurrence of horizontal gene transfer from human GGS/GCS to GAS and vice versa. The presence of GGS/GCS DNA fragments in GAS in genes such as those encoding hyaluronidase, streptokinase and M protein was observed some years ago, and it has recently become clear that many superantigen genes are also found in subsets of GGS/GCS (Sachse *et al.* 2002; Kalia and Bessen 2003). It is likely that this horizontal gene transfer plays a crucial role in the evolution and biology of these organisms with the potential to modify pathogenicity and serve as a source of antigenic variation.

Most work with the two *S. equi* subspecies has concerned itself with *S. equi* subsp. *equi*, resulting in the characterisation of many virulence factors equivalent to those seen in other β-haemolytic streptococci. Characterisation of *S. equi* subsp. *zooepidemicus* remains incomplete; however, the organisms are known to possess a fibronectin-binding protein and an M-like protein (SzP). In contrast to *S. equi* subsp. *equi*, the subspecies *zooepidemicus* appears to lack superantigens (Harrington, Sutcliffe and Chanter 2002). Indeed, this has been postulated as an explanation for the difference in disease severity observed between the subspecies.

Reports of streptococcal toxic shock-like syndrome in dogs have led to searches for GAS virulence gene equivalents in *S. canis* (DeWinter, Low and Prescott 1999), with little success to date. The factors involved in the pathogenesis of disease caused by *S. canis* consequently remain poorly understood.

Genomes, Genomics and Proteomics of β-Haemolytic Streptococci

At the time of writing, the genomic sequences of four GAS strains (one M1 isolate, two M3 isolates and one M18 isolate) and two GBS

strains (serotype III and V isolates) are completed and publicly available, with genomic sequencing of others likely to be completed shortly.

The first GAS sequence completed (M1) confirmed that the versatility of this pathogen is reflected in the presence of a huge array of putative virulence factors in GAS (>40) and identified the presence of four different bacteriophage genomes (Ferretti *et al.* 2001). These prophage genomes encode at least six potential virulence factors and emphasise the importance of bacteriophage in horizontal gene transfer and as a possible mechanism for generating new strains with increased pathogenic potential. Subsequent sequencing of other genomes confirmed that phage, phage-like elements and insertion sequences are the major sources of variation between genomes (Beres *et al.* 2002; Smoot *et al.* 2002; Nakagawa *et al.* 2003) and that the creation of distinct arrays of potential virulence factors by phage-mediated recombination events contributes to localised bursts of disease caused by strains marked by particular M types. A potential example of this is the increase in severe invasive disease caused by M3 isolates in recent years. Integration of the M3 genome sequence data with existing observations provided an insight into this – contemporary isolates of M3 express a particularly mitogenic superantigen variant (SpeA3) that is 50% more mitogenic *in vitro* than SpeA1 made by isolates recovered before the 1980s. They also harbour a phage encoding the superantigen SpeK and the extracellular phospholipase Sla not present in M3 isolates before 1987 and many also have the superantigen Ssa, again, not present in older isolates (Beres *et al.* 2002). The two *S. agalactiae* genomes also reveal the presence of potential virulence factors associated with mobile elements including bacteriophage, transposons and insertion sequences, again suggesting that horizontal gene transfer may play a crucial role in the emergence of hypervirulent clones (Glaser *et al.* 2002; Tettelin *et al.* 2002).

The use of comparative genomics, proteomics and microarray-based technologies promises to add substantially to current understanding of the β-haemolytic streptococci and provide means of rapidly identifying novel bacterial proteins that may participate in host–pathogen interactions or serve as therapeutic targets. For example, as described already, many new surface proteins have been identified from genome sequences (Reid *et al.* 2002). In addition, microarray technology is being used in GAS comparative genomic studies (Smoot *et al.* 2002) and in the analysis of differential gene expression (Smoot *et al.* 2001; Graham *et al.* 2002; Voyich *et al.* 2003), and proteomic approaches have been used to identify major outer surface proteins of GBS (Hughes *et al.* 2002).

EPIDEMIOLOGY OF β-HAEMOLYTIC STREPTOCOCCUS INFECTION

Our understanding of the epidemiology of β-haemolytic streptococcal infections and their related diseases is relatively poor compared with that of many other infectious diseases. Many countries with established infectious disease surveillance programmes undertake relatively little surveillance of diseases caused by these streptococci. However, most countries are expanding or modifying their surveillance programmes to include β-haemolytic streptococcal diseases, not least in the light of recent worrying trends in incidence.

To fully understand the epidemiology of these diseases in terms of how these organisms spread, host and strain characteristics of importance to onward transmission, disease severity and inter- and intraspecies competition for ecological niches, one would need to undertake the most comprehensive of investigations following a large cohort for a substantial period of time. Understanding these factors would allow us to develop effective prevention strategies. An important such measure, discussed in the section *Vaccines for β-haemolytic streptococcal disease*, is the introduction of a multivalent vaccine. Although existing M-typing data allow us to predict what proportion of disease according to current serotype distribution could be prevented, the possibility of serotype replacement occurring is

something which dramatically limits the impact of such a measure (Lipsitch 1999), a phenomenon witnessed for pneumococcal infection and suggested in at least one GAS carriage study (Kaplan, Wotton and Johnson 2001).

The Burden of Disease Caused by β -Haemolytic Streptococci

Superficial Infections

For the reasons specified above the bulk of incidence monitoring is focused at the severe end of streptococcal disease. Our understanding of the epidemiology of less severe but vastly common superficial infections is severely limited despite the substantial burden represented by these diseases, especially the ubiquitous streptococcal pharyngitis. Such diseases represent a significant burden on healthcare provision and also provide a constant reservoir for deeper-seated infections. Pharyngitis is one of the most common reasons for patients to consult their family practitioner. Acute tonsillitis and pharyngitis account for over 800 consultations per 10 000 patients annually, in addition to the economic impact of days missed from school or work (Royal College of General Practitioners 1999).

Since the end of the nineteenth century, clinicians in the United Kingdom have been required by law to notify local public health officials of the incidence of scarlet fever, among other conditions. Reports of scarlet fever plummeted dramatically since the mid-1900s, with between 50 000 and 130 000 reports per year being typically reported until the 1940s. Annual reports dropped dramatically, with around 2000 cases still reported each year (HPA 2004a).

Severe Disease Caused by β -Haemolytic Streptococci

Data from the United Kingdom indicate streptococci to be the fourth most common cause of septicaemia caused by bacterial or fungal pathogens, 15% of monomicrobial and 12% of polymicrobial positive blood cultures isolating a member of the *Streptococcus* genus (HPA 2003a). β -Haemolytic streptococci themselves accounted for 5% of blood culture isolations (HPA 2004b), a similar estimate to that from the United States (Diekema, Pfaller and Jones 2002), with rates of infection being highest for GBS bacteraemia at 1.8 per 100 000 population, substantially lower, however, than estimates in the United States of around 7.0 per 100 000 (Centers for Disease Control and Prevention 2003), although this includes other sterile-site isolations. Recent estimates of early-onset GBS disease incidence in countries without national screening programmes range from 0.48 in the United Kingdom to 1.95 in South Africa (Madhi *et al.* 2003; Heath *et al.* 2004), with current estimates in the United States of around 0.4 per 1000 live births (Centers for Disease Control and Prevention 2003).

In contrast, invasive GAS disease rates in the United States and United Kingdom are more similar, around 3.8 per 100 000 in 2003 (Centers for Disease Control and Prevention 2004a; HPA 2004c), the UK data being derived from a pan-European enhanced surveillance programme (Strep-EURO). Current estimates from Netherlands are also reasonably similar at 3.1 per 100 000 in 2003 (Vlaminckx *et al.* 2004).

Less widely available than for GAS and GBS, data for GGS from the United Kingdom suggest an incidence of GGS bacteraemia of just over 1 case per 100 000 population, with GCS being reported in 0.4 per 100 000.

Global Trends in Severe Diseases Caused by β -Haemolytic Streptococci

Since the mid-1980s, a proliferation of global reports has suggested an upturn in the incidence of severe diseases caused by β -haemolytic streptococci. Many possible explanations could account for this rise, including a proliferation of strains with additional virulence properties or a decrease in the proportion of the population with immunological

protection. A further factor fuelling the rise in opportunistic infections generally is the enlargement of the pool of susceptible individuals resulting from improved medical treatments for many life-threatening conditions (Cohen 2000). This has been borne out in the rises in incidence seen for many nonvaccine-preventable diseases caused by a range of bacterial and fungal pathogens.

Trends in Invasive GAS Disease

Many reports published during the 1980s and 1990s suggested resurgence of invasive diseases caused by GAS. The United States was among the first to document this upturn, although some estimates were based on restricted populations. Subsequent findings from multistate sentinel surveillance conducted in the second half of the 1990s failed to show any clear trends in incidence (O'Brien *et al.* 2002). Surveillance activities in Canada during the early 1990s identified such an increase, although rates of disease were relatively low (Kaul *et al.* 1997). Norway was among the first European countries to report an increase in severe GAS infections during the late 1980s (Martin and Høiby 1990). Several other European countries subsequently stepped up surveillance activities and began to show similar trends. Among these was Sweden, where the incidence of invasive GAS increased at the end of the 1980s and again during the mid-1990s (Svensson *et al.* 2000). The United Kingdom also saw rises of GAS bacteraemia, from just over 1 per 100 000 in the early 1990s to a figure approaching 2 per 100 000 in 2002 (Figure 1.1). Other European countries reported more equivocal changes – surveillance of bacteraemia in Netherlands showing a fall in invasive GAS disease from the late 1990s to 2003 (Vlaminckx *et al.* 2004). National incidence estimates from Denmark have shown an unclear pattern, although recent upturns have been reported (Statens Serum Institut 2002).

Trends in Invasive GBS Disease

The introduction of neonatal screening programmes has had a substantial impact on the incidence of neonatal GBS disease in the United States (Schrag *et al.* 2000, 2002). Centers for Disease Control and Prevention's (CDC) Active Bacterial Core (ABC) programme showed a dramatic fall in the incidence of early-onset disease between 1993 and 1997 as increasing numbers of hospitals implemented antimicrobial prophylaxis, with little change in late-onset disease (Schuchat 1999).

Neonatal disease aside, trends in overall GBS infection point to a general rise in incidence, including in the United States (Centers for Disease Control and Prevention 1999, 2004b). Surveillance of bacteraemia in England and Wales shows a 50% rise in reporting rates from the early 1990s to the early 2000s (Figure 1.1).

Figure 1.1 Annual rate of reports of bacteraemia caused by β -haemolytic streptococci – England and Wales. Source: Health Protection Agency.

Trends in Invasive GGS and GCS Disease

Few countries undertake national surveillance of invasive GGS or GCS disease. Population-based surveillance from England and Wales has shown some interesting trends in GCS in particular, which has shown a steeper rise in rates of reports than any of the other β -haemolytic streptococci, from 0.16 per 100 000 in 1990 to 0.42 per 100 000 in 2002 (Figure 1.1). Rates of GGS bacteraemia have showed a similar magnitude of rise to that for GAS, from 0.73 to 1.15 per 100 000 over the same time period.

CLINICAL ASPECTS OF β -HAEMOLYTIC STREPTOCOCCAL INFECTION

Clinical Presentation of Disease

Superficial Infections

All β -haemolytic streptococci cause colonisation and superficial infection of epithelial and mucosal surfaces. The clinical scenarios are summarised in Table 1.3 and, for the purposes of this description, include all conditions affecting the upper respiratory tract. These infections are only rarely associated with bacteraemia. The occurrence of streptococcal bacteraemia in a patient with streptococcal pharyngitis should prompt a search for additional, more deep-seated foci of infection.

Streptococcus pyogenes accounts for 15–30% of pharyngitis cases (Gwaltney and Bisno 2000). The classical presentation is of

bilateral acute purulent tonsillitis with painful cervical lymphadenopathy and fever. With prompt antibiotic treatment the illness normally lasts less than 5 days. Outbreaks have occurred in institutionalised settings such as military recruitment centres. Illness is common in the young, and the incidence declines dramatically with age. In children *S. pyogenes* also is a recognised cause of perianal disease and vulvovaginitis, presenting as pruritus with dysuria and discharge in the latter case (Mogielnicki, Schwartzman and Elliott 2000; Stricker, Navratil and Sennhauser 2003). Most sufferers have throat carriage of *S. pyogenes* or might have had recent contact with throat carriers. Outbreaks of both pharyngitis and perineal disease are common in the winter months in temperate regions.

Impetigo is the other most common superficial manifestation of β -haemolytic streptococcal infection. The condition presents with small-to-medium-sized reddish papules, which when de-roofed reveal a crusting yellow/golden discharge. Often complicated by coexisting *Streptococcus aureus* infection, the condition is contagious and spreads rapidly amongst children living in proximity to each other. Although group C streptococci (GCS) and G group streptococci (GGS) are recognised causes of impetigo in tropical climates, this would be unusual in temperate areas (Belcher *et al.* 1977; Lawrence *et al.* 1979).

Complications of Superficial Disease

In addition to the direct effects of clinical infection several major immunological syndromes are associated with or follow superficial streptococcal infection, such as scarlet fever, RF, poststreptococcal reactive arthritis, poststreptococcal glomerulonephritis and guttate psoriasis. It is extremely rare for true superficial streptococcal disease to be associated with streptococcal toxic shock syndrome (STSS). Most cases where pharyngitis is diagnosed in association with STSS often also have bacteraemia or additional foci of infection.

Table 1.3 Superficial infections associated with β -haemolytic streptococci

	Group A	Group B	Group C	Group G
Pharyngitis	+++	–	+	(+)
Otitis externa	+	–	–	–
Otitis media	(+)	–	–	–
Laryngitis	+	–	(+)	–
Vulvovaginitis/perianal	+++	+ ^a	–	–
Impetigo	+++	(+)	(+) ^b	+ ^b

+++ , common identified bacterial cause; +, recognised but uncommon pathogen; (+), rare or poorly described; –, not known to be associated.

^a Association with diabetes mellitus.

^b Reported in tropical climates.

Invasive GAS Infections (Figure 1.2)

Invasive GAS disease has been the subject of several studies since the late 1980s and early 1990s because of its apparent reemergence during this period. Although the common manifestation of invasive GAS disease is cellulitis and other types of skin and soft-tissue infections (almost 50% of invasive disease cases), it is notoriously difficult to diagnose microbiologically because bacterial isolates are seldom recovered from infected tissue. Most invasive infections are confirmed because of bacteraemia.

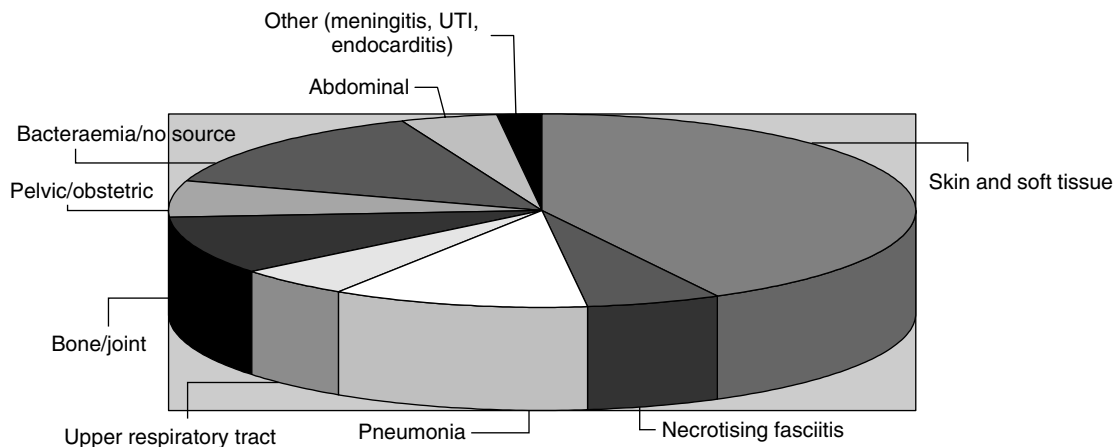

Figure 1.2 Clinical syndromes associated with invasive GAS disease. Adapted from data in Kristensen and Schonheyder (1995), Davies *et al.* (1996) and Zurawski *et al.* (1998).

Cellulitis, which spreads along the long axis of a limb, rather than in a centrifugal pattern, is more likely to be streptococcal than staphylococcal. Furthermore, cellulitis occurring in a butterfly distribution on the face (erysipelas) is almost always due to the GAS. Occasionally, cracks between digits, or behind the ears, reveal likely portals of entry. Large-colony GCS and GGS, as well as GBS, cause cellulitis, although the incidence of premorbid illness or advanced age is more common in these latter groups.

In some circumstances bacteria spread between the fascial planes, along fibrous and fatty connective tissues, which separate muscle bundles. This results in necrotising fasciitis (Plate 1), where connective tissues become inflamed and rapidly necrotic. In several recent series necrotising fasciitis has accounted for approximately 6% of all invasive GAS cases (Davies *et al.* 1996; Ben-Abraham *et al.* 2002). Streptococcal necrotising fasciitis often arises because of bacteraemic seeding into fascia underlying otherwise quite normal-looking skin. In some cases there is history of prior blunt trauma to an infected region. In other cases there is an obvious portal of entry, such as recent surgery or varicella. It is useful to distinguish streptococcal necrotising fasciitis from synergistic or mixed-infection necrotising infections. Streptococcal necrotising fasciitis often occurs as a pure infection and may arise in previously healthy individuals, often affecting the limbs, resulting in extreme pain in a febrile or septic patient. In contrast, synergistic necrotising fasciitis tends to follow surgery or debilitation and occurs in areas where enteric and anaerobic bacteria have opportunity to mix with normal skin flora, such as abdominal and groin wounds.

Although less common than skin and soft-tissue infection, puerperal sepsis with endometritis and pneumonia due to *S. pyogenes* still occur and should not go unrecognised (Zurawski *et al.* 1998; Drummond *et al.* 2000). Epiglottitis because of GAS infection is also well recognised in adults (Trollfors *et al.* 1998). Importantly, a significant proportion of invasive GAS disease occurs as isolated bacteraemia in a patient without other apparent focus. This does not obviate the need for careful inspection of the whole patient in an effort to rule out areas of tissue necrosis.

Predisposition to Invasive GAS Disease

Although capable of occurring during any stage of life, invasive GAS disease is more common in early (0–4 years) and later life (>65 years). As for the other β -haemolytic streptococci, incidence in males generally exceeds that in females (HPA 2003b).

Many underlying medical conditions have been associated with increased risk of invasive GAS disease (Table 1.4). Some, such as varicella, provide obvious portals of entry for the bacterium, whilst

Figure 1.3 Weekly distribution of *Streptococcus pyogenes* bacteraemia – England, Wales, Northern Ireland and Channel Islands, 1995–2003. Source: Health Protection Agency.

others appear to result in more subtle immunoparesis. Injecting-drug users are now recognised as a major risk group for invasive GAS disease, accounting for up to a fifth of cases in some countries (Factor *et al.* 2003; Lamagni *et al.* 2004). Most infections are thought to be sporadic community-acquired infections, around 5% resulting from nosocomial infection. However, importantly, in approximately 30% of invasive disease cases there is no underlying medical or other predisposing condition. This distinguishes the GAS from other β -haemolytic streptococci.

Invasive GAS infections exhibit a distinct seasonal pattern, with striking late winter/early spring peaks (Figure 1.3). How much of this can be attributed to winter vulnerability to GAS pharyngitis and carriage and how much is likely to be the result of postviral infection susceptibility to bacterial infections is unclear.

Complications of Invasive GAS Disease

The mortality from invasive GAS disease is high (14–27%) and rises considerably with patient age and number of organ system failures, reaching 80% in the presence of STSS (Davies *et al.* 1996; Efstratiou 2000). STSS complicates roughly 10–15% of all cases of invasive GAS disease, accounting for most patients with invasive GAS disease who require admission to an intensive care facility (Eriksson *et al.* 1998).

Streptococcal Toxic Shock Syndrome

In the late 1980s it was recognised that invasive GAS disease could be associated with a syndrome of multiorgan system failure coupled with erythematous blanching rash. The similarity to staphylococcal toxic shock syndrome (described a decade earlier) was striking, particularly as both conditions were associated with a rash that subsequently desquamates and as both conditions were associated with bacteria that produced superantigenic exotoxins. Streptococcal pyrogenic exotoxin A (SPEA) was particularly implicated in GAS infections (Cone *et al.* 1987; Stevens *et al.* 1989).

Scarlet fever: *S. pyogenes* produces many phage-encoded classical superantigens, in particular, SPEA and SPEC. Intriguingly, isolates producing these toxins historically were linked to the development of scarlet fever, a disease accompanying streptococcal pharyngitis in children that was characterised by fever and widespread blanching erythema. A similar, more feared syndrome known as septic scarlet fever could accompany invasive streptococcal infection, classically

Table 1.5 Clinical syndrome of STSS (from Working Group on Severe Streptococcal Infections 1993)

<i>Symptoms</i>
Renal impairment (raised creatinine)
Coagulopathy or low platelets
Liver dysfunction (raised transaminases)

puerperal fever, and often resulted in death from multiorgan failure (Katz and Morens 1992). Although the incidence of scarlet fever regressed markedly during the twentieth century, it seems likely that STSS represents the reemergence (or re-recognition) of septic scarlet fever.

Modern STSS: In 1990 a consensus definition for the diagnosis of STSS was established (Working Group on Severe Streptococcal Infections 1993) (Table 1.5). Epidemiological studies suggested that 10–15% of all invasive disease cases were complicated by STSS. The development of STSS became an important marker of subsequent morbidity and mortality, and many therapeutic approaches were developed specifically for the management of STSS cases. Although a disproportionately large number of STSS isolates are found to be positive for the *speA* gene, this may be caused by a preponderance of certain clones sharing common M serotypes (Cleary *et al.* 1992; Musser *et al.* 1993). Cases of STSS caused by *speA* and *speC* strains are recognised (Hsueh *et al.* 1998). Recent advances in bacterial genomics have led to the identification of many novel *S. pyogenes* superantigen genes, several of which appear to be chromosomal rather than phage derived (Proft and Fraser 2003). It seems plausible that many cases of STSS are attributable to superantigens other than SPEA or SPEC.

Invasive Disease due to GCS and GGS

Recognition of invasive group C and G β -haemolytic streptococcal disease is rising, though dependent largely on the identification of bacteraemic cases (Kristensen and Schonheyder 1995; Hindsholm and Schonheyder 2002; Sylvestsky *et al.* 2002). Unlike GAS disease, diseases due to GCS and GGS usually have comorbidity from other medical conditions, with cases being common in those over 75 years of age and in males (Figure 1.4).

The reported mortality from invasive GCS or GGS bacteraemia is 15–23%, slightly lower than that reported for GAS disease. There have been sporadic reports of toxic shock-like syndromes associated with group C and G infections, and very recently a novel set of superantigen toxin genes has been identified in GCS (Wagner *et al.* 1996; Hirose *et al.* 1997; Proft and Fraser 2003).

Invasive Disease due to GBS

Although predominantly feared as a neonatal disease, GBS can also cause invasive infection in adults.

Figure 1.4 Age-specific rates of GGS bacteraemia reports – England, Wales and Northern Ireland, 2002. Source: Health Protection Agency.

Neonatal GBS Disease

A full discussion of the neonatal presentation of GBS disease is beyond the scope of this chapter. Between 65 and 80% of cases are early onset and arise from colonisation during or at the time of birth (Kalliola *et al.* 1999; Madhi *et al.* 2003; Heath *et al.* 2004). Early-onset GBS disease is defined as that occurring within the first 7 days of life, although most cases are diagnosed within the first 48 hours of life. Because of this several countries have instituted intrapartum antibiotic prophylaxis for women known to be colonised with GBS or those assessed to be at high risk. Though still under debate in many countries, the implementation of intrapartum antibiotic prophylaxis in the United States was followed by a 65% reduction in early-onset neonatal GBS infection, which is otherwise associated with a mortality rate of 28% (Schrag *et al.* 2000). Most infections present as bacteraemia, without identified focus of infection, though meningitis and pneumonia are also frequent (Kalliola *et al.* 1999). Late-onset disease (7–90 days) is thought to occur because of postnatal transmission of GBS, potentially from within hospital sources.

Many maternal and pregnancy-related factors have been associated with increased risk of neonatal GBS infection, including preterm birth and prolonged rupture of membranes (Heath *et al.* 2004). Black ethnicity is also associated with increased risk of GBS infection, as is multiple births, although it is unclear whether these are acting as risks independent of each other.

Adult GBS Disease

GBS also cause adult invasive disease, though mainly in those with predisposing factors, in particular diabetes (11–49%), cancer, alcoholism, HIV infection, the bedridden/elderly or during pregnancy. The most common sources of bacteraemia in nonpregnant adults are pneumonia, soft-tissue infections (including wound infections) and urinary tract infection, although bacteraemia without identified source is also common (Farley *et al.* 1993; Trivalle *et al.* 1998; Larppanichpoonphol and Watanakunakorn 2001). Amongst pregnant women the risk of invasive GBS bacteraemia is also increased – pregnant women account for approximately 20% of all cases of GBS bacteraemia amongst adults (Farley *et al.* 1993). The introduction of intrapartum antibiotic prophylaxis has reduced the incidence of pregnancy-related invasive GBS disease by 21% in some parts of the United States (Schrag *et al.* 2000). Aside from diseases in women of

childbearing age, adult and childhood infection is more common in males than females (HPA 2003b).

Immunologically Mediated Disease: Nonsuppurative Sequelae of β -Haemolytic Streptococcal Disease

In addition to toxin-mediated complications, such as scarlet fever and STSS, GAS infection can also be complicated by defined postinfectious sequelae. Although the aetiology of these heterogeneous conditions is poorly understood, it is likely that some, if not all, result from cross-reactive T- and B-cell epitopes shared by streptococcal cell wall and human matrix protein antigens. It is also possible that bacterial superantigens drive some of these conditions in susceptible individuals.

A full description of all these conditions is beyond the scope of this chapter. The references in Table 1.6 provide good overviews of each subject.

Rheumatic Fever

RF affects 1–4% of children with untreated streptococcal pharyngitis and is a major cause worldwide of acquired cardiovascular disease, with an incidence of 100–200 per 100 000 children in countries where RF is endemic (Guilherme *et al.* 2000; Olivier 2000). Although the incidence of RF in developed countries is usually low (1–2 per 100 000), the disease occurs with marked frequency amongst the economically deprived native communities of New Zealand and Australia. RF can also cause outbreaks in affluent communities: an eightfold increase in RF incidence occurred across Utah and other states within the United States in the late 1980s, leading to carditis in over 90% of cases (Veasy *et al.* 1987; Bisno 1991). Rheumatic heart disease follows acute RF in 30–50% of cases (Majeed *et al.* 1992; Guilherme *et al.* 2000). The so-called rheumatogenic *S. pyogenes* serotypes have been associated with outbreaks of RF (M1 and M18 in the United States and M1, M3 and M5 in the United Kingdom), although RF can be associated with a broad range of strains. Epidemiological study is hampered because isolates are rarely available for typing (Veasy *et al.* 1987; Colman *et al.* 1993). Study of the pathogenesis of RF has focused on the role of streptococcal M protein. Cases with arthritis not meeting the acknowledged criteria for RF are often designated as poststreptococcal reactive arthritis. Here, the risk of cardiac involvement appears low (Shulman and Ayoub 2002). The diagnosis of RF requires clinical recognition of a collection of signs coupled with laboratory evidence of recent streptococcal infection (Table 1.7). Although numerous cases suggest that acute RF follows GAS infection of the skin, best-documented cases and outbreaks have followed episodes of pharyngitis.

It is difficult to predict how RF may evolve in the coming years. It is not clear whether the epidemic outbreaks or the observed rare cases are aberrations in the generally declining profile currently observed in developed countries or whether there is a true risk of resurgence of the disease. Consequently, accurate identification of GAS pharyngitis and follow-up of rheumatogenic strains with their appropriate treatment are still important (Olivier 2000).

LABORATORY DIAGNOSIS AND IDENTIFICATION

Serological grouping provides the first precise method for identifying the β -haemolytic streptococci, in particular the human pathogens of Lancefield groups A, B, C and G. The main characteristics of these β -haemolytic streptococci are summarised in Table 1.8. Isolates from primary culture are traditionally identified by colony morphology, Gram stain, catalase test and Lancefield grouping. If Lancefield grouping does not provide sufficient identification, full biochemical identification may be obtained usually using a commercial identification system. *Streptococcus pyogenes* is identified in a diagnostic laboratory from its polysaccharide group A antigen, using commercial grouping systems. Presumptive identification is usually made by bacitracin susceptibility or pyrrolidonylamidase activity. *Streptococcus pyogenes* is the only species within the genus that is positive for both tests (Facklam 2002). *Streptococcus agalactiae* is the most common cause of neonatal sepsis and is the only species that carries the Lancefield group B antigen. Lancefield grouping usually identifies the organism, but the organism can also be identified presumptively by the CAMP test and hippurate hydrolysis. *Streptococcus dysgalactiae* subsp. *equisimilis* is the revised taxonomic species for the human streptococci of Lancefield group C (*S. equisimilis*) and group G (nameless). Detection of the group antigen in combination with the phenotypic characteristics will subdivide these organisms into the appropriate species (Table 1.8). Studies have also revealed that strains of Lancefield group L should also be included within this species. To complicate this even further some strains of *S. dysgalactiae* subsp. *equisimilis* possess the group A antigen. Therefore, the group antigen can only be used as an aid in species identification. The phenotypic tests listed in Table 1.8 should be used, together with the haemolytic reaction and group antigen, to identify the species.

Streptococcus equi subsp. *equi* is the classic cause of strangles in horses. Identification of the species is again based upon the phenotypic test reactions and demonstration of the group C antigen. *Streptococcus equi* subsp. *zooepidemicus* is usually identified according to Lancefield group and phenotypic profile. The animal pathogen *S. canis* carries

the group G antigen. *Streptococcus porcinus* may cause difficulties in identification as it carries the group E, P, U or V antigen and also cross-reacts with group B sera in commercial kit systems.

Rapid Identification Assays for β -Haemolytic Streptococci

The signs and symptoms of pharyngitis caused in particular by GAS can be nonspecific, hampering accurate clinical diagnosis. Microbiological investigation offers the most robust diagnostic route, although not always feasible. A significant limitation of culturing throat swabs is the delay in obtaining the results. In the early 1980s commercial rapid antigen tests were developed for detecting GAS directly from throat swabs. These became quite widely used in the United States in particular (Gerber and Shulman 2004). Most of these kits exhibit high specificities; however, there is considerable variability in sensitivity. Current published data are inadequate to allow definitive conclusions to be made regarding the relative performance characteristics of these kits, in particular for GAS pharyngitis. Also, the rarity of serious consequences of acute GAS pharyngitis also suggests the need for careful cost–benefit and risk–benefit analyses of different diagnostic strategies in various clinical settings.

Given the importance of GBS as a cause of neonatal sepsis, point-of-care or rapid laboratory tests for GBS have been developed in recent years primarily for identifying GBS-colonised women in labour. These tests are used in the United States; however, their use in Europe is somewhat limited. Identification of GBS-colonised women is critical to the prevention of GBS neonatal infections. Currently, antenatal screening culture using broth culture in selective medium is the gold standard for detecting anogenital GBS colonisation. Rapid tests have been developed, but again they lack specificity and sensitivity and have yet to offer a potential substitute for culture. GBS-specific polymerase chain reaction (PCR)-based assays have demonstrated better sensitivity than those for GAS, but they require complicated procedures that are not applicable to clinical use. More promising results have emerged from the development of a rapid assay using the LightCycler technology (Bergeron *et al.* 2000). It was found that GBS could be detected rapidly and reliably by a PCR assay of combined vaginal and anal secretions from pregnant women at the time of delivery. The use of such technology at the time of delivery is, however, not entirely practical, and simpler assays are currently under development using technologies such as microfluidics.

Typing of β -Haemolytic Streptococci

Many methods have been developed for the serological classification of the β -haemolytic streptococci, in particular for GAS, GBS, GCS

and GGS, based primarily on the characterisation of cell-wall protein and polysaccharide antigens.

Typing of GAS

The best-known scheme for GAS is that based upon the characterisation of the T- and M-protein antigens, as developed by Griffith (1934) and Lancefield (1962). The variable sequences of the surface-exposed amino terminal end of the M protein provide the basis for the classic M typing scheme. Thus far, there are more than 100 validated M proteins amongst GAS and 30 T-protein antigens. The correlation between M and T type is not always clear. For instance, for each T type more than one M type can exist, and to further complicate matters, an M-type strain can express one or more different T-type antigens (Johnson and Kaplan 1993). Approximately 50% of GAS strains also produce an apoproteinase, an enzyme that causes mammalian serum to increase in opacity. This reaction is called the serum opacity factor (OF), and the enzyme responsible is referred to as OF. The OF has proved useful for the serological identification of GAS. Antibody to OF is specific in its inhibition of the opacity reaction of the M type producing it, and this characteristic has proved extremely useful as a supplementary aid to the classical typing scheme. Table 1.9 summarises the common reactions observed amongst GAS currently isolated within the United Kingdom and the relationship of T, M and OF antigens. Most epidemiological studies classify the organisms by M type, but it is sometimes difficult to identify the M-protein types in this way because of the unavailability of typing reagents and difficulties in their preparation and maintenance.

Molecular typing is now increasingly replacing classical serological methods for typing GAS, with few national reference centres still using the classical schemes. Sequencing of the *emm* gene, which encodes the M protein, has now become the key method for typing

Table 1.9 Some common group A streptococcus (GAS) M types (in boldface) within the United Kingdom and Europe and their related T and OF antigens

T pattern	Opacity factor	
	Positive	Negative
1	68	1
3/13/B3264	73, 77, 82, 83, 89	3, 33, 52, 53
4	4, 48, 60, 63	24, 26
5/27/44	82	5
12	22, 62, 66, 76	12
28	28, 87	–

GAS. Currently, more than 150 validated *emm* types exist. The extensive variability within the N-terminus of *emm* genes forms the basis for distinguishing between the different *emm* types. Depending on the *emm* genotype between 160 and 660 nucleotide bases are sequenced from the 5'-terminal end and matched with available sequences in the *emm* gene database (<http://www.cdc.gov/ncidod/biotech/strep/strepindex.html>). Two strains are regarded to represent the same *emm* type if they share greater than or equal to 95% identity in the N-terminal end (Beall, Facklam and Thompson 1996; Facklam *et al.* 2002).

There are primarily four major subfamilies of *emm* genes that are defined by sequence differences within the 3' end encoding the peptidoglycan-spanning domain (Hollingshead *et al.* 1993). The chromosomal arrangement of *emm* subfamily genes reveals five major *emm* patterns, denoted *emm* A to E (Bessen *et al.* 2000). Patterns B and C are rare and are currently grouped with *emm* pattern A strains. A GAS isolate has one, two or three *emm* genes lying in tandem on the chromosome, and each gene differs in sequence from the others. In strains having three *emm* genes the determinants of *emm* type lie within the central *emm* locus. The *emm* pattern serves as a genotypic marker for tissue-site preferences amongst GAS strains.

Most GAS *emm* sequence types represent M-protein types that are widely distributed according to geographic region. This information is vital to researchers currently formulating multivalent M-protein vaccines representative of common circulating GAS isolates.

Several molecular subtyping methods have been used to characterise and measure the genetic diversity of these organisms. These include multilocus sequence typing (MLST), restriction endonuclease analysis of genomic DNA, ribotyping, random-amplified polymorphic DNA (RAPD) fingerprinting, PCR-restriction fragment length polymorphism (PCR-RFLP) analysis of the *emm* gene, pulsed-field gel electrophoresis (PFGE) and fluorescent amplified fragment length polymorphism (FAFLP) analysis. The most reproducible of these methods, PFGE, is time consuming and labour intensive. The PCR-based methods are poorly reproducible. FAFLP is a modification of the amplified fragment length polymorphism analysis (AFLP) methodology using a fluorescently labelled primer and has been used to characterise GAS isolates from an outbreak of invasive disease and was found to be an effective and more discriminatory method than PFGE. As well as being able to distinguish between different M types, the method was also able to subtype isolates within an M type (Desai *et al.* 1999).

MLST is a relatively new tool for the molecular typing of GAS strains (Enright *et al.* 2001). The main advantage of MLST over gel-based methods is that the sequence data, which are generated for a series of neutral housekeeping loci, are unambiguous, electronically portable and readily queried via the Internet (<http://www.mlst.net>). A recent study by McGregor *et al.* (2004) has documented a comprehensive catalogue of MLST sequence types (STs) and *emm* patterns for most of the known *emm* types and thus has provided the basis for addressing questions on the population structure of GAS. In brief *emm* pattern D and E strains account for greater than 80% of *emm* types, and therefore, from a global perspective, these strains are said to be of medical importance. The classic throat strains (*emm* patterns A–C) displayed the least diversity.

Typing of GCS and GGS

Early typing methods for group C and G streptococci were based upon bacteriophage typing (Vereanu and Mihalcu 1979) and bacteriocins (Tagg and Wong 1983). A serological typing scheme described in the 1980s (Efstratiou 1983) can subdivide GCS and GGS of human origin into more than 20 different T-protein types. M proteins described amongst these isolates have also been used in a complementary typing scheme and are clinically relevant in view of their virulence characteristics (Efstratiou *et al.* 1989). However, these schemes have only been

used in specialist reference centres (e.g. in the United Kingdom and also in Thailand where GCS and GGS infections exceed those of GAS). Other typing methods for these streptococci have also been explored, but M typing and molecular typing (PFGE and ribotyping) appeared to be the most discriminating (Efstratiou 1997; Ikebe *et al.* 2004). Ribotyping was useful for examining representative isolates from three different outbreaks caused by one serotype T204 in the United Kingdom and overseas (Efstratiou 1997). This technique has also been successfully applied to the outbreaks caused by *S. equi* subsp. *zooepidemicus* in humans (Francis *et al.* 1993). In this instance ribotyping was useful because phenotypic typing schemes for *S. equi* subsp. *zooepidemicus* are unavailable.

Because the *emm* genes of GAS and GCS/GGS share some homology *emm*-based sequence typing has also been described for these organisms and is based upon the heterogeneity of the 5' ends of the gene, which give rise to different STs. Approximately 40 *emm* types of GGS and GCS have thus far been identified (<http://www.cdc.gov/ncidod/biotech/strep/emmtypes.htm>). However, in contrast to GAS, little is known about which *emm* types are dominant in the GGS/GCS population and genetic diversity within an *emm* type, whether *emm* types represent closely related groups as reported for GAS (Enright *et al.* 2001) or whether particular *emm* types are associated with invasive disease. Recent typing studies have shown the distribution of these STs amongst strains from invasive disease, with the emergence of two novel types (Cohen-Poradosu *et al.* 2004).

An important distinguishing feature of GAS and GCS/GGS lies in the relationship between *emm* type and clone (Kalia *et al.* 2001). Among GAS most isolates of a given *emm* type are clones or form a clonal complex, as defined by MLST STs with greater than or equal to five housekeeping alleles in common (Enright *et al.* 2001). In contrast, GCS and GGS have distinct allelic profiles and only one pair of isolates bearing the same *emm* type has similar genotypes (Kalia *et al.* 2001).

Typing of GBS

Serotyping has been traditionally the predominant method used to classify GBS. Type-specific capsular polysaccharide antigens allow GBS to be classified into nine serotypes – Ia, Ib, II–VIII – and there are also three protein antigens that are serologically useful – c, R and X. Serotype III strains are of particular importance as they are responsible for most infections, including meningitis in neonates worldwide (Kalliola *et al.* 1999; Davies *et al.* 2001; Dahl, Tessin and Trollfors 2003; Weisner *et al.* 2004). Thus, serotyping offers low discrimination for these organisms. Bacteriophage typing was developed in the 1970s primarily to enhance the power of serotyping. But again phage typing is also somewhat limited in that there is a high incidence of nontypability. The method itself is cumbersome and requires rigid quality control with the use of specific reagents (Colman 1988).

In recent years there has been a shift towards molecular methods for typing GBS. Diverse lineages of, for example, serotype III strains can be distinguished with multilocus enzyme electrophoresis (MLE), PFGE and restriction digest pattern analysis, ribotyping. MLE was found not to be useful for differentiating serotype III because most (particularly from patients with invasive disease) grouped into a single MLE type. More recently, MLST has been applied to a collection of globally and ecologically diverse human GBS strains that included representatives of the capsular serotypes Ia, Ib, II, III, V, VI and VIII. A website was also established for the storage of GBS allelic profiles from across the globe and can be accessed at <http://sagalactiae.mlst.net>. Seven housekeeping genes are amplified, and the combination of alleles at the seven loci provides an allelic profile or ST for each strain. Most of the strains (66%) are assigned to four major STs. ST-1 and ST-19 are significantly associated with asymptomatic carriage, whereas ST-23 includes both carriage and invasive strains. All

isolates of ST-17 are serotype III clones, and this ST apparently defines a homogenous clone that had a strong association with neonatal invasive infections. The variation in serotype with a single ST and the presence of genetically diverse isolates with the same serotype suggested that the capsular biosynthesis genes of GBS are subjected to relatively frequent horizontal gene transfer, as observed with *S. pneumoniae* (Coffey *et al.* 1998; Jones *et al.* 2003). A single gene therefore confers serotype specificity in GBS of capsular types III and Ia (Chaffin *et al.* 2000), and recombinational replacement of this gene with that from an isolate of a different type results in a change of capsular type. Therefore, confirmation of serotype identity is possible when a DNA sequence-based serotyping method is used, such as the one described recently by Kong *et al.* (2003). They used three sets of markers – the capsular polysaccharide synthesis (*cps*) gene cluster, surface protein antigens and mobile genetic elements. The use of three sets of markers resulted in a highly discriminatory typing scheme for GBS as it provides useful phenotypic data, including antigenic composition, thus important for epidemiological surveillance studies especially in relation to potential GBS vaccine use. Further studies are needed on the distribution of these mobile genetic elements and their associations with virulence and pathogenesis of GBS disease.

International Quality Assurance Programmes for GAS Characterisation

The various reported additions to the classical serotyping methods for these organisms have increased the likelihood of differences both in the determination of previously unknown types and in the confirmation of previously unrecognised serotypes. Although international reference laboratories have informally exchanged strains and confirmed the identification of unique isolates for many years, the ‘new’ molecular techniques have made precise confirmation and agreement even more important to clinical and epidemiological laboratory research. The first international quality assurance programme was established amongst six major international streptococcal reference centres (two in United States and one each in United Kingdom, Canada, New Zealand and Czech Republic). Five distributions were made, and both traditional and genotypic methods were used. The correlation of results between centres was excellent, albeit with a few differences noted. This continuing self-evaluation demonstrated the importance of comparability, verification, standardisation and agreement of methods amongst reference centres in identifying GAS M and *emm* types. The results from this programme also demonstrate and emphasise the importance of precisely defined criteria for validating recognised and accepted types of GAS (Efstratiou *et al.* 2000). There have been more recent distributions amongst European and other typing centres (20 centres), within the remit of a pan-European programme ‘Severe *Streptococcus pyogenes* infections in Europe’ (Schalén 2002).

ANTIMICROBIAL RESISTANCE

β-Haemolytic streptococci of Lancefield groups A, B, C and G remain exquisitely sensitive to penicillin and other β-lactams, but resistance to sulphonamides and tetracyclines has been recognised since the Second World War. Penicillin has, therefore, always been the drug of choice for most infections caused by β-haemolytic streptococci, but macrolide compounds, including erythromycin, clarithromycin, roxithromycin and azithromycin, have been good alternatives in penicillin-allergic patients.

β-Lactam Resistance

In striking contrast to erythromycin no increase in penicillin resistance has been observed *in vitro* among clinical isolates of β-haemolytic

streptococci, in particular GAS. Penicillin tolerance, however, amongst GAS, defined as an increased mean bactericidal concentration (MBC) : minimum inhibitory concentration (MIC) ratio (usually >16), has been reported at a higher frequency in patients who were clinical treatment failures than in those successfully treated for pharyngitis (Holm 2000). The presence of β-lactamase-producing bacteria in the throat has been assumed to be another significant factor in the high failure rate of penicillin V therapy. Although many β-lactamase-producing bacteria are not pathogenic to this particular niche, they can act as indirect pathogens through their capacity to inactivate penicillin V administered to eliminate β-haemolytic streptococci.

Macrolide Resistance

Macrolide resistance amongst GAS has increased between the 1990s and early 2000s in many countries (Seppala *et al.* 1992; Cornaglia *et al.* 1998; Garcia-Rey *et al.* 2002). The resistance is caused by two different mechanisms: target-site modification (Weisblum 1985) and active drug efflux (Sutcliffe, Tait-Kamradt and Wondrack 1996). Target-site modification is mediated by a methylase enzyme that reduces binding of macrolides, lincosamides and streptogramin B antibiotics (MLS_B resistance) to their target site in the bacterial ribosome, giving rise to the constitutive (CR) and inducible (IR) MLS_B resistance phenotypes (Weisblum 1985). Another phenotype called noninducible (NI) conferring low-level resistance to erythromycin (MIC <16 mg/L) and to other 14- or 15-membered compounds but sensitive to the 16-membered macrolides has also been described (Seppala *et al.* 1993). This phenotype is invariably susceptible to clindamycin and has been designated as NI because of an efflux mechanism.

Since the identification of plasmid-mediated MLS resistance in the *Streptococcus* sp. in the early 1970s it has been shown that conjugation is the most common dissemination mode of resistance. Transduction may also contribute to the spread of antibiotic resistance amongst GAS but has not been reported for other streptococci (Courvalin, Carlier and Chabbert 1972). Transposon-mediated MLS resistance in GAS has been described, and chromosomally integrated resistance genes of presumed plasmid origin have been found in many plasmid-free strains (Le Bouguenec, de Cespedes and Horaud 1990).

The genes encoding the methylases have been designated *erm* (erythromycin ribosome methylation). The methylases of the various species have been characterised at the molecular level and are subdivided into several classes, named by letters (Levy *et al.* 1999). In GAS the so-called *ermB* (*ermAM*) gene is among the most common, found to be present in 31% of 143 macrolide-resistant GAS lower respiratory tract infection strains obtained from 25 countries participating in the Prospective Resistant Organism Tracking and Epidemiology for the Ketolide Telithromycin (PROTEKT) study during 1999–2000 (Farrell *et al.* 2002). A closely related gene, *ermTR* (*ermA*) (Seppala *et al.* 1998), was found in 23% of these isolates, whilst *mefA*, the resistance gene due to macrolide efflux (Levy *et al.* 1999), was detected in 46% of these strains.

The increase in erythromycin resistance amongst GAS has been shown to be caused by isolates with the M phenotype, known to be associated with active efflux (Tait-Kamradt *et al.* 1997). The increase in the prevalence of erythromycin-resistant GAS carrying the *ermA*, *ermB* and/or *mefA* genes has been the subject of many recent reports (Giovanetti *et al.* 1999; Kataja, Huovinen and Seppala 2000; Leclercq 2002). In contrast, less work has been undertaken to characterise the mechanism of tetracycline resistance amongst β-haemolytic streptococci. For GAS, only the *tetM* gene has been the commonly identified gene. Other streptococcal species that carry the *tet(O)* gene, which codes for another tetracycline resistance ribosomal protection protein, or the *tet(K)* and the *tet(L)* genes, which code for efflux-mediated tetracycline resistance, have also been identified (Chopra and Roberts 2001).

Current estimates of macrolide resistance in GAS strains within Europe show some variation, from 1.8% in a collection of invasive

and noninvasive strains from Denmark (Statens Serum Institut, Danish Veterinary and Food Administration, Danish Medicines Agency and Danish Institute for Food and Veterinary Research 2004), 4% of bacteraemic strains in the United Kingdom (HPA 2004b) to 20% of noninvasive strains from across Spain (Perez-Trallero *et al.* 2001). In a mixed collection of GAS strains obtained from Russia 11% were found to be erythromycin resistant (Kozlov *et al.* 2002). Among the β -haemolytic streptococcal strains collected as part of the SENTRY worldwide antimicrobial susceptibility monitoring programme between 1997 and 2000, 10% of European isolates from invasive and noninvasive disease were found to be erythromycin resistant and 11% of strains collected from Asia-Pacific region, 19% from North American and only 3% from Latin American exhibited erythromycin resistance (Gordon *et al.* 2002).

Resistance to Other Therapeutic Agents

Rifampicin is a particularly active agent against Gram-positive bacteria and mycobacteria. There have been few reports about the susceptibility of *S. pyogenes* to rifampicin; however, resistance has been estimated to be approximately 0.3% amongst isolates from Spain. Resistance is caused by an alteration of one or more regions of the target site, the β -subunit of RNA polymerase. Most of the mutations associated with rifampicin resistance are located in a segment in the centre of the *rpoB* gene cluster (Herrera *et al.* 2002).

TREATMENT STRATEGIES

Antimicrobial Therapy for β -Streptococcal Disease

Superficial Disease

β -Haemolytic streptococci have remained exquisitely sensitive to penicillin. It is normal to give 10 days of treatment with penicillin V to fully treat streptococcal pharyngitis and prevent RF, although there is some preliminary evidence to suggest that 5 days of azithromycin will suffice (Bisno *et al.* 2002). Up to 30% of streptococcal sore throats treated with penicillin may relapse, possibly because of the internalisation of bacteria into buccal or tonsillar epithelial cells (Sela *et al.* 2000; Kaplan and Johnson 2001). Macrolides have a theoretical advantage over β -lactams because of intracellular penetration. Such compounds may afford the best eradication rate. Although macrolides have traditionally been considered as alternatives to β -lactams in patients with penicillin allergy, it is noteworthy that up to 45% of GAS isolates are reported to be resistant to macrolides in certain European countries. In the United Kingdom the incidence of erythromycin resistance is lower, at around 5–10%.

For impetigo initial empiric oral systemic treatment directed against both *S. aureus* and *S. pyogenes* (e.g. flucloxacillin) is normally combined with agents to clear carriage of the organisms. Notably, the use of topical fusidic acid may be of little benefit, as only approximately half of GAS are sensitive to this drug, and many *S. aureus* strains are now demonstrating fusidic resistance.

Invasive β -Haemolytic Disease

For invasive β -haemolytic disease intravenous treatment with penicillin (or ceftriaxone) is mandatory, at least until an initial response is observed. Most authorities now recommend the use of clindamycin alongside penicillin, because it has been shown to improve outcome both in animal models of invasive streptococcal disease and in clinical studies (Stevens *et al.* 1988; Stevens, Bryant and Yan 1994; Zimelman, Palmer and Todd 1999). Clindamycin appears to inhibit the synthesis or release of many streptococcal virulence factors such

as superantigen toxins and cell-wall components (Gemmell *et al.* 1981; Brook, Gober and Leyva 1995; Sriskandan *et al.* 1997).

In some cases of invasive GBS disease an aminoglycoside is added to β -lactam therapy for the first 2 weeks. This is particularly true for neonatal GBS disease.

Surgery for β -Streptococcal Disease

In addition to appropriate antibiotic therapy it is essential that cases of invasive disease be examined for evidence of tissue necrosis or gangrene. This may present subtly, and many cases will require surgical exploration. All necrotic tissue must be removed promptly, and reexploration at daily intervals may be necessary (Stamenkovic and Lew 1984; Heitmann *et al.* 2001). Early liaison with plastic surgery specialists can facilitate appropriate debridement. Following extensive surgery the patient remains at risk of nosocomial infection.

Immunological Therapies

Intravenous immunoglobulin (IVIG) is recommended as an adjunct to treatment of severe invasive GAS infection, in particular those cases complicated by STSS. Although there are no controlled trials to support its use in treatment, anecdotal reports and a retrospective clinical study suggest that there are some benefits (Lamothe *et al.* 1995; Kaul *et al.* 1999). A European clinical trial was abandoned because of difficulties in patient recruitment, though initial responses were promising (Darenberg *et al.* 2003). Although the cost of the proposed doses of IVIG is likely to be high, surprisingly there are no preclinical studies that have yet demonstrated the efficacy of IVIG.

There are many mechanisms that may explain the apparent efficacy of IVIG. Firstly, IVIG-mediated neutralisation of superantigenic toxins leads to recovery from STSS, and secondly, it has been shown that IVIG can assist in the opsonisation of GAS in nonimmune hosts (Skansen-Saphir *et al.* 1994; Norrby-Teglund *et al.* 1996; Basma *et al.* 1998). Of course, IVIG is likely to contain an abundance of polyclonal antistreptococcal antibodies, including antibodies to a wide range of secreted virulence factors, which may be of importance in disease progression.

Phage Therapy

Although antibiotic resistance has not yet affected therapy for β -haemolytic streptococcal disease substantially, the identification of novel compounds that can specifically target pathogens is welcome. Recently, purified recombinant phage lytic enzymes (lysins) have been demonstrated to have excellent rapid bactericidal activity. Although not developed to a degree that would allow systemic use, phage lytic enzyme has been recently used to successfully eradicate pharyngeal carriage of *S. pyogenes* (Nelson, Loomis and Fischetti 2001).

PREVENTION AND CONTROL

Vaccines for β -Haemolytic Streptococcal Disease

GAS opsonic antibodies directed against the N-terminal sequences of the streptococcal M protein are known to confer strain-specific immunity to *S. pyogenes*. There is therefore an obvious advantage to exploiting the M protein as a vaccine candidate. Unfortunately, there are in excess of 100 M serotypes and in excess of 150 *emm* gene types, impeding the process of choosing vaccine candidates. Indeed, the prevalent M serotypes in different communities differ significantly. To counter this multivalent vaccines have been designed that incorporate several dominant M serotypes. A recombinant multivalent vaccine has recently undergone phase I clinical trial evaluation

(Kotloff *et al.* 2004), which has provided the first evidence that a hybrid fusion protein is a feasible strategy for evoking type-specific opsonic antibodies against multiple serotypes of GAS without eliciting antibodies that cross-react with host tissues. This represents a critical step in GAS vaccine development.

The conserved C-terminus of the M protein has also been considered as a vaccine candidate. Conserved T-cell epitopes, which are thought to be rheumatogenic, reside in the C-terminus of the protein (Robinson, Case and Kehoe 1993; Pruksakorn *et al.* 1994), though rheumatogenic T-cell epitopes may also exist in the variable N-terminus (Guilherme *et al.* 2000). These considerations have greatly complicated GAS vaccine development because of fears of precipitating RF in vaccinated individuals (Pruksakorn *et al.* 1994; Brandt *et al.* 2000).

Recent studies suggest that opsonic antibodies to M protein alone are insufficient for opsonophagocytosis of *S. pyogenes*, emphasising the need to seek additional vaccine candidates. Certain non-M-protein antigens have already been evaluated in preclinical models, including the streptococcal C5a peptidase, the streptococcal cysteine protease (SPEB) and the GAS carbohydrate.

Although maternal intrapartum antibiotic prophylaxis is clearly effective and has reduced the incidence of early-onset GBS neonatal disease substantially in the United States, it cannot prevent late-onset GBS disease. Vaccination of women of childbearing age against GBS could theoretically prevent both early-onset and late-onset GBS disease in the neonate, in addition to preventing GBS disease in pregnant women. Opsonic antibodies directed against the capsular polysaccharide of GBS confer serotype-specific protection. Initial vaccines developed focused on capsular type III isolates, but the emergence of type V isolates in recent years has prompted the development of a polyvalent GBS vaccine (Baker and Edwards 2003). Vaccines have been developed by coupling purified capsular polysaccharide antigen of GBS with an immunogenic protein carrier. Glycoconjugate vaccines against all nine currently identified GBS serotypes have been synthesised and shown to be immunogenic in animal models and in human phase I and II trials. The recent results strongly suggest that GBS conjugate vaccines may be effective in the prevention of GBS disease (Paoletti and Kasper 2003).

Oral and Other Non- β -Haemolytic Streptococci

Roderick McNab¹ and Theresa Lamagni²

¹GlaxoSmithKline, Surrey; and ²Health Protection Agency, Centre for Infection, London, UK

INTRODUCTION

The genus *Streptococcus* consists of Gram-positive cocci that are facultatively anaerobic, nonsporing and catalase negative, with cells arranged in chains or pairs. Their nutritional requirements are complex, and carbohydrates are fermented to produce L-(+)-lactic acid as the main end product.

All streptococci are obligate parasites of mammals, and within the genus are many species that are important pathogens of humans and domestic animals as well as many well-known opportunistic pathogens.

The determination of haemolysis on blood agar plates is a useful characteristic for identifying streptococci. Members of this genus may be broadly divided into β -haemolytic (pyogenic) and non- β -haemolytic groups. The latter group comprises species that are α -haemolytic on blood agar (the so-called viridans streptococci that produce a greenish discoloration surrounding colonies on blood agar plates) as well as nonhaemolytic (γ -haemolytic) strains.

This chapter focuses on these non- β -haemolytic streptococci, with the exception of *Streptococcus pneumoniae*, a close relative of the mitis group of oral streptococci, which is given its own chapter (Chapter 3) as befits its more pathogenic status. For a list of non- β -haemolytic streptococci, see Tables 2.1 and 2.2.

DESCRIPTION OF THE ORGANISMS

Current Taxonomic Status

Since the 1980s the genus *Streptococcus* has undergone considerable upheaval including the removal of lactic and enteric species into separate genera (*Lactococcus* and *Enterococcus*, respectively). Additionally, many new genera of Gram-positive cocci that grow in pairs or chains were established, primarily through reclassification from the genus *Streptococcus* by genotypic and phenotypic characteristics. For reviews, see Whiley and Beighton (1998) and Facklam (2002).

Classification of species that remain within the genus *Streptococcus* has been fraught with difficulty partly due to the early overreliance on serological and haemolytic reactions. Although Lancefield serological grouping, based on carbohydrate antigens present in the cell walls of streptococci, has proved a very useful tool for the more pathogenic β -haemolytic streptococci (see Chapter 1), its application to non- β -haemolytic streptococci is of little value for identification where group-specific antigens may be absent or shared by several distinct taxa, for example. Similarly, although the type of haemolysis demonstrated by streptococci is a useful marker in the initial examination of clinical isolates, the distinction between α - and γ -haemolytic reactions on blood agar plates may be of limited taxonomical value. β -Haemolysis by

<i>S. macacae</i>	Monkey	Serotype c
<i>S. hyovaginalis</i>	Swine	

The generic term oral streptococcus is used with caution since many of the species listed may also be found in the gastrointestinal and genitourinary tracts. (human), rarely found in humans.

^a Proposed correction to epithet (Trüper and de'Clari, 1997, 1998).

^b *S. sanguis* group separated from larger *S. mitis* group by Facklam (2002).

streptococci is caused by well-characterized haemolysins (see Chapter 1), whereas the α -haemolytic reaction on blood agar plates results from the production and release of hydrogen peroxide by streptococcal colonies grown under aerobic conditions that causes oxidation of the haeme iron of haemoglobin in erythrocytes (Barnard and Stinson, 1996, 1999). Differences exist in the haemolytic reaction within species, and the reaction is dependent on culture conditions and the origin of the blood incorporated into the agar.

From the 1980s onwards the taxonomy of the streptococci has been developed using a wide range of approaches, thereby reducing the emphasis previously placed on serology and haemolysis. Significant contributions have included the analysis of cell-wall composition,

Table 2.2 Lancefield group D *S. bovis*/*S. equinus* complex as proposed by Schlegel *et al.* (2003a)

Species	Previous designation	Comments
<i>S. bovis</i> / <i>S. equinus</i> ^a	Bovis II.1 (mannitol- and β -glucuronidase-negative and α -galactosidase-positive)	Bovine, equine, human ^b
<i>S. gallolyticus</i> subsp. <i>gallolyticus</i>	Bovis I, II.2 (mannitol-negative and β -glucuronidase- and β -mannosidase-positive) isolates	Human, bovine, environmental
subsp. <i>pasteurianus</i> subsp. <i>macedonicus</i>		Biotype I strains more commonly associated with colonic cancer patients than <i>S. bovis</i> II.1 (Rouff <i>et al.</i> , 1989)
<i>S. infantarius</i> subsp. <i>infantarius</i> subsp. <i>coli</i>	New species designation, Schlegel <i>et al.</i> (2000)	Human, environmental
<i>S. alactolyticus</i>		Porcine

^aThe epithet *equinus* has nomenclatorial priority; however, the epithet *bovis* remains widely used in the medical literature.

^bRarely found in humans.

metabolic studies, numerical taxonomy and genotypic analysis such as DNA–DNA hybridization, DNA base composition [mol% guanine + cytosine (G+C)] and comparative sequence analysis of small subunit (16S) ribosomal DNA (reviewed by Facklam, 2002). This latter technique was used to subdivide the genus *Streptococcus* into six major clusters that broadly conform to the results of previous taxonomic studies (Kawamura *et al.*, 1995a) (Figure 2.1).

To further complicate matters, a taxonomic note by Trüper and de'Clari (1997, 1998) called for grammatical corrections in the Latin epithets of four streptococcal species, among 20 species. For the sake of clarity, where the epithets *sanguis*, *rattus* and *crista* have been used in the scientific literature for over 30 years, we have chosen to retain the historical nomenclature throughout this chapter (Kilian, 2001).

Anginosus Group Streptococci

These streptococci are common members of the oral flora and are found in the gastrointestinal and genital tracts and are clinically significant owing to their association with purulent infections in humans. The classification of these streptococci was confused for many years, and the term *Streptococcus milleri* has been used for a biochemically and serologically diverse collection of streptococci, despite not being accepted by taxonomists as a confirmed taxonomic entity. The weight of evidence from nucleic acid studies currently supports the recognition of three separate, albeit closely related, species – *Streptococcus anginosus*, *Streptococcus constellatus* and *Streptococcus intermedius* – and these have been published with amended species descriptions (Whiley and Beighton, 1991; Whiley *et al.*, 1993). Isolates of *S. intermedius* rarely have Lancefield group antigens, whereas isolates of *S. anginosus* and *S. constellatus* may have Lancefield F, C, A or G antigens. There are β -haemolytic strains of each of the three species; however, these are outnumbered by the non- β -haemolytic strains.

Mitis Group Streptococci

The mitis group of streptococci are prominent components of the human oropharyngeal microflora and are among the predominant

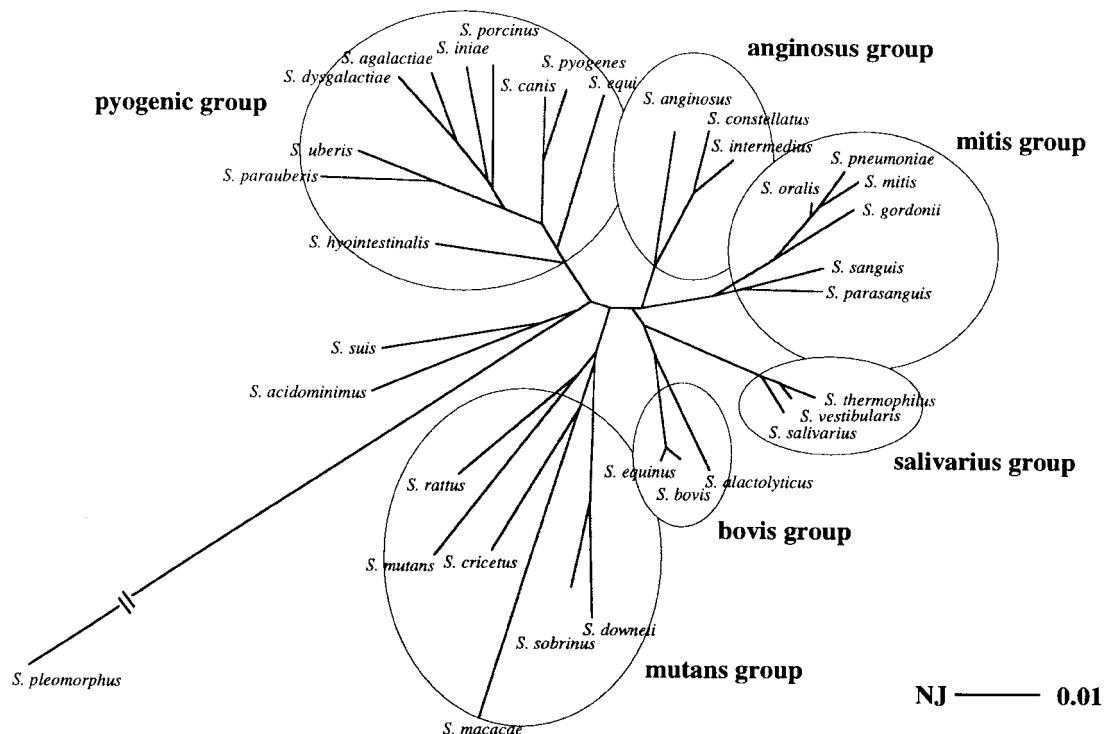

Figure 2.1 Phylogenetic relationships among 34 *Streptococcus* species. Distances were calculated from the neighbour-joining (NJ) method. Reproduced from Kawamura *et al.* (1995a) with permission of the International Union of Microbiological Societies.

causes of bacterial endocarditis. The application of nucleic acid studies has enabled some clarity to be derived for this taxonomically refractory group of oral streptococci. The mitis group as originally described by Kawamura *et al.* (1995a) included *Streptococcus sanguis*, *Streptococcus parasanguis*, *Streptococcus gordonii*, *Streptococcus crista*, *Streptococcus oralis*, *Streptococcus mitis* and *S. pneumoniae* (considered separately in Chapter 3). For several species, notably *S. sanguis*, *S. oralis* and *S. mitis*, combined taxonomic and nomenclatorial changes have been the cause of considerable confusion. Part of this confusion arose from the emphasis placed on the possession of Lancefield group H antigen, which was not well defined. Additionally, alternative nomenclature schemes have added to the confusion, particularly the use of *S. mitior*, a name traditionally assigned to an ill-defined species from the early days of streptococcal classification. The legacy of confusion that stems from a poor definition of the Lancefield group H antigen and the emphasis placed on its possession highlights the difficulties associated with the application of Lancefield grouping as a taxonomic tool for non- β -haemolytic streptococci.

Three additional mitis group species have been described: *Streptococcus peroris* and *Streptococcus infantis* were isolated from the human oral cavity (Kawamura *et al.*, 1998), whereas *Streptococcus orisratti* was isolated from the oral cavity of rats (Zhu, Willcox and Knox, 2000). Continued refinement and redefining of the mitis group of streptococci seem likely as the application of molecular taxonomic tools expands, and consequently it may be some time before we can fully correlate new and revised species in this group with human infections. The classification system proposed by Facklam (2002) and used in epidemiology reporting by the US Centers for Disease Control and by the Health Protection Agency in the UK has split *S. sanguis*, *S. parasanguis* and *S. gordonii* from the mitis group and placed them in a separate sanguis group on the basis of phenotypic characteristics. The division is used here for epidemiology reporting purposes, although 16S rRNA sequencing supports the taxonomic position described in Figure 2.1 (Kawamura *et al.*, 1995a; Whiley and Beighton, 1998).

Salivarius Group Streptococci

Streptococcus salivarius is commonly isolated from most areas within the human oral cavity, particularly from the tongue and other mucosal surfaces and from saliva, though it is rarely associated with disease. This species is considered to be an important component of the oral ecosystem because of the production of an extracellular fructose polysaccharide (levan) from dietary sucrose and the production of urease by some strains. DNA–DNA reassociation experiments have revealed that *S. salivarius* is closely related to *Streptococcus thermophilus*, a nonoral bacterium from dairy sources, and also to an oral species *Streptococcus vestibularis* which is an α -haemolytic, urease-producing streptococcus that is found predominantly on the vestibular mucosa of the human oral cavity (Hardie and Whiley, 1994). *Streptococcus vestibularis* does not produce extracellular polysaccharide. The formation of a distinct species group by these three streptococci was confirmed by 16S rDNA sequence comparisons (Bentley, Leigh and Collins, 1991; Kawamura *et al.*, 1995a).

Mutans Group Streptococci

The mutans group of streptococci exclusively colonize the tooth surfaces of humans and certain animals and are associated with dental caries, one of the most common infectious diseases of humans. Their characteristics include the ability to produce both soluble and insoluble extracellular polysaccharides from sucrose which are important in the formation of dental plaque and in the pathogenicity (cariogenicity) of the organism. Following the original species description of *Streptococcus mutans* from carious teeth by Clarke (1924) and its isolation from a case of bacterial endocarditis shortly afterwards, little attention was

paid to this species until the 1960s when it was demonstrated that caries could be experimentally induced and transmitted in animals. Similar caries-inducing streptococci were found in the dental plaque of humans, and from this point on, *S. mutans* became the focus of considerable attention. Studies revealed that isolates identified as *S. mutans* comprised a phenotypically and genetically heterogeneous taxon. Eight serotypes or serovars (designated a–h) have so far been identified, and six distinct species are currently recognized within the mutans group: *S. mutans* (serotypes c, e and f), *Streptococcus sobrinus* (serotypes d and g), *Streptococcus rattus* (serotype b), *Streptococcus downei* (serotype h), *Streptococcus cricetus* (serotype a) and *Streptococcus macacae* (serotype c). A seventh species initially included in the mutans group, *Streptococcus ferus* (serotype c), was shown to be only distantly related to all currently described streptococci, with no strong evidence to support its inclusion in this group (Whatmore and Whiley, 2002). Of these streptococci, *S. mutans* and *S. sobrinus* are commonly isolated from humans, whereas *S. cricetus* and *S. rattus* are occasionally recovered. *Streptococcus hyovaginalis*, isolated from the genital tract of pigs, is included in the mutans group because of similar phenotypic characteristics; however, identification from human sources has not yet been documented.

Bovis Group Streptococci

Streptococcus bovis was originally described as a bovine bacterium causing mastitis. Strains described as *S. bovis* have been isolated from patients with endocarditis, and this species is also reported to be associated with colon cancer and inflammatory bowel disease in humans. Human *S. bovis* strains are divided into two biotypes based on their ability (biotype I) or inability (biotype II) to ferment mannitol. Despite the recognition of the clinical significance of this organism, its classification remains confused. Schlegel *et al.* (2000) described a new species isolated from human and environmental sources, *Streptococcus infantarius*, and have proposed that the *S. bovis*/*Streptococcus equinus* complex be reorganized into seven species or subspecies (Table 2.2) based on a combination of phenotypic, genetic and phylogenetic methods (Schlegel *et al.*, 2003a). In this classification system, *S. bovis* biotype II.1 and *S. equinus* form a single genospecies. The epithet *equinus* has nomenclatorial priority; however, the epithet *bovis* remains widely used in the medical literature. *Streptococcus bovis* biotype II.2 isolates were reclassified along with *Streptococcus macedonicus* as *Streptococcus gallolyticus*.

Nutritionally Variant Streptococci

This clinically important group of bacteria, so named because of the need to supplement complex growth medium with cysteine or one of the active forms of vitamin B6 (pyroxidol hydrochloride or pyridoxamine hydrochloride) to obtain growth, forms part of the normal flora of the human throat and urogenital and intestinal tracts. They are of clinical interest because of their association with infective endocarditis and other conditions including otitis media, abscesses of the brain and pancreas, pneumonia and osteomyelitis (Bouvet, Grimont and Grimont, 1989). The names *Streptococcus adjacens* and *Streptococcus defectivus* were first proposed by Bouvet, Grimont and Grimont in 1989 but were subsequently reclassified on the basis of 16S rRNA gene sequence data and other phylogenetic analysis within a new genus, *Abiotrophia*, as *Abiotrophia adiacens* and *Abiotrophia defectiva*, respectively (Kawamura *et al.*, 1995b). *Abiotrophia adiacens* was subsequently transferred to *Granulicatella adiacens* (Collins and Lawson, 2000).

INFECTIONS CAUSED BY NON- β -HAEMOLYTIC STREPTOCOCCI

Non- β -haemolytic streptococci comprise a significant proportion of the normal commensal flora of the human body. However, they are

involved in many types of infections, in which the source of the infection is almost invariably endogenous, being derived from the host's microflora. The streptococcal species themselves are generally thought to be of relatively low virulence, not normally associated with acute, rapidly spreading infections such as those caused by *Streptococcus pyogenes*, although they clearly have phenotypic features that result in the production of disease under appropriate circumstances.

Since many of these streptococci are present in the mouth, upper respiratory tract, genitourinary tract and, to a lesser extent, gastrointestinal tract, they are sometimes involved in pathological processes at these sites, possibly following some local or systemic change in host susceptibility or an alteration in local environmental conditions. A classic example is the manifestation of dental caries that arises following excessive consumption of dietary sugars, particularly sucrose. Alternatively, the streptococci at a mucosal site may gain access to the blood stream because of some local traumatic event and set up an infection at a distant location, such as the heart valve in endocarditis or in the brain or liver, giving rise to an abscess. The key event for infections at distant body sites is bacteraemia.

Epidemiology

Our understanding of the importance of non- β -haemolytic streptococci as bacteraemic pathogens has been hampered by a dearth of surveillance activity in many countries. Robust estimates of incidence have been, and to a degree remain, few and far between. Most quantitative studies undertaken have been based on case series originating from localized areas whose catchment populations are often difficult to enumerate and, therefore, difficult to translate into estimates of incidence.

In England and Wales a comprehensive laboratory-based surveillance network gathers reports of bacteraemia caused by all pathogens. Data from this surveillance on non- β -haemolytic streptococci indicate an incidence of 3.8 per 100 000 population in 2002 (HPA, 2003a). Non- β -haemolytic streptococci comprised approximately 3% of all bacteraemia reported through this system (HPA, 2002), broadly in line with estimates from other European countries and the Americas, which range from 1.5% to 5.9% (Jacobs *et al.*, 1995; Casariego *et al.*, 1996; Diekema *et al.*, 2000; Fluit *et al.*, 2000).

Of the non- β -haemolytic streptococci, mitis group organisms appear to be the most common cause of bacteraemia overall (Venditti *et al.*, 1989; Doern *et al.*, 1996; HPA, 2003a), the rate of reports in England and Wales being 1.4 per 100 000 population in 2002, with *S. oralis* being the most common single species identified (12% of all non- β -haemolytic streptococci). A smaller study from The Netherlands similarly found *S. oralis* to be the most common non- β -haemolytic streptococci causing bacteraemia, particularly associated with infection in haematology patients (Jacobs *et al.*, 1995). Studies focusing on neutropenic patients, one of the most vulnerable patient groups, suggest that between 13% and 18% of bacteraemias are due to non- β -haemolytic streptococci (Wisplinghoff *et al.*, 1999; Marron *et al.*, 2001), with *S. mitis* featuring as one of the most prominent species (Alcaide *et al.*, 1996).

Interestingly, the relative contribution of each non- β -haemolytic streptococcal group to bacteraemic episodes in England and Wales has changed over 1990–2000. The incidence of the formerly dominant sanguis group (*S. sanguis*, *S. parasanguis* and *S. gordonii*) has declined by half, whereas those of mitis and anginosus group streptococci have increased dramatically by three- and twofold, respectively (Figure 2.2).

Estimates of the relative importance of healthcare exposure in the aetiology of non- β -haemolytic streptococcal bacteraemia have differed between studies. Two studies of *S. bovis* bacteraemia in Hong Kong (Lee *et al.*, 2003) and Israel (Siegman-Igra and Schwartz, 2003) found none and 10% of cases, respectively, to have been hospital acquired, whereas 6 of 31 (19%) *S. milleri* bacteraemias identified in a case series from Spain were considered to be hospital acquired

Figure 2.2 Annual rate of laboratory reports of bacteraemia caused by non- β -haemolytic streptococci, England and Wales. Source: Health Protection Agency (Communicable Disease Surveillance Centre).

(Casariego *et al.*, 1996). Nosocomial infection surveillance from the United States (Emori and Gaynes, 1993; Pfaller *et al.*, 1997) and England (NINSS, 2003) identified between 1% and 3% of hospital-acquired bacteraemia to involve non- β -haemolytic streptococci.

Being opportunistic pathogens, bacteraemia involving non- β -haemolytic streptococci tend to be concentrated in vulnerable individuals, namely the very young and older age groups (Figure 2.3). Much like many other blood stream infections, non- β -haemolytic streptococcus infection tends to have rates that are higher in males than in females, this pattern being seen across all non- β -haemolytic streptococcal groups (HPA, 2003b) and often also seen in studies of infective endocarditis (Mylonakis and Calderwood, 2001; Hoen *et al.*, 2002; Mouly *et al.*, 2002), with some exceptions (Hogevik *et al.*, 1995).

Infective Endocarditis

Infective endocarditis involving non- β -haemolytic streptococci usually occurs in patients with preexisting valvular lesions and is typically subacute, whereas the acute form of endocarditis which can occur in those with previously undamaged heart valves is associated with more virulent bacteria such as *Staphylococcus aureus*, *S. pyogenes* or *S. pneumoniae*. Patients at particular risk of developing subacute endocarditis include those with congenital heart defects affecting valves, those with acquired cardiac lesions following rheumatic fever

Figure 2.3 Age- and sex-specific incidence of anginosus group streptococcus laboratory reports in 2002, England and Wales. Source: Health Protection Agency (Communicable Disease Surveillance Centre).

and those who have undergone valve replacement therapy. These predisposing conditions may cause the development of noninfected platelet–fibrin vegetations (nonbacterial thrombotic vegetations) on the endocardium that may subsequently become infected by circulating microorganisms in the bloodstream during a transient bacteraemia.

It is often difficult to pinpoint the exact precipitating event that gives rise to the development of endocarditis, and some controversy exists over the incubation period between the bacteraemia that results in infection and the first symptoms of disease. An important potential source of the organisms that cause infectious bacteraemia is the oral cavity, although streptococci and other causative organisms may also enter the bloodstream from other body sites. Most invasive dental procedures (e.g. tooth extraction) may cause transient bacteraemia (Hall, Heimdahl and Nord, 1999). However, formal epidemiological studies suggest that dental procedures cause relatively few cases (van der Meer *et al.*, 1992; Strom *et al.*, 1998), and the value of antibiotic prophylaxis has been questioned (Durack, 1998; Morris and Webb, 2001). Considered more relevant is bacteraemia associated with poor dental hygiene and with routine oral procedures including brushing, flossing and chewing (Lockhart and Durack, 1999). Nevertheless, antibiotic prophylaxis is still recommended before certain invasive dental procedures on patients known to be at risk of developing bacterial endocarditis (see *Prevention and Control*).

Pathogenesis

The pathogenesis of infectious endocarditis is highly complex, involving numerous host–pathogen interactions. Review of the literature has

indicated that many of the oral species are cultured from blood following oral procedures (Lockhart and Durack, 1999). Nevertheless, the non- β -haemolytic streptococci account for many cases of infective endocarditis (see *Epidemiology*), indicating that these species may possess specific pathogenic features. Some factors thought to be important are listed in Table 2.3, although only a limited number of these postulated pathogenic features have been studied in experimental models of infective endocarditis. The pathogenesis of infective endocarditis may be divided into several distinct and sequential steps. The first event is bacterial adhesion to the damaged tissue following an episode of bacteraemia. The second step is the establishment and persistence of streptococci, followed, thirdly, by bacterial growth and local tissue damage.

Bacterial attachment to damaged tissue is critical to disease, and bacterial adhesins that recognize and bind to host tissue components such as fibronectin and fibrinogen have been implicated in the disease process. Bacterial adhesion to fibronectin is demonstrated by numerous non- β -haemolytic streptococci (Table 2.3). Fibronectin binding was shown to be important for *S. sanguis* induction of experimental endocarditis in rats, and a mutant lacking fibronectin-binding activity was significantly less infective than the parent strain (Lowrance, Baddour and Simpson, 1990). Numerous fibronectin-binding proteins have been characterized among non- β -haemolytic streptococci, including CshA of *S. gordonii* that is expressed by most members of the mitis and sanguis groups of streptococci (McNab *et al.*, 1996; Elliott *et al.*, 2003).

The development of valvular vegetations in *S. sanguis*-induced endocarditis in rabbits has been shown to depend, at least in part, on the availability of fibrin (Yokota *et al.*, 2001). FimA protein of *S. parasanguis* has been identified as an adhesin mediating the attachment of bacteria

Table 2.3 Streptococcal virulence properties in infective endocarditis

Pathogenic feature	Determinant	Comment	Reference
Adherence to fibronectin			
<i>S. sanguis</i> ^a	Unidentified	Rat model	Lowrance, Baddour and Simpson (1990)

to fibrin clots, and inactivation of the *fimA* gene in *S. parasanguis* abrogates the ability of cells to bind to fibrin and to cause endocarditis in rats (Burnette-Curley *et al.*, 1995). Further, immunization of rats with *S. parasanguis* FimA conferred protection against subsequent challenge with *S. parasanguis* (Viscount *et al.*, 1997). FimA homologues in diverse streptococcal species share significant antigenic similarity, and Kitten *et al.* (2002) have demonstrated that vaccination with *S. parasanguis* FimA protected rats from endocarditis caused by other oral streptococci, raising the possibility of FimA being used as a vaccine for at-risk individuals. Studies have demonstrated that the FimA-like family of proteins function in manganese transport (Kolenbrander *et al.*, 1998) and so may also contribute to infective endocarditis through acquisition of this essential growth factor.

Many of the oral streptococcal species produce high-molecular mass glucans, through the enzymatic activity of glucosyltransferase (GTF), when grown in the presence of sucrose, a property that has been implicated in the pathogenesis of infective endocarditis. Thus, rats inoculated with an isogenic mutant of *S. mutans* lacking GTF activity developed endocarditis less frequently than those inoculated with the parental strain, and additionally, the isogenic mutant adhered in lower numbers to fibrin *in vitro* (Munro and Macrina, 1993). In contrast, there was no difference in virulence between sucrose-grown wild-type *S. gordonii* and its isogenic GTF-negative mutant (Wells *et al.*, 1993), highlighting species differences and indicating that multiple virulence factors may be involved in pathogenesis.

Bacterial interaction with platelets is considered a major factor in endocarditis (reviewed by Herzberg, 1996; Herzberg *et al.*, 1997). As well as the direct adhesion of bacteria to platelets (Table 2.3), many streptococci, particularly *S. sanguis* strains, induce the aggregation of platelets *in vitro*. These aggregates show densely compacted and degranulated platelets and contain entrapped streptococcal cells. Thus, bacterial aggregation of platelets has been proposed to contribute to the establishment and persistence of adherent bacteria through the creation of a protective thrombus. The interactions between *S. sanguis* and platelets have been studied in some detail (Herzberg, 1996). Interactions are complex and involve at least three streptococcal sites, and these interactions result in platelet activation and the release of ATP-rich dense granules. Platelet aggregation-associated protein (PAAP) plays an important role through interaction with a signal-transducing receptor on the platelet surface, inducing platelet activation and aggregation. Platelet-aggregating strains of *S. sanguis* induce significantly larger vegetations than nonaggregating strains in a rabbit model of endocarditis, and antibodies to PAAP can ameliorate the clinical severity of disease (Herzberg *et al.*, 1992). Nevertheless, non-platelet-aggregating *S. sanguis* isolates can still cause endocarditis, again highlighting the multiplicity of bacterial–host interactions that are involved in the disease process (Douglas, Brown and Preston, 1990; Herzberg *et al.*, 1992).

In addition to contributing to the disease process, platelet activation and aggregation are also a key aspect of host defence against disease, and the persistence of adherent streptococci is related, at least in part, to their resistance to microbicidal factors released from activated platelets as well as to circulating defence mechanisms (Dankert *et al.*, 1995). In one study over 80% of the oral streptococcal strains isolated from the blood of patients with infective endocarditis were resistant to platelet microbicidal activity compared with only 23% of streptococcal strains isolated from the blood of neutropenic patients without infective endocarditis (Dankert *et al.*, 2001). Further, immunizing rabbits to produce neutralizing antibodies against platelet microbicidal components rendered these animals more susceptible to infective endocarditis when challenged with a sensitive *S. oralis* strain (Dankert *et al.*, 2001).

Two studies have applied modern molecular screens to identify streptococcal genes encoding potential virulence factors for endocarditis. Using *in vivo* expression technology (IVET) in conjunction with a rabbit model of endocarditis, Kiliç *et al.* (1999) identified 13 genes whose expression was required for *S. gordonii* growth within valvular

vegetations. One of these genes encoded methionine sulphoxide reductase (MSR), a protein involved in the repair of oxidized proteins. MSR has been proposed to play a role in the maintenance of the structure and function of proteins, including adhesins, where sulphur groups of methionine residues are highly sensitive to damage by oxygen radicals. In a separate study a shift in pH from 6.2 to 7.3 was used to mimic the environmental clues experienced by *S. gordonii* entering the blood stream from their normal habitat of the mouth (Vriesema, Dankert and Zaat, 2000). Among five genes induced by this pH shift was one encoding the MSR described above. Further application of molecular techniques should help dissect the complex host–bacterial interactions required for disease caused by these otherwise nonpathogenic bacteria.

Epidemiology

It has been estimated that about 20 cases of infective endocarditis per million of the population per year can be expected in England and Wales, with an associated mortality rate of approximately 20% (Young, 1987). Between 1975 and 1987 around 200 (± 30) deaths per year were recorded in these countries. There have been numerous surveys of the causative agents in infective endocarditis over the years. Streptococci remain the predominant cause of infective endocarditis, accounting for up to 50% of cases in most published series, despite reported changes in the spectrum of disease due, in part, to an increased frequency of intravenous drug abuse, more frequent use of invasive procedures involving intravenous devices and heart surgery with prosthetic valves and a decrease in the incidence of rheumatic fever-associated cardiac abnormalities. It has sometimes been difficult to equate the identity of streptococci reported in earlier studies with the currently accepted classification and nomenclature, particularly with respect to the continued use of the term *Streptococcus viridans* as a catch-all for streptococci that are α -haemolytic on blood agar. Nevertheless, a study by Douglas *et al.* (1993) of 47 streptococcal isolates from 42 confirmed cases of infective endocarditis revealed that members of the mitis group of streptococci, particularly *S. sanguis*, *S. oralis* and *S. gordonii*, comprised the most commonly isolated oral streptococci (Table 2.4). Nonoral *S. bovis* is also a significant aetiological agent of both native and prosthetic heart valve infections (Duval *et al.*, 2001; Siegman-Igra and Schwartz, 2003). In a French study (390 patients) the incidence of infective endocarditis was 31 cases per million of the population (Hoen *et al.*, 2002). Streptococci were isolated in 48% of these cases, with the second

Table 2.4 Streptococci isolated from infective endocarditis

Species	Isolation frequency (% of streptococcal isolates)	
	Douglas <i>et al.</i> (1993)	Hoen <i>et al.</i> (2002)
Mitis and sanguis groups		
<i>S. sanguis</i>	31.9	4
<i>S. oralis</i>	29.8	5.8
<i>S. gordonii</i>	12.7	1.3
<i>S. parasanguis</i>	4.2	0.9

Nutritionally variant streptococci	Not detected	1.3
Enterococci	Not detected	12.9
Pyogenic group	Not detected	9.8
<i>S. pneumoniae</i>	Not detected	1.8
Unidentified/other	2.1	2.2

The Douglas *et al.* (1993) study focused on oral viridans streptococci.

most frequently isolated genus being *Staphylococcus* (29% of cases). Among the streptococci, oral (30%) and group D species (43.5%, the bulk of which were identified as *S. gallolyticus*) comprised most isolates, with the remainder being predominantly pyogenic streptococci (9.8% of streptococci) or enterococci (12.9%) (Table 2.4). In comparison with a similar study conducted in 1991 the incidence of infective endocarditis due to oral streptococci decreased slightly (Hoen *et al.*, 2002).

Clinical Features

Infective endocarditis due to non- β -haemolytic streptococci is usually subacute and may be difficult to diagnose in the earlier stages because of the vagueness and nonspecificity of the signs and symptoms. The patient often presents initially with fever, general malaise and a heart murmur, and other symptoms such as emboli, cardiac failure, splenomegaly, finger clubbing, petechial haemorrhages and anaemia may also be observed at some stage. In addition to fever, rigours and malaise, patients may also suffer from anorexia, weight loss, arthralgia and disorientation. Because of the decline in the number of cases of rheumatic heart disease in some countries and the increase in other predisposing causes, the clinical presentation of infective endocarditis may vary considerably and may not conform to classical descriptions of the disease. This variability in the clinical presentation of infective endocarditis presents a continuing challenge to diagnostic strategies that must be sensitive for disease and specific for its exclusion across all forms of the disease. The Duke Criteria were developed by Durack and colleagues from Duke University in a retrospective study (Durack, Lukes and Bright, 1994) and validated in a prospective cohort (Bayer *et al.*, 1994). The Duke Criteria have proven to be more sensitive at establishing definitive diagnoses than previous systems (reviewed by Bayer *et al.*, 1998).

Laboratory Diagnosis

Positive blood cultures are a major diagnostic criterion for infective endocarditis and are key in identifying aetiological agent and its antimicrobial susceptibility. Therefore, whenever there is a clinical suspicion of infective endocarditis it is important to take blood cultures as soon as possible, before antibiotic treatment is started. At least 20 ml of blood should be taken from adults on each sampling occasion, and it is usually recommended that three separate samples be collected during the 12–24-h period following the initial provisional diagnosis. Most positive cultures are obtained from the first two sets of blood cultures. Administration of antimicrobial agents to patients with infective endocarditis before blood cultures are obtained may reduce the recovery rate of bacteria by 35–40%. Thus, if antibiotic therapy has already been commenced, it may be necessary to collect several more blood cultures over a few days to increase the likelihood of obtaining positive cultures.

Aseptically collected blood samples should, ideally, be inoculated into at least two culture bottles to allow reliable isolation of both aerobic and anaerobic bacteria. The nutritionally variant streptococci (NVS) (see *Nutritionally Variant Streptococci*) are fastidious and require the addition of pyridoxal and/or L-cysteine to the medium for successful identification. Many laboratories now use highly sensitive (semi)automated systems for processing blood culture specimens, but both these and conventional methods sometimes yield culture-negative results from patients with suspected endocarditis. Such negative results may be due to previous antibiotic therapy, the presence of particularly fastidious bacteria, use of poor culture media or isolation techniques or infection due to microorganisms other than bacteria. If blood cultures remain negative after 48–72 h, they should be incubated for a more prolonged period (2–3 weeks) and should be examined microscopically on day 7, day 14 and at the end of the incubation period. Additionally, aliquots should be subcultured on chocolate agar for further incubation in an atmosphere with increased CO₂ levels.

Molecular techniques may be used for the detection and identification of bacteria in blood or on cardiac tissue taken from patients with suspected endocarditis, but that otherwise remains blood culture negative. Techniques include polymerase chain reaction (PCR) amplification of target sequences, and routine DNA sequencing of the amplified DNA may additionally allow for rapid identification of the causative organism (reviewed by Lisby, Gutschik and Durack, 2002).

Management

Effective management of infective endocarditis includes both treatment to control and eliminate the causative infectious agent and other measures to maintain the patient's life and well-being. Increasingly, cardiac surgery is carried out at a relatively early stage to replace damaged and ineffective heart valves.

The antimicrobial treatment depends upon maintaining sustained, high-dose levels of appropriate bactericidal agents, usually administered parenterally, at least in the early stages. It is vital that the aetiological agent, once isolated from repeated blood cultures, be fully identified and tested for antibiotic sensitivity. In addition to determining which antibiotics are most likely to be effective against the particular organisms isolated, the microbiology laboratory will also be required to periodically monitor whether bactericidal levels of the selected drug(s) are being maintained in the patient's blood.

Clearly, the choice of antimicrobial agent depends upon the identity of the causative agent. Most of the oral streptococcal and *S. bovis* strains remain sensitive to penicillin [defined as minimum inhibitory concentrations (MIC)=0.1 mg/l, although see *Antibiotic Susceptibility*] and to glycopeptides; consequently, a combination of benzylpenicillin and gentamicin is recommended (Table 2.5). Penicillin-allergic patients should be treated with a combination of vancomycin and gentamicin.

Table 2.5 Endocarditis treatment regimens

Treatment regimens for adults not allergic to the penicillins

Viridans streptococci and *S. bovis*

- (A) Fully sensitive to penicillin (MIC \leq 0.1 mg/l)
Benzylpenicillin 7.2 g daily in six divided doses by intravenous bolus injection for 2 weeks plus intravenous gentamicin 80 mg twice daily for 2 weeks^a
- (B) Reduced sensitivity to penicillin (MIC > 0.1 mg/l)
Benzylpenicillin 7.2 g daily in six divided doses by intravenous bolus injection for 4 weeks plus intravenous gentamicin 80 mg twice daily for 4 weeks^a

Treatment regimens for adults allergic to the penicillins

Viridans streptococci, *S. bovis* and enterococci

- Initially either vancomycin 1 g by intravenous infusion given over at least 100 min twice daily (determine blood concentrations and adjust dose to achieve 1-h postinfusion concentrations of about 30 mg/l and trough concentrations of 5–10 mg/l) or teicoplanin 400 mg by intravenous bolus injection 12 hourly for three doses and then a maintenance intravenous dose of 400 mg daily
- Give vancomycin or teicoplanin for 4 weeks plus intravenous gentamicin 80 mg twice daily. Viridans streptococcal and *S. bovis* endocarditis should be treated with gentamicin for 2 weeks and enterococcal endocarditis for 4 weeks^a

Conditions to be met for a 2-week treatment regimen for viridans streptococcal and *S. bovis* endocarditis

- Penicillin-sensitive viridans streptococcus or *S. bovis* (penicillin MIC \leq 0.1 mg/l)
- No cardiovascular risk factors such as heart failure, aortic insufficiency or conduction abnormalities
- No evidence of thromboembolic disease
- Native valve infection
- No vegetations more than 5 mm in diameter on echocardiogram
- Clinical response within 7 days. Temperature should return to normal, and patient should feel well and appetite should return

Table adapted from Simmons *et al.* (1998), based on the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy.

^a Gentamicin blood levels must be monitored.

Under certain conditions (Table 2.5) a 2-week course of treatment with penicillin and gentamycin is adequate for endocarditis caused by fully sensitive organisms.

Infective endocarditis occurs less frequently in children than in adults, although the frequency of disease in children appears to be increasing since the 1980s despite a decline in the incidence of rheumatic fever, a major predisposing factor in the past. This is due, at least in part, to improved survival of children who are at risk, such as those with congenital heart disease. In children over 1 year old with endocarditis, the oral streptococci are the most frequently isolated organisms (32–43% of patients; reviewed by Ferrieri *et al.*, 2002). In general, the principles of antibiotic treatment of paediatric endocarditis are similar to those for the treatment of adults.

Prevention and Control

When patients are known to have predisposing cardiac abnormalities, great care should be taken to protect them from the risk of endocarditis when undergoing any dental, surgical or investigational procedures which might induce a transient bacteraemia. However, even if carried out perfectly, this approach is not likely to prevent all episodes of endocarditis since up to 50% of cases occur in individuals without previously diagnosed cardiac abnormalities (Hoen *et al.*, 2002). For the identified at-risk group, the appropriate antibiotic prophylaxis is summarized in Table 2.6.

The main principle governing these prophylactic regimens is that a high circulating blood level of a suitable bactericidal agent should be achieved at a time when the bacteraemia would occur. For bacteraemia arising during dental surgery, additional protection may be achieved by supplementing the use of systemic antibiotics with locally applied chlorhexidine gluconate gel (1%) or chlorhexidine gluconate mouthwash (0.2%) 5 min before the procedure. Dental procedures that require antibiotic prophylaxis include extractions, scaling and surgery involving gingival tissues. A most important consideration for patients who are at risk of endocarditis is that their dental treatment be planned in such a way that the need for frequent antibiotic prophylaxis and the consequent selection for resistant bacteria among the resident flora is avoided. For multistage dental procedures, a maximum of two single doses of penicillin may be given in a month and alternative drugs should be used for further treatment, and penicillin should not be used again for 3–4 months.

Abscesses Caused by Non- β -Haemolytic Streptococci

Streptococci are frequently isolated from purulent infections in various parts of the body, including dental, central nervous system (CNS), liver and lung abscesses. Commonly, there is a mixture of several organisms in the pus, which may contain obligate anaerobes as well as streptococci and other facultative anaerobes. Consequently, it may be difficult to determine the contribution that any single strain or species is making to the infectious process. The source of these bacteria is usually the patient's own commensal microflora and may be derived from the mouth, upper respiratory tract, gastrointestinal tract or genitourinary tract.

Members of the anginosus group of streptococci (previously known as *S. milleri* group, or SMG, streptococci) have a particular propensity to cause abscesses. The development of reliable identification and speciation methods for this group of streptococci has allowed epidemiological analysis to determine whether there is a correlation between species and anatomical site of infection (reviewed by Belko *et al.*, 2002). Studies indicate that *S. intermedius* was more frequently isolated from infections of the CNS and liver, *S. constellatus* was more frequently isolated from lung infections, whereas *S. anginosus* was more frequently associated with infections of the gastrointestinal and genitourinary tracts and with soft-tissue infections. Although studies have identified several virulence determinants of anginosus

Table 2.6 Recommended antibiotic prophylaxis for endocarditis

Dental procedures under local or no anaesthesia

Patients who have not received more than a single dose of a penicillin in the previous month, including those with a prosthetic valve (but not those who have had endocarditis)

- Oral amoxicillin 3 g 1 h before procedure (children under 5 years, quarter adult dose; 5–10 years, half adult dose)

Patients who are penicillin-allergic or have received more than a single dose of a penicillin in the previous month

- Oral clindamycin 600 mg 1 h before procedure (children under 5 years, clindamycin quarter adult dose or azithromycin 200 mg; 5–10 years, clindamycin half adult dose or azithromycin 300 mg)

Patients who have had endocarditis

- Amoxicillin plus gentamycin, as under general anaesthesia

Dental procedures under general anaesthesia

No special risk (including patients who have not received more than a single dose of a penicillin in the previous month)

Either

- Intravenous amoxicillin 1 g at induction, then oral amoxicillin 500 mg 6 hours later (children under 5 years, quarter adult dose; 5–10 years, half adult dose)

Or

- Oral amoxicillin 3 g 4 h before induction, then oral amoxicillin 3 g as soon as possible after procedure (children under 5 years, quarter adult dose; 5–10 years, half adult dose)

Special risk (patients with a prosthetic valve or who have had endocarditis)

- Intravenous amoxicillin 1 g plus intravenous gentamicin 120 mg at induction, then oral amoxicillin 500 mg 6 h later (children under 5 years, amoxicillin quarter adult dose, gentamicin 2 mg/kg; 5–10 years, amoxicillin half adult dose, gentamicin 2 mg/kg)

Patients who are penicillin-allergic or who have received more than a single dose of a penicillin in the previous month

- Intravenous vancomycin 1 g over at least 100 min, then intravenous gentamicin 120 mg at induction or 15 min before procedure (children under 10 years, vancomycin 20 mg/kg, gentamicin 2 mg/kg)

Or

- Intravenous teicoplanin 400 mg plus gentamicin 120 mg at induction or 15 min before procedure (children under 14 years, teicoplanin 6 mg/kg, gentamicin 2 mg/kg)

Or

- Intravenous clindamycin 300 mg over at least 10 min at induction or 15 min before procedure, then oral or intravenous clindamycin 150 mg 6 h later (children under 5 years, quarter adult dose; 5–10 years, half adult dose)

Table adapted from the British National Formulary (2003), based on Recommendations of the Endocarditis Working Party of the British Society for Antimicrobial Chemotherapy.

group streptococci (see *Pathogenesis*), we have little understanding of the bacterial–host interactions that define the body-site specificity identified by these epidemiological studies.

Pathogenesis

Members of the anginosus group of streptococci possess multiple pathogenic properties that may contribute to disease. These include adhesion to host tissue components such as fibronectin, fibrinogen and fibrin–platelet clots (Willcox, 1995; Willcox *et al.*, 1995) and the aggregation of platelets (Willcox *et al.*, 1994; Kitada, Inoue and Kitano, 1997) (Table 2.7).

Abscesses are frequently polymicrobial in nature, and studies suggest that coinfection of streptococci with strict anaerobes such as *Fusobacterium nucleatum* and *Prevotella intermedia*, both common oral isolates, enhanced pathology. Thus, coinfection of anginosus group streptococci with *F. nucleatum* in a mouse subcutaneous abscess model resulted in increased bacterial survival and increased abscess size compared with abscesses formed following monoculture inoculation of streptococcus or *F. nucleatum* alone (Nagashima,

Table 2.7 Pathogenic properties of anginosus group streptococci

Property	Reference
Adhesion to host components	Willcox (1995), Willcox <i>et al.</i> (1995)
Platelet aggregation	Willcox <i>et al.</i> (1994), Kitada, Inoue and Kitano (1997)
Synergistic interactions with anaerobes	Shinzato and Saito (1994, 1995), Nagashima, Takao and Maeda (1999)
Production of hydrolytic enzymes	Unsworth (1989), Jacobs and Stobberingh (1995), Shain, Homer and Beighton (1996)
Intermedilysin-specific haemolytic activity	Nagamune <i>et al.</i> (1996)

Takao and Maeda, 1999). In a second study, coinfection of *S. constellatus* with *P. intermedia* resulted in an increased mortality rate in mouse pulmonary infection model (Shinzato and Saito, 1994). In both cases *in vitro* studies indicated that coculture enhanced the growth of the streptococcus and suggested that secreted factors produced by the anaerobic bacteria suppressed host bactericidal activity.

The streptococci themselves may secrete enzymes capable of degrading host tissue components including chondroitin sulphate and hyaluronic acid (Unsworth, 1989; Jacobs and Stobberingh, 1995; Shain, Homer and Beighton, 1996). In one clinical study most (85%) of the anginosus group streptococci isolated from abscesses produced hyaluronidase compared with only 25% of strains isolated from the normal flora of healthy sites (Unsworth, 1989). Despite such epidemiological evidence, the role of hydrolytic enzymes in the disease process has not yet been investigated in any detail.

In 1996, Nagamune and coworkers reported on a human-specific cytotoxin, intermedilysin, that was secreted by a strain of *S. intermedius* isolated from a human liver abscess and shown to be able to directly damage host cells including polymorphonuclear cells (Nagamune *et al.*, 1996; Macey *et al.*, 2001). Intermedilysin-specific haemolytic activity is distinct from the haemolytic activity found on blood agar with some anginosus group streptococci. The 54-kDa protein is a member of cholesterol-binding cytotoxin family of pore-forming toxins expressed by a range of Gram-positive bacteria (Billington, Jost and Songer, 2000) including *S. pneumoniae* (pneumolysin). PCR amplification studies demonstrated that the intermedilysin gene, *ily*, is restricted to typical *S. intermedius* isolates and is absent from *S. anginosus* and *S. constellatus* strains (Nagamune *et al.*, 2000). The occurrence of human-specific haemolysis and/or the presence of the *ily* gene consequently offers a useful marker of *S. intermedius* (Jacobs, Schot and Schouls, 2000; Nagamune *et al.*, 2000). In the study by Nagamune *et al.* (2000), intermedilysin-specific haemolytic activity was approximately 6–10-fold higher in brain abscess or abdominal infection strains compared with *S. intermedius* isolates from dental plaque. In contrast, in this study no apparent association was observed between the degree of hydrolytic activity and site of infection, and dental plaque isolates demonstrated comparable chondroitin sulphatase, hyaluronidase and sialidase (neuraminidase) activity (Nagamune *et al.*, 2000).

Clinical and Laboratory Considerations

There are no particular features that clearly distinguish abscesses associated with non- β -haemolytic streptococci from those caused by other microorganisms. The actual presentation depends upon the site and extent of the abscess as well as upon the nature of the causative organism(s). Since the infections are often polymicrobial, sometimes with obligate anaerobes, streptococci may be isolated from foul-smelling, apparently anaerobic pus. Successful diagnosis depends to a large extent on obtaining adequate clinical material that has not been contaminated with normal commensal bacteria from the skin or mucosal surfaces. Whenever possible, aspirated pus samples should be collected and inoculated into appropriate culture media for aerobic,

microaerophilic and anaerobic incubation. Isolates of presumptive streptococci should be identified, as described in the section *Laboratory Diagnosis*, and tested for antibiotic sensitivity.

The clinical management of all abscesses, whether or not streptococci are involved, requires both surgical drainage and antimicrobial chemotherapy. Since the infection is frequently mixed, a combination of agents may be indicated to combat the different species present. For example, a combination of penicillin and metronidazole may be appropriate for abscesses caused by streptococci in conjunction with one or more strict anaerobes, as is often the case with infections around the head and neck.

Streptococcal Infections in the Immunocompromised

Advances in organ transplantation and the treatment of patients with cancer have resulted in increased numbers of immunocompromised individuals at risk of infection from endogenous organisms. Between 1970 and 2000, the non- β -haemolytic streptococci have emerged as significant pathogens in these patients, capable of causing septicaemia, acute respiratory distress syndrome and pneumonia. Non- β -haemolytic streptococci are also implicated in neonatal septicaemia and meningitis. Centres in North America and Europe have reported variable experiences with infection by these species in cancer and transplant patients, with a mortality rate of up to 50% (reviewed by Shenep, 2000). The source of infection is generally the oral cavity or gastrointestinal tract, and risk factors, in addition to profound neutropenia, include chemotherapy-induced mucositis, use of cytosine arabinoside (over and above its association with mucositis) and the use of certain prophylactic antimicrobial therapies (quinolones and cotrimoxazole) with reduced activity against the non- β -haemolytic streptococci (Kennedy and Smith, 2000; Shenep, 2000).

The species which are most commonly associated with infection in immunocompromised individuals are *S. oralis*, *S. mitis* and *S. sanguis*; however, little is known regarding the virulence determinants or pathogenic mechanisms involved in these infections beyond the ability of the streptococci to induce the production of proinflammatory cytokines (Vernier *et al.*, 1996; Scannapieco, Wang and Shiau, 2001).

Clinical and Laboratory Considerations

The initial clinical feature of septicaemia is typically fever, which is generally at least 39°C and may persist for several days despite clearance of cultivable organisms from the blood. Most patients respond to appropriate antibiotic therapy; however, in few cases there is progression to fulminant septicaemia associated with prolonged fever and severe respiratory distress, some 2–3 days after the initial bacteraemia. Identification of the causative organism is routinely by culture of blood or other normally sterile tissue.

Empiric antimicrobial therapy for episodes of febrile neutropenia should ideally have activity against both Gram-negative and Gram-positive bacteria, and consequently, combination therapy or use of a broad-spectrum antibiotic is recommended. As discussed in the section *Antibiotic Susceptibility*, some streptococcal isolates from neutropenic patients are found to be relatively resistant to penicillin and other antibiotics, and the choice of empiric therapy where infection by non- β -haemolytic streptococci is suspected should take into account the local pattern of antibiotic susceptibilities among recent isolates. For endocarditis prophylaxis, the establishment and maintenance of good oral hygiene is an important preventative measure both before and during the period of neutropenia.

Caries

Dental caries is a disease that destroys the hard tissues of the teeth. If unchecked, the disease may progress to involve the pulp of the tooth and, eventually, the periapical tissues surrounding the roots. Once the

process has reached the periapical region, infection either may remain localized as an acute dental abscess or as a chronic granuloma or may spread more widely in various directions depending on its anatomical position. In some cases such spreading infections may cause a life-threatening situation, for example, if the airway is obstructed by submandibular swelling (Ludwig's angina).

The disease is initiated by acid demineralization of the teeth because of the metabolic activities of saccharolytic bacteria, including streptococci, which are situated on the tooth surface as part of the complex microbial community known as dental plaque. Dental plaque accumulates rapidly on exposed tooth surfaces in the mouth and consists of a complex mixture of bacteria and their products. Many of the oral streptococci listed in Table 2.1 are prominent components of dental plaque. When an external source of carbohydrate becomes available, in the form of dietary carbohydrate (particularly sucrose), streptococci and other plaque bacteria rapidly utilize the fermentable sugars and release acidic metabolic end products such as lactic acid. This can result in a rapid drop in pH in the vicinity of teeth that, if sufficiently low (pH 5.5 or less), in turn results in the demineralization of the dental enamel.

Most detailed studies on the pathogenesis of dental caries have focused on the mutans streptococci since these are widely regarded as the most significant initiators of the disease. Properties of these streptococci that are considered to be important in caries include ability to survive and grow at relatively low pH, production of extracellular polysaccharides from glucose and production of acid from carbohydrates, and mutant strains lacking in one or more of these attributes have been shown to be less cariogenic in experimental animals (reviewed by Kuramitsu, 2003). The frequent consumption of sugar is proposed to shift the plaque population in favour of aciduric species able to grow and survive in low pH conditions, which in turn results in greater plaque acidification and, consequently, greater enamel dissolution (Marsh, 2003). However, oral species other than mutans group streptococci are thought to contribute to the disease process.

The main approaches to caries prevention include the control of dietary carbohydrates, particularly by reducing the frequency of sugar intakes, the use of fluorides (both topically and systemically), maintenance of good oral hygiene and plaque control, application of fissure sealants and regular dental check-ups. With a better understanding of mucosal immunity and using new technologies available in molecular biology, researchers have developed novel caries preventative measures. These include local passive and active immunization, replacement therapy (the use of engineered noncariogenic *S. mutans* strains to replace cariogenic species within dental plaque) and the use of anti-adhesive peptides (Kelly *et al.*, 1999; Hillman, 2002; Koga *et al.*, 2002). Despite growing evidence from laboratory animal and human clinical studies of the ability of these approaches to control *S. mutans* numbers, their potential as anti-caries treatments has yet to be fully realized.

LABORATORY DIAGNOSIS

Specimens and Growth Media

Non- β -haemolytic streptococci are isolated from a wide range of clinical specimens such as blood, pus, wounds, skin swabs and biopsies as well as from dental plaque, saliva and other oral sites. Obtaining pus from an oral abscess is best done by direct aspiration using a hypodermic syringe rather than by swabbing, to reduce the risk of contaminating the sample with the oral flora, although in some instances (e.g. with infants), swab samples may be the only option available, unless the patient is undergoing a general anaesthesia. When sampling oral sites for ecological studies, it is necessary to ensure that the area sampled is small enough to be representative of a discrete site to avoid the risk of obscuring the differences between sites by sampling too big an area.

Where the laboratory processing of a specimen may be delayed, the clinical sample is best held in a suitable reduced transport fluid such as the one described by Hardie and Whiley (1992).

The non- β -haemolytic streptococci are fastidious organisms, with a need for a carbohydrate source, amino acids, peptides and proteins, fatty acids, vitamins, purines and pyrimidines. These bacteria therefore need complex growth media commonly containing meat extract, peptone and blood or serum. Non- β -haemolytic streptococci are best isolated from clinical samples on a combination of nonselective and selective agar media. Nonselective examples include blood agar 2 (Oxoid, Hampshire, UK), Columbia agar (Gibco BRL, Life Technologies, Paisley, UK), fastidious anaerobic agar (Laboratory M, Amersham, UK) and brain-heart infusion agar (Oxoid) supplemented with 5% defibrinated horse or sheep blood. Several selective media are available for the non- β -haemolytic streptococci. The two most commonly used agars are trypticase-yeast-cystine (TYC) and mitis-salivarius (MS) agars that contain 5% sucrose to promote the production of extracellular polysaccharides, resulting in the production of characteristic colonial morphologies as an aid to identification. TYC is available commercially from Laboratory M; MS agar is available from Oxoid and from Difco (Detroit, MI, USA). Other selective media commonly used for the isolation of mutans streptococci are based on TYC or MS agars and have the addition of bacitracin (0.1–0.2 U/ml) and an increased amount of sucrose (20%). Nalidixic acid-sulphamethazine (NAS) agar is a selective medium for the anginosus group streptococci and uses 40 g/l of sensitivity agar supplemented with 30 μ g/ml of nalidixic acid, 1 mg/ml of sulphamethazine (4-amino-*N*-[4,6-dimethyl-2-pyrimidinyl]benzene sulphonamide) and 5% defibrinated horse blood. This medium is also selective for *S. mutans*.

As streptococci are facultative anaerobes, incubation is best carried out routinely in an atmosphere of air plus 10% carbon dioxide or in an anaerobic gas mix containing nitrogen (70–80%), hydrogen (10–20%) and carbon dioxide (10–20%). Some strains have an absolute requirement for carbon dioxide, particularly on initial isolation. Colonies on blood agar are typically 1 mm or less in diameter after incubation for 24 h at 37°C, are nonpigmented and often appear translucent. On blood agar the streptococci discussed in this chapter usually produce α -haemolysis or are non- (γ) -haemolytic. However, as mentioned previously, the haemolytic reactions of different strains within a species may vary and are sometimes influenced by the source of blood (e.g. horse, sheep) and by the incubation conditions. Some examples of colonial morphology on different culture media are illustrated in Figure 2.4.

Liquid culture of these streptococci may be carried out in a commercial broth such as Todd-Hewitt broth or brain-heart infusion broth (Oxoid) with or without supplementation with yeast extract (0.5%). The growth obtained in broth cultures varies from a diffuse turbidity to a granular appearance with clear supernatant depending on strain and species.

Initial Screening Tests

Streptococci are usually spherical, with cells of approximately 1- μ m diameter arranged in chains or pairs. The length of the chains may vary from only a few cells to over 50 cells, depending on the strain and cultural conditions (longer chains are produced when the organisms are grown in broth culture). Streptococci stain positive in the Gram stain, although older cultures may appear Gram variable. Some strains may appear as short rods under certain cultural conditions. Isolates should be tested for catalase reaction, and only catalase-negative strains should be put through further streptococcal identification tests.

The clinical microbiologist should be aware that, because of developments in taxonomic studies, several other genera of facultative anaerobic Gram-positive cocci that grow in pairs or chains have been proposed that may superficially resemble streptococci. The scheme described in Table 2.8 should allow the differentiation of these genera on the basis of a few cultural and biochemical tests, with great caution to be exercised in the interpretation of morphological observations.

Figure 2.4 Colonial appearance of non- β -haemolytic streptococci on blood agar (BA) or 5% sucrose containing agars [trypticase–yeast–cystine (TYC) and mitis–salivarius (MS)]: (a) *S. anginosus* (BA); (b) *S. anginosus* (TYC); (c) *S. anginosus* (MS); (d) *S. intermedius* (BA) showing rough and smooth colony variants; (e) *S. salivarius* (BA); (f and g) *S. salivarius* (TYC) showing extracellular polysaccharide (fructan) production; (h) *S. salivarius* (MS); (i) *S. sanguis* (BA); (j) *S. sanguis* (TYC) showing extracellular polysaccharide (glucan) production; (k) *S. sanguis* (MS); (l) *S. mutans* (BA); (m) *S. mutans* (TYC) showing extracellular polysaccharide (glucan) production; (n) *S. mutans* (MS); (o) *S. bovis* (BA); (p) *S. bovis* (MS) showing extracellular polysaccharide (glucan) production.

Figure 2.4 (Continued).

Identification to Species Level

The identification of isolates to species level may be carried out using either laboratory-based biochemical test schemes or commercial identification kits with accompanying databases. Although species-level identification of non- β -haemolytic streptococci is not

routinely carried out in many clinical laboratories, this may be deemed necessary for suspected pneumococcal infection, isolates obtained from deep-seated abscesses, specimens from endocarditis or where pure cultures have been grown. Differential tests for the identification of non- β -haemolytic streptococci are summarized in Tables 2.9–2.13.

Table 2.8 Differential characteristics of *Streptococcus* and other Gram-positive, catalase-negative, facultatively anaerobic coccus genera that grow in pairs or chains

Genus	Pyrrolidonyl arylamidase	Leucine aminopeptidase production	6.5% NaCl	BE	Growth at		Susceptibility to vancomycin	Haemolysis
					10 °C	45 °C		
<i>Streptococcus</i> ^a	–	+	– ^b	– ^c	–	V	S	α, β, γ
<i>Enterococcus</i> ^d	+	+	+	+	+	+	S ^e	α, β, γ
<i>Lactococcus</i>	+	+	V	+	+	– ^f	S	α, γ
<i>Vagococcus</i> ^d	+	+	+	+	+	–	S	α, γ
<i>Globicatella</i>	+	–	+	–	–	–	S	α
<i>Leuconostoc</i> ^g	–	–	V	V	+	V	R	α, γ

BE, reaction on bile–aesculin medium. +, ≥95% of strains are positive; –, ≥5% of strains are negative; V, variable reaction; R, resistant; S, susceptible.

^a *Abitrophia* and *Granulicatella* (formerly nutritionally variant streptococci strains) are weakly pyrrolidonyl arylamidase and leucine aminopeptidase production positive and grow in 6.5% NaCl broth. Some group A streptococci are pyrrolidonyl arylamidase positive.

^b Some β-haemolytic streptococci grow in 6.5% NaCl broth.

^c 5–10% of viridans streptococci are bile–aesculin positive.

^d Some enterococci are motile; *Vagococcus* is motile (formerly called group N streptococci).

^e Some strains are vancomycin resistant.

^f Some strains grow very slowly at 45 °C.

^g Gas is produced by *Leuconostoc* from glucose in Mann, Rogosa, Sharpe (MRS) *Lactobacillus* broth.

Table 2.9 Differential biochemical characteristics of the anginosus group

We do not have permission to reproduce the table electronically

The rapid and extensive taxonomic revision of the genus *Streptococcus*, including the demonstration of several new species and amended descriptions of others, has, to some extent, outpaced the availability of comprehensive schemes for routine identification. However, significant improvements to this situation have come about through the incorporation of fluorogenic and chromogenic substrates into identification schemes for the rapid detection of preformed enzyme activities. These test schemes combine tests for the detection of glycosidase and arylamidase reactions with more traditional tests that detect carbohydrate fermentation, arginine dihydrolase and acetone production. A further development has been the inclusion of these tests in a more standardized format in some commercially available test kits, which helps reduce the degree of discrepancy between biochemical test results from different laboratories. Currently, a 32 Test Kit for identifying streptococci is available, which takes into account

most of the currently recognized species (Rapid ID32 Strep system; bioMérieux Vitek, bioMérieux, Durham, NC, USA). In an independent evaluation the kit gave correct identification for 95.3% (413/433) of strains examined, including 109 strains that required some additional tests for complete identification. Sixteen strains remained unidentified and four were misidentified (Freney *et al.*, 1992). In another study the test kit gave correct identification for 87% of strains examined. However, *S. mitis* and *S. oralis* were not easily differentiated using this method (Kikuchi *et al.*, 1995). Other phenotypic markers that have been reported to be potentially useful, particularly for the oral streptococci, include acid and alkaline phosphatases, neuraminidase (sialidase), IgA1 protease production, salivary amylase binding, extracellular polysaccharide production and the detection of hyaluronidase and chondroitin sulphate depolymerase activities. Several other approaches to species identification have been investigated such as pyrolysis–mass spectrometry, whole-cell–derived polypeptide patterns by sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) or other electrophoretic separation techniques and the analyses of long-chain fatty acids and cell-wall components. However, these strategies have not been widely adopted and remain a part of the repertoire of the specialist research laboratory.

Significant progress has been already made in developing genetic-based approaches to species identification. DNA probes for this purpose have been described that utilize whole chromosomal preparations or cloned DNA fragments. However, as with most other groups of bacteria, by far the greatest promise for a genetically based identification approach lies in the analysis of nucleotide sequence data derived from the 16S rRNA gene. Published studies have provided 16S rRNA gene sequence data for most, but not all, non-β-haemolytic streptococci, which have been found to be distinct for each of the species so far examined (Bentley, Leigh and Collins, 1991; Kawamura *et al.*, 1995a). Other approaches have been described including restriction fragment length polymorphism (RFLP) analysis of amplicons of 16S–23S rDNA and intergenic spacer regions (Rudney and Larson, 1993; Schlegel *et al.*, 2003b) or tDNA intergenic spacer regions (De Gheldre *et al.*, 1999) and PCR amplification and sequence analysis of the gene encoding manganese-dependent superoxide dismutase (Poyart, Quesne and Trieu-Cuot, 1998).

Serology

The success obtained in producing a serological classification for the pyogenic streptococci was not extended to the non-β-haemolytic species. Several early attempts to this end were unsatisfactory and failed to produce an all-encompassing scheme for these streptococci.

Table 2.10 Differential biochemical characteristics of the mitis group

In retrospect, these studies were probably frustrated by the unsatisfactory classification of the viridans streptococci at the time, as well as by the numerous serological cross-reactions that characterize these species. Serological studies have also been undertaken on the *S. milleri* group (anginosus group) with the aim of developing a useful scheme for serotyping clinical isolates. In one study (Kitada *et al.*, 1992) 91 clinical isolates were tested for the possession of a Lancefield group antigen and/or one of eight cell-surface carbohydrate serotyping antigens. Unfortunately, 19 of 91 isolates (21%) failed to react against any of the antisera, added to which the identity of the streptococci examined cannot be related to currently accepted species with any certainty. However, serological analysis of some of these streptococci has provided useful data with important consequences. Serological subdivisions within the mutans streptococci together with biochemical and genetic data led to the recognition of several distinct species of acidogenic oral bacteria, and this is of considerable significance in studies of dental caries. There are currently eight serotypes (serovars) recognized within these streptococci (a-h) based on the possession of serotype-specific cell-wall polysaccharide antigens (Hamada and Slade, 1980) (Table 2.1).

ANTIBIOTIC SUSCEPTIBILITY

Although antibiotic activity against non- β -haemolytic streptococci has long since been known to be poorer than for their β -haemolytic counterparts, the 1990s has witnessed some alarming changes in the susceptibility of non- β -haemolytic streptococcal strains to key therapeutic agents. Early indications of emerging β -lactam resistance came from the United States, Italy and the United Kingdom (Wilson *et al.*, 1978; Bourgault, Wilson and Washington, 1979; Venditti *et al.*, 1989;

^a Different reactions were observed for isolates formerly assigned to *S. equinus* or *S. bovis*.

McWhinney *et al.*, 1993; Renneberg, Niemann and Gutschik, 1997), with further reports emerging throughout the 1990s from almost all continents, indicating emerging penicillin resistance.

Within Europe, many reports from the late 1980s, and continuing throughout the 1990s, observed an increase in the numbers of antibiotic-resistant non-β-haemolytic streptococcal strains implicated in severe disease in neutropenic and other patient groups. Research from Barcelona, Spain, based on non-β-haemolytic streptococcal strains

causing bacteraemia in neutropenic patients collected between 1987 and 1992 documented such an emergence of penicillin resistance (Carratala *et al.*, 1995). The strain collection was expanded to span from 1986 to 1996, and microbiological analysis revealed a remarkably high number of strains to have reduced susceptibility to penicillin (39%), with resistance to erythromycin and ciprofloxacin being found in just over a third of isolates (Marron *et al.*, 2001). Susceptibility to fourth-generation cephalosporins was also tested in 35 of these

isolates, 5 of which were found to be resistant to cefpirome and 12 to cefepime. How widespread this phenomenon of penicillin resistance was is difficult to ascertain, since a study from the opposite side of the Iberian Peninsula (Lugo), although admittedly based on a small collection of anginosus group bacteraemic strains (1988–1994), found all to be sensitive to penicillin and erythromycin (Casariego *et al.*, 1996). More recent evidence from central Spain (Madrid) also reported a high proportion of non- β -haemolytic streptococci isolated from blood culture between 1998 and 2001 to be to erythromycin (42%), tetracycline (35%) and clindamycin (25%) resistant (Rodríguez-Avial *et al.*, 2003). Researchers also found evidence of cross-resistance between erythromycin and tetracycline, with resistance to one agent being associated with the occurrence of the other. Also of note is that 3 of the 111 isolates tested by Rodríguez-Avial *et al.* (2003) were found to be resistant to the streptogramin quinupristin/dalfopristin.

National surveillance data from England and Wales also point to a similar increase in resistant phenotypes (PHLS, 2001, 2002; HPA, 2003a). The numbers of bacteraemic strains reported through routine surveillance as having reduced susceptibility to penicillin increased between 2000 and 2002 for all non- β -haemolytic streptococcal groups, with yearly increases for *S. mitis* group being particularly pronounced, stepping from 9 reports in 2000 to 33 in 2001 to 73 in 2003. Of the multitude of species that constitute the non- β -haemolytic streptococci, *S. mitis*, *S. sanguis* and *S. oralis*, have been described as most frequently exhibiting reduced susceptibility to penicillin (Alcaide *et al.*, 1995; Mouton *et al.*, 1997; de Azavedo *et al.*, 1999; Wisplinghoff *et al.*, 1999; Gershon *et al.*, 2002). Analysis of streptococcal isolates submitted to the UK national reference laboratories between 1996 and 2000, originating from patients with endocarditis, found one in four of *S. mitis* isolates to have reduced susceptibility to penicillin (MIC >0.125 mg/l), with one in seven of *S. sanguis* and one in eight of *S. oralis* isolates also showing reduced penicillin susceptibility (Johnson *et al.*, 2001). Tetracycline and erythromycin resistance similarly increased over this period, with *S. mitis* group showing highest frequency of erythromycin resistance and *S. bovis* group showing the highest frequency of tetracycline resistance (HPA, 2003a). In the light of the common target of activity for streptogramins and macrolides, studies have found evidence of cross-resistance between erythromycin and quinupristin/dalfopristin (Mouton *et al.*, 1997).

Similarly worrying reports of antibiotic resistance in non- β -haemolytic streptococci causing bacteraemia and/or endocarditis emerged from other parts of Europe during this period. Although frequently based on small collections of strains, studies in France, Germany, Sweden and Denmark documented substantial proportions of non- β -haemolytic streptococcal strains as having decreased sensitivity to erythromycin and/or penicillin (Wisplinghoff *et al.*, 1999; Lefort *et al.*, 2002; Westling *et al.*, 2002). Pooled data for 1997–1998 from European countries participating in the SENTRY Antimicrobial Surveillance Programme found 39% of non- β -haemolytic streptococci to be nonsusceptible to penicillin, whereas 30% exhibited reduced susceptibility to erythromycin (Fluit *et al.*, 2000).

Interestingly, two studies from the Far East both showed high levels of macrolide resistance in bacteraemic isolates. Sixty-three per cent of non- β -haemolytic streptococcal strains collection from Taiwan were reported as having reduced susceptibility to erythromycin and clarithromycin, although all strains were sensitive to penicillin, cefotaxime, imipenem, vancomycin and teicoplanin (Teng *et al.*, 2001). Similarly, in Hong Kong, characterization of bacteraemic *S. bovis* isolates showed all to be sensitive to penicillin, cephalothin and vancomycin, whereas 65% had reduced susceptibility to erythromycin. Forty-one per cent also showed reduced susceptibility to clindamycin (Lee *et al.*, 2003). Subsequent reports from participants in the Asia-Pacific region SENTRY Antimicrobial Surveillance Programme, which includes Hong Kong and Taiwan, documented a frequency of penicillin and erythromycin resistance in non- β -haemolytic streptococci more akin to that documented in Europe and the Americas,

possibly due to the effect of pooling data from many countries, including Australia and South Africa (Gordon *et al.*, 2002).

Research from North America began to show a similar pattern of emerging penicillin resistance as that seen in Europe among non- β -haemolytic streptococci. Studies conducted in the United States during the mid-1990s began to report levels of penicillin tolerance (nonsusceptibility) at between 39% and 44% of isolates (Doern *et al.*, 1996; Pfaller *et al.*, 1997). Cases of quinupristin/dalfopristin-resistant *S. mitis* have also been uncovered in the United States through the SENTRY Antimicrobial Surveillance Programme (Kugler *et al.*, 2000). Similarly, research from the Canadian Bacterial Surveillance Network found levels of penicillin resistance increasing from the mid-1990s (28% of blood culture isolates) to 2000 (37%) (de Azavedo *et al.*, 1999; Gershon *et al.*, 2002). Bigger increases still were seen in the frequency of isolates nonsusceptible to erythromycin, from 29% to 42%, with frequency of reduced clindamycin susceptibility also increasing from 4% to 10%.

Following the mottled array of reports describing the emergence of resistant phenotypes over 1990s, more recent descriptions from the SENTRY global antimicrobial surveillance network suggest that some degree of uniformity of antibiotic resistance may now exist among non- β -haemolytic streptococci causing blood stream infection (Gordon *et al.*, 2002). The increase in resistance in these important pathogens presents a challenge to the treatment and control of infections and warrants further vigilance, especially in the light of the first description of a naturally occurring vancomycin-resistant *S. bovis* strain (Poyart *et al.*, 1997).

Streptococcus pneumoniae

Indran Balakrishnan

Department of Medical Microbiology, Royal Free Hospital, London, UK

INTRODUCTION

The pneumococcus was discovered in 1881 simultaneously by Sternberg in the United States, who named it *Micrococcus pasteuri*, and by Pasteur in France, who named it *Microbe septicémique du salive* (Watson *et al.*, 1993). Within 10 years, the great propensity of this organism to cause serious infection was recognised and its causative role in pneumonia, meningitis, otitis media, arthritis and bacteraemia described. The identification of this organism as the most frequent cause of lobar pneumonia led to common use of the term pneumococcus, and its microscopic morphology in Gram-stained sputum led to it being renamed *Diplococcus pneumoniae* in 1926. Based on its ability to form short chains in liquid media, the organism was subsequently reclassified into the genus *Streptococcus* in 1974 and its name changed to *Streptococcus pneumoniae*.

Research performed during the first half of the twentieth century revealed that the pneumococcus could be divided into numerous serotypes using antisera against its capsular polysaccharides.

The history of *S. pneumoniae* is inextricably intertwined with that of microbiology. The pneumococcus played a pivotal role in the elucidation of the process of opsonisation in the 1890s, providing the basis for our understanding of humoral immunity. These principles soon found application when, in the early twentieth century, vaccination with killed pneumococci was successful in reducing the incidence of lobar pneumonia amongst African miners (reviewed in Musher, Watson and Dominguez, 1990). The first pneumococcal capsular polysaccharide vaccine was shown to be effective in 1938 (Smillie, Wornock and White, 1938).

The most significant role played by the pneumococcus in expanding our understanding of science, however, was in the discovery of DNA. The pneumococcus led to the discovery of the process of transformation in the 1920s by Griffith (1928). This process remained somewhat mysterious until the 1940s, when Avery, MacLeod and McCarty (1944) demonstrated that transformation is mediated by the transfer of DNA and that DNA is in fact the carrier of genetic information.

DESCRIPTION OF THE ORGANISM

Microscopic and Colonial Appearance

Streptococcus pneumoniae is a small (0.5–1.0 µm diameter) lanceolate Gram-positive coccus (Figure 3.1). It replicates in chains in liquid media but forms pairs joined along the horizontal axis on solid media. Pneumococci grow better in the presence of a source of catalase and form small (0.5–2 mm diameter) colonies that are dome-shaped initially but collapse centrally owing to autolysis after longer incubation, producing the classic draughtsman shape. Pneumococci breakdown haemoglobin by production of pneumolysin, resulting in a greenish

Figure 3.1 Gram stain appearance of *S. pneumoniae*.

discolouration of blood agar surrounding the colonies – this characteristic continues to be termed α -haemolysis, although lysis of erythrocytes is not a feature.

Physiology

Streptococcus pneumoniae is a facultative anaerobe. It is capnophilic, preferring atmospheres of 5–10% carbon dioxide. Pneumococci exhibit fermentative metabolism, utilising glucose via the hexose monophosphate pathway.

Four characteristics are especially useful in laboratory identification. The organism is

1. catalase negative;
2. inhibited by ethyl hydrocupreine (optochin);
3. bile soluble (bile salts activate autolytic activity, producing cell lysis);
4. α -haemolytic.

PATHOGENICITY

Streptococcus pneumoniae has a collection of characteristics that permit it to colonise a variety of niches. Most pneumococci are found in the nasopharynx, a location where transformation can readily take place. This location also provides a convenient niche from which invasive disease can occur, and a complex interplay of factors determines whether the colonising organisms go on to establish invasive

infection. Severe pneumococcal infection and its complications result partly from the direct actions of pneumococcal virulence determinants and partly from the host immune response to various pneumococcal components. Pneumococcal virulence determinants and the corresponding immune responses produce four key effects: adhesion, invasion, inflammation and shock.

Adhesion

Opacity

Changes in colonial opacity of mucosal pathogens that alter their ability to colonise these surfaces have been described (James and Swanson, 1978; Weiser, 1993). Opacity variants have been described after culture on tryptose soya agar supplemented with catalase. The organisms spontaneously revert between transparent and opaque phases at a rate of between 10^{-3} and 10^{-6} . Transparent variants are able to colonise the nasopharynx in the infant rat model more easily than opaque variants, and this is in keeping with their greater capacity for adhering to a variety of cells (e.g. human buccal epithelial cells, type II pneumocytes and vascular endothelial cells) (Cundell *et al.*, 1995b). The adherence of transparent variants is enhanced by treatment with interleukin-1 (IL-1) and tumour necrosis factor- α (TNF- α). This is probably due to cytokine-induced expression of cellular platelet-activating factor (PAF) receptors, to which the transparent phenotype binds via a phosphorylcholine (PC) ligand (see *Attachment and Phase Variation*) (Cundell *et al.*, 1995a).

The variants do not change the physical characteristics of the peptidoglycan stem peptides, but opaque variants do not undergo autolysis as quickly as transparent variants. The opaque phenotype is associated with enhanced production of capsular polysaccharide and PspA and the transparent phenotype with increased amounts of C-polysaccharide (Kim and Weiser, 1998). The choline-binding protein CbpA is present in higher concentrations in transparent phenotypes, and this protein is required for efficient colonisation in the infant rat model [see *Choline-Binding Protein A (CbpA, PspC, SpsA and PbcA)*] (Rosenow *et al.*, 1997). Opaque variants have been shown to be more virulent in the mouse intraperitoneal model of infection, with a reduction of 2–3 days in the time to death (Kim and Weiser, 1998). Mice dying after inoculation with opaque phenotypes have organisms of the same phenotype recovered from their spleen, whereas those mice inoculated with a transparent phenotype had organisms of a more opaque phenotype recovered from their spleen. Table 3.1 summarises the differences between opaque and transparent phenotypes.

Attachment and Phase Variation

Streptococcus pneumoniae binds to oral epithelial cells via *N*-acetyl galactosamine- β 1–3-galactose (Andersson *et al.*, 1983, 1988). Resting pneumocytes express two classes of receptors: *N*-acetyl-D-galactosamine linked by either β 1,3 or β 1,4 to galactose. Transparent and opaque phenotypes bind equally well to these receptors. Activated type II pneumocytes express a PAF receptor when stimulated by cytokines such as IL-1. Transparent, but not opaque, colonial variants of

pneumococci adhere to the PAF receptor via a PC ligand. It has been proposed that the pneumococcus binds to the PAF receptor by mimicking PAF, which, like the pneumococcal cell surface, contains PC – transparent phenotypes harbour more PC-containing cell-wall teichoic acid components, and binding is reduced by PAF receptor antagonists and exogenous choline (Cundell *et al.*, 1995a).

Pneumococci cannot enter resting endothelial cells, but experiments with activated cells show that they can allow internalisation of 2–3% of the inoculum (Geelen, Bhattacharyya and Tuomanen, 1993). Activated endothelial cells upregulate PAF receptor expression and allow pneumococcal entry using the PAF receptor recycling pathway – this may provide a route of transition across the alveolar space into the bloodstream and across the blood–brain barrier into the meninges. It is thought that either viral infections or cell-wall components released from dividing pneumococci could provide the initial stimulus for cytokine production (Tuomanen, 1999).

Pneumococcal Surface Adhesin A

Pneumococcal surface adhesin A (PsaA) is a recently identified 37-kDa surface lipoprotein essential for pneumococcal virulence. Sequencing studies have shown homology between PsaA and lipoprotein adhesins found in other viridans-type streptococci, such as FimA in *Streptococcus parasanguis* and SsaB in *Streptococcus sanguis* (Fenno, LeBlanc and Fives-Taylor, 1989; Ganeshkumar *et al.*, 1991). PsaA is a component of an ABC-type manganese permease membrane transport system – many such transporters exist in the pneumococcal genome, and some, such as Adc and PsaA, are particularly important for virulence.

PsaA is encoded by the *psaA* gene, which is part of the *psa* locus. This locus contains three other open-reading frames, encoding an ATP-binding protein (PsaB), a hydrophobic membrane protein (PsaC) and another protein (PsaD) which has homology with a periplasmic thiol peroxidase of *E. coli*.

In keeping with the actions of other pneumococcal permeases, the *psa* operon appears to have a regulatory role in adhesion. This operon affects the expression of choline-binding proteins on the pneumococcal surface, *psa* mutants demonstrating a complete absence of CbpA (Novak *et al.*, 1998). PsaA and PsaD mutants have been shown to display reduced virulence in mice and reduced adherence to lung cells *in vitro* (Berry and Paton, 1996). *psaB*, *psaC* and *psaD* mutants have been noted to have a reduced capacity for transformation. Mutations within the *Psa* operon have also been shown to confer penicillin tolerance, mutants being able to survive 10 \times minimum inhibitory concentration (MIC) of penicillin (Novak *et al.*, 1998).

Choline-Binding Protein A (CbpA, PspC, SpsA and PbcA)

Choline-binding protein A was the first pneumococcal surface protein adhesin to be described (Rosenow *et al.*, 1997). It is composed of 663 amino acids and has a molecular mass of 75 kDa. The protein has two distinct domains: a C-terminal that shares >95% homology with PspA and a unique N-terminal that, although different in primary sequence, has an α -helical coiled-coil structure like PspA. Like PspA, the choline-binding C-terminal of CbpA has a proline-rich region and the ten tandem, direct repetitive sequences of 20 amino acids that are characteristic of choline-binding proteins.

CbpA is thought to play an important role in the adhesion of pneumococci to human cells – its expression is upregulated in the transparent phenotype, and it has been shown that CbpA is essential for pneumococcal penetration across the blood–brain barrier (see *Meningitis*) (Ring, Weiser and Tuomanen, 1998). It has been suggested that pneumococci first adhere to cell-surface glycoconjugates. Cytokine activation of the cells leads to a change in the expression of glycoprotein ligands, allowing increased pneumococcal adherence, and it is in this second stage, the change from colonisation to invasion, that CbpA has a function (Cundell, Masure and Tuomanen, 1995).

Table 3.1 Summary of differences between opaque and transparent phenotypes

Characteristic	Transparent	Opaque
Capsule production	+	+++
Teichoic acid	++++	+
Surface expression <i>lytA</i>	+++	+
PspA	+	++
Colonisation	+++	+
Virulence	+	+++

CbpA may act as a bridge between pneumococcal PC and activated human cell glycoconjugates. It could also mask PC by preventing it from binding the PAF receptor. It is apparent that the adhesive/invasive process is a complex interplay between CbpA and PC, and their precise relationship and relative importance remain unclear.

The importance of the interactions between CbpA and both secretory component (SC) and the polymeric immunoglobulin receptor (pIgR) in adhesion and invasion is being increasingly recognised (Zhang *et al.*, 2000; Kaetzel, 2001). SC is a peptide found free in several secretions including respiratory secretions, milk and bile as well as in association with pIgR and human secretory IgA (sIgA) (Zhang *et al.*, 2000; Kaetzel, 2001). The polymeric immunoglobulin receptor is an integral membrane protein of 764 amino acids in humans that is initially targeted to the basolateral surface of epithelial cells. An important function of pIgR is the transcytosis of polymeric immunoglobulins synthesised by plasma cells in the lamina propria. These immunoglobulins bind covalently to SC, an extracellular ligand-binding domain of about 550 amino acids at the N-terminal of pIgR. Internalisation signals cause pIgR (with or without pIg) to be endocytosed and transported from the basolateral epithelial surface via a series of endosomal compartments to the mucosal surface. Here, SC is proteolytically cleaved from pIgR and released into mucosal secretions, either free or as a pIg-SC complex termed secretory immunoglobulin (Mostov *et al.*, 1999). Uncleaved pIgR on the mucosal surface can be internalised and transcytosed back to the basolateral surface of the cell. The major consequences of the interaction between CbpA and pIgR are that it provides both a mechanism for adherence and, therefore, colonisation of mucosal surfaces and a pathway for the translocation of pneumococci across epithelial cells by co-opting the transcytosis machinery.

SC-binding domains of 107 amino acids each have been identified at two sites in CbpA, with a hexapeptide motif (Y(H/R)RNYPT) between amino acids 198 and 203 being the SC/sIgA-binding motif (Hammerschmidt *et al.*, 1997, 2000; Zhang *et al.*, 2000). CbpA has also been shown to directly bind domains D3 and D4 of pIgR (Lu *et al.*, 2003).

Several other functions have also been ascribed to CbpA under different names, including C3-binding activity and inhibition of the complement cascade by factor H-binding activity (Cheng, Finkel and Hostetter, 2000; Janulczyk *et al.*, 2000).

Invasion

The most important event in pneumococcal infection is invasion of the lower respiratory tract. Pneumococcal pneumonia is in itself a life-threatening illness, and it also serves as a focus for bloodstream invasion. Paradoxically, pneumococci also have an ability to establish systemic invasion in the absence of a clinically evident focus of infection.

At the alveolar level, the factors that determine whether or not invasive disease is established could be viewed as a dynamic balance between adherence and uptake into pneumocytes versus clearance by alveolar macrophages. Table 3.2 summarises the various scenarios and their likely outcomes.

Table 3.2 Factors determining risk of pneumococcal pulmonary invasion

Situation	Pneumocyte uptake	Macrophage clearance	Outcome
Resting pneumocytes and opsonic antibody absent	Low	Low	Low risk of invasion
Resting pneumocytes and opsonic antibody present	Low	High	Very low risk of invasion
Activated pneumocytes and opsonic antibody absent	High	Low	Invasion likely
Activated pneumocytes and opsonic antibody present	High	High	Invasion risk uncertain

The global population of pneumococci consists of more than 90 serotypes, but human infection/colonisation is dominated by a relatively small number of these. Multilocus sequence typing has shown that some sequence types define strains with an increased capacity to cause invasive disease (Enright and Spratt, 1998). These apparently successful clones may have gathered a collection of genes (or have enhanced expression of a group of genes) that confers a selective advantage that shifts the host-pathogen balance, facilitating the transition from colonisation to invasion. Some of the proteins encoded by these genes are discussed below.

Hyaluronidase

This enzyme could facilitate pneumococcal invasion by degrading connective tissue. The importance of this enzyme has been illustrated by the demonstration that pneumococcal strains with higher hyaluronidase activity breach the blood-brain barrier and disseminate more effectively (Kostyukova *et al.*, 1995). Studies have shown that pneumococcal strains isolated from patients with meningitis and meningoencephalitis have significantly higher hyaluronidase activity than strains causing purulent otitis media, indicating the importance of hyaluronidase in the pathogenesis of human pneumococcal meningitis (Volkova, Kostyukova and Kvetnaia, 1994).

Neuraminidase

These enzymes cleave sialic acid residues from a wide variety of molecules, damaging host tissues. This action may serve to expose receptors for pneumococcal adhesins, thus facilitating both colonisation and invasion. The role of neuraminidase in adhesion has been demonstrated in the chinchilla respiratory tract – neuraminidase treatment of the trachea increased pneumococcal adherence and reversed the inhibition produced by prior incubation with glycoconjugate analogues of known pneumococcal receptors. These data suggest that neuraminidase facilitates adhesion by increasing the number of adhesins available for pneumococcal binding (Tong *et al.*, 1999).

The importance of neuraminidase activity in pneumococcal virulence has been suggested by the finding that patients with pneumococcal meningitis with high levels of *N*-acetyl neuraminic acid in their cerebrospinal fluid (CSF) were more likely to develop coma and bacteraemia (O'Toole, Goode and Howe, 1971).

Pneumococcal Surface Protein A

Pneumococcal surface protein A (PspA) has been confirmed as a pneumococcal virulence determinant. Immunisation of X-linked immunodeficient mice with recombinant PspA conferred protective immunity to challenge with three of four virulent pneumococcal strains (McDaniel *et al.*, 1991), and monoclonal anti-PspA provided passive protection (McDaniel *et al.*, 1984).

Hammerschmidt *et al.* (1999) have shown that PspA functions as a specific receptor for lactoferrin, the N-terminal being responsible for lactoferrin binding. PspA, hence, plays an essential role in enabling iron acquisition by *S. pneumoniae*. Mutant strains lacking PspA expression fix more complement than isogenic parent strains expressing PspA (Fenno, LeBlanc and Fives-Taylor, 1989) – this interference with complement activation serves to facilitate pneumococcal survival and host invasion.

Pneumolysin

The importance of pneumolysin as a virulence determinant has been recognised following active and passive immunisation studies of mice (Paton, Lock and Hansman, 1983). This finding has since been confirmed by studies demonstrating considerable loss of

virulence in isogenic mutants of *S. pneumoniae* in which the gene for pneumolysin had been disrupted (Berry *et al.*, 1989a).

Pneumolysin is a cytoplasmic toxin released by autolysis of the cell. It belongs to the family of thiol-activated cytolytins, the mechanism of action of which is thought to follow a two-stage common pathway (Bhakdi and Trantum-Jensen, 1986). The first stage entails binding of the monomeric toxin to the target-cell membrane. The second stage comprises lateral movement and oligomerisation of the monomers to form a high-molecular-weight transmembrane pore. This results in the leakage of intracellular solutes and an influx of water, resulting in colloid-osmotic lysis of the cell. By this mechanism, pneumolysin is able to damage a wide range of eukaryotic cells. Pneumolysin also has modulatory effects on cells at sublytic concentrations, e.g. stimulation of TNF- α and IL-1 β production by human monocytes (Houldsworth, Andrew and Mitchell, 1994).

Pneumolysin is a 52.8-kDa polypeptide consisting of 470 amino acids. Although much of its structure-function relationship remains unclear, the functional relevance of some areas has been elucidated. Pneumolysin contains eight histidine residues, one of which (position 367 in pneumolysin) is conserved in all thiol-activated toxins. Mutagenesis of this residue seriously impairs oligomerisation, causing a dramatic loss of activity (Mitchell *et al.*, 1992). Also in common with other thiol-activated toxins, pneumolysin contains only a single cysteine residue (at position 428 in a domain towards the carboxyl terminus). Substitution of this residue has been shown to greatly reduce cytolytic activity without affecting binding or oligomerisation (Saunders *et al.*, 1989), implying that there is a crucial action required for target-cell lysis beyond oligomerisation, in which this residue plays an essential role. Deletion studies have shown that the C-terminus is involved in membrane binding via cholesterol (Alouf and Geoffroy, 1991; Owen *et al.*, 1994).

The secondary structure of pneumolysin consists of 36% β -sheet and 31% α -helix (Morgan *et al.*, 1993). Hydrophathy plots suggest that it is a highly hydrophilic molecule with no significant regions of hydrophobicity; hence, oligomerisation is essential for the formation of channels. Electron micrographs show that pneumolysin monomers are asymmetric molecules composed of four domains (Morgan *et al.*, 1994). Three of the domains lie side by side, forming the stalk of the oligomer, from which domain 4 projects out as a flexible flange.

Oligomeric pneumolysin exists as large arc-and-ring structures in cell membranes, measuring 30–40 nm in diameter (Morgan *et al.*, 1995). The problem posed by this is the apparent absence of hydrophobic areas both on the surface of pneumolysin and at the domain interfaces, making membrane insertion impossible. There is, however, a hydrophobic pocket that could act as a cholesterol-binding site. This pocket is blocked by a tryptophan-rich region at the tip of domain 4, of which one residue (Trp 433) is crucial for maintaining a loop conformation. It is hypothesised that cholesterol could displace the tryptophan-rich region to reveal the hydrophobic pocket, which could then initiate membrane penetration (Rossjohn *et al.*, 1998).

The cytolytic properties of pneumolysin enable it to inflict damage on a wide variety of eukaryotic cells, including bronchial epithelial cells, alveolar epithelial cells and pulmonary endothelium. Its detrimental effects on bronchial epithelium result in the slowing of the ciliary beat, impairing the ability of the mucociliary escalator to effectively clear particles. Pneumolysin also induces separation of the tight junctions of the alveolar epithelial cells (Rayner *et al.*, 1995). This, together with its direct cytotoxic effect on the cells of the alveolar capillary barrier, serves to facilitate bloodstream invasion by pneumococci. Pneumolysin also inhibits the respiratory burst and chemotaxis of polymorphs at doses as low as 1 ng/mL, hence facilitating pneumococcal survival and invasion (Paton, Lock and Hansman, 1983).

Opsonophagocytosis by the complement system is essential for the clearance of pneumococci from the lung (Winkelstein, 1984). The ability of pneumolysin to activate the classical complement pathway may allow pneumococci to evade opsonophagocytosis by consuming the limited supply of complement factors in the alveoli, facilitating invasion.

Inflammation and Shock

Pneumolysin

An interesting mechanism of injury that mediates both the activation of the inflammatory response and direct lung damage is suggested by the finding that phospholipase A in pulmonary artery endothelium is strongly activated by pneumolysin and, once activated, breaks down a wide variety of cell-membrane phospholipids (Rubins *et al.*, 1994). This results in the release of free fatty acids and lysophosphatides, which are directly cytotoxic. Arachidonic acid released by phospholipase activity, together with its eicosanoid cascade metabolites, is a potent neutrophil chemotaxin. Recruitment and activation of neutrophils further contribute to lung damage as well as to the inflammatory response. Inflammation would be enhanced by the ability of pneumolysin to activate the classical complement pathway without the need for specific antibody (Paton, Rowan-Kelly and Ferrante, 1984).

Autolysin

The major enzyme responsible for cell-wall turnover is the autolysin of *S. pneumoniae*, *N*-acetyl muramoyl-L-alanine amidase. This enzyme is responsible for cellular autolysis that occurs at the end of log phase in pneumococci and for lysis of the cell wall in response to treatment with deoxycholate or with β -lactam antibiotics. Autolysin is one of about a dozen proteins that is held on the pneumococcal surface by noncovalently docking with the choline of the pneumococcal cell wall, instead of the usual method of anchorage in Gram-positive bacteria using the LPXTGE motif. These choline-binding proteins have a common choline-binding carboxy terminal, their functional diversity being produced by the amino terminal.

Autolysin contributes to pneumococcal virulence in several ways. Its role in cell-wall turnover means that autolysin activity generates cell-wall breakdown products that are highly inflammatory. The cell-wall-degrading activity of autolysin also allows the release of intracellular toxins (e.g. pneumolysin) into the external medium. Many experimental studies have demonstrated the role of autolysin in virulence. Reduced virulence has been demonstrated when normally virulent strains are transformed with inactivated *lytA* (the gene that encodes pneumococcal autolysin), and the deficit has been shown to be reversible by back transformation (Berry *et al.*, 1989b).

C-Polysaccharide (PnC)

The cell wall of *S. pneumoniae* has an important role in generating inflammatory mediators and consequent pathological changes. Injection of cell-wall preparations but not heat-killed capsulate strains or isolated capsular antigen has been shown to generate a strong inflammatory response in chinchilla rabbits (Tuomanen *et al.*, 1985a,b). The teichoic acid C-polysaccharide is important as removal of this antigen diminishes complement activation by cell-wall components (Tomasz and Saukkonen, 1989). The components of the complement cascade generated by interaction with PnC are thought to be crucial for the generation of an inflammatory reaction in the alveoli, the meninges and the middle ear (Tuomanen *et al.*, 1985a,b; Tuomanen, Rich and Zak, 1987). PnC activates the alternate complement pathway via its PC component (Winkelstein, Abramovitz and Tomasz, 1980; Hummell *et al.*, 1985). The pneumococcal plasma membrane is also a weak activator of the alternate pathway through the PnC analogue lipoteichoic acid (F antigen) (Hummell *et al.*, 1985). In the chinchilla model of otitis media, death of the organism induced by penicillin was responsible for a rapid increase in the inflammatory response. This was thought to be due to the release of cell-wall products and pneumolysin (Sato *et al.*, 1996). Organisms with high cell-wall turnover, resulting in a greater release of teichoic acid components, induce a greater inflammatory response in rabbit meninges (Schmidt and Täuber, 1993).

PC is of considerable functional relevance in organisms colonising mucosal surfaces, particularly the respiratory tract. The expression of this epitope is subject to phase variation, there being a selection for PC+ variants during nasopharyngeal colonisation. PC has been shown to protect organisms against clearance, hence contributing to persistence in the respiratory tract. However, PC+ variants exhibit increased serum sensitivity. Hence, it appears that there is differential expression of PC, with upregulation occurring in the initial colonisation phase and downregulation in the subsequent invasive phase to avoid anti-PC antibody, C-reactive protein (CRP) binding and complement activation (Weiser, 1998).

Immunopathology

Pneumonia

The interactions that occur between the pneumococcus and host during the evolution of infection are complex and remain to be fully elucidated. Using a mouse model, Bergeron *et al.* (1998) have broadly divided pulmonary pneumococcal infection into five stages. In the first stage (0–4 h), infection is established – there is evidence of ineffective phagocytosis by alveolar macrophages and cytokine release. The major pneumococcal antiphagocytic components are its polysaccharide capsule and pneumolysin (see *Invasion*). The predominant cytokines vary between sites, with TNF- α , IL-6 and nitric oxide (NO) predominating in bronchial lavage (BAL) fluid; TNF, IL-6 and IL-1 in lung tissue; and IL-6 in serum. The second stage (4–24 h) is marked by the multiplication of pneumococci in the alveoli and neutrophil chemotaxis into lung tissue – TNF, IL-6, IL-1 and leukotriene B4 levels all increase in both lung tissue and BAL fluid. Serum IL-1 levels also rise transiently. Neutrophil chemotaxis is mediated by the complement-activating properties of pneumolysin and C-polysaccharide as well as the cytokines listed above. Lung damage is seen in the third stage (24–48 h) – there is evidence of alveolar injury and interstitial oedema, reflecting the cytolytic actions of pneumolysin. There is also evidence of regeneration during this stage: type II pneumocytes proliferate to regenerate both type I and type II cells. This stage sees the progression of infection from the pre-septicaemic to the septicaemic phase, bacteria shifting from the alveoli through lung tissue into the bloodstream and there being a reduction in IL-1 and TNF in the lung tissue. Both CbpA and the changes made to the alveolar–capillary barrier made by pneumolysin (see *Invasion*) would facilitate bloodstream invasion. The fourth stage (48–72 h) is characterised by a sharp increase in alveolar monocyte and lymphocyte activity, together with NO release in lung tissue and alveolar spaces. The effects of pneumococcal bacteraemia are manifest – leucopenia and thrombocytopenia are seen, together with an increase in blood TNF and IL-6. The final stage (72–96 h) is characterised by further bacterial proliferation, high NO levels, massive tissue damage, lipid peroxidation and high mortality.

Cytokine production is stimulated by both CD14-dependent and -independent pathways, with as many as two receptors other than CD14 being involved (Cauwels *et al.*, 1997). Although the precise roles and effects of the various cytokines produced at the different stages of the pathogenesis of pneumococcal pneumonia remain to be fully elucidated, some progress has been made towards unravelling this maze.

There is considerable evidence to suggest that IL-1 plays a far more dominant role in Gram-positive inflammation than it does in Gram-negative sepsis (Riesenfeld-Orn *et al.*, 1989). Work indicates that TNF, although pivotal in the pathogenesis of Gram-negative sepsis syndrome, plays a protective role in pneumococcal pneumonia, inhibiting the onset of bacteraemia by stimulating antibody production, neutrophil recruitment and granulocyte–macrophage colony-stimulating factor production by endothelial cells (Takashima *et al.*, 1997). IL-10, on the other hand, demonstrates a protective role in Gram-negative

sepsis, but elevated lung levels have been shown to be detrimental in a murine model of pneumococcal pneumonia (van der Poll *et al.*, 1996). There is also evidence that IL-6 plays an important role as a mediator of inflammation, controlling the production of both pro- and anti-inflammatory cytokines. Its net effect has, however, been shown to be protective (van der Poll *et al.*, 1997).

Meningitis

There has been considerable advance in our understanding of pneumococcal meningitis. Whether meningeal invasion is the result of specific targeting or purely a chance process remains unclear. However, pneumococci have been shown to be nearly twice as efficient at invading cerebral as compared with peripheral endothelium. Transparent phenotypes, with less capsular polysaccharide, more teichoic acid and more CbpA, are three to five times more efficient at invading cerebral microvascular endothelia than are opaque phenotypes, which are killed intracellularly. This is in contrast to the bloodstream, where opaque phenotypes are more invasive. Inflammatory activation is a prerequisite for the migration of pneumococci through cerebral microvascular endothelial cells. It is thought that transparent phenotypes are able to enter by PAF receptor-mediated endocytosis and corrupt the PAF receptor recycling pathway, producing a greater degree of vesicular transcytosis to the basolateral surface of the cell, with some recycling to the apical surface. Opaque variants, in contrast, appear to be killed intracellularly (Ring, Weiser and Tuomanen, 1998).

Streptococcus pneumoniae does not directly mediate cytotoxicity. Rather, tissue damage is the result of inflammation and its sequelae. The critical stimuli for the inflammatory response are the major components of the pneumococcal cell wall (teichoic acid and peptidoglycan) and pneumolysin, and not the polysaccharide capsule, which lacks inflammatory potential and acts mainly to protect pneumococci against phagocytosis in the absence of anticapsular antibody (Tuomanen *et al.*, 1985a,b). Although different inflammatory responses have been found with strains of different capsular serotypes, the strains studied were not otherwise isogenic, and therefore, it is not possible to ascribe these differences to any one parameter. Cell-wall components released by autolytic activity induce the release of proinflammatory cytokines (e.g. TNF- α , IL-1, IL-6) from mononuclear cells within the central nervous system (CNS) such as ependymal cells, astrocytes and macrophages/microglia. These cytokines trigger a complex cascade of inflammatory mediators, which in concert regulate the various arms of the inflammatory response (Tuomanen *et al.*, 1986).

The cytokines released induce an opening of the tight junctions between brain capillary endothelial cells associated with enhanced pinocytotic activity, allowing an influx of serum components, notably chemotactic complement factors (Ernst *et al.*, 1984; Quagliariello, Long and Scheld, 1986). They also upregulate adhesion molecules [e.g. intercellular adhesion molecule-1 (ICAM-1)] on cerebral vascular endothelial cells and attract neutrophils across the blood–brain barrier (Täuber, 2000). In consequence, a neutrophil infiltrate is evident in the CSF within 8–12 h of bacterial inoculation (Sande and Täuber, 2000). However, the neutrophils have no effect on pneumococcal multiplication, reflecting the low concentration of opsonins in the CSF (Propp, Jabbari and Barron, 1973; Smith and Bannister, 1973; Ernst, Decazes and Sande, 1983).

The cytokine milieu may also have more direct neurotoxic effects by contributing to a metabolic shift to anaerobic glycolysis, astrocyte dysfunction and neuronal damage (Täuber, 2000).

Probably the most important consequence of this inflammatory reaction in the CSF is increased intracranial pressure, which results from cerebral oedema, increased cerebral blood volume and alterations of CSF hydrodynamics (in particular, reduced CSF resorption) (Scheld *et al.*, 1980; Täuber, 1989; Tureen, Täuber and Sande, 1992; Tureen, Liu and Chow, 1996). This increased intracranial pressure,

together with the impairment of autoregulation of cerebral blood flow seen in pneumococcal meningitis, plays a significant role in reducing cerebral blood flow, resulting in ischaemic necrosis and neuronal loss from energy failure. Several vasoconstrictive mediators, such as endothelin and reactive oxygen intermediates, counteract the vasodilatory effects of the increased NO production seen in meningitis and further contribute to cerebral ischaemia. These agents also have a variety of deleterious effects on cells and macromolecules, including lipid peroxidation, DNA damage and protein oxidation (Sande and Täuber, 2000).

Direct neurotoxicity is another important mechanism by which brain damage occurs. It is mediated by pneumolysin and several other agents released during pneumococcal meningitis. NO can be directly neurotoxic or can combine with superoxide to form peroxynitrite, a highly cytotoxic agent (Sande and Täuber, 2000). The production of NO by neuronal oxide synthase (NOS) and oxidative radical release is increased by excitatory amino acids (e.g. glutamate), which are released at higher levels from neurones under stress. A commonly affected site is the dentate gyrus in the hippocampus, cell death occurring by apoptosis (Täuber, 2000).

EPIDEMIOLOGY

High-Risk Groups

Both the rate of nasopharyngeal carriage and the rate of pneumococcal infection are highest at the extremes of age. Invasive pneumococcal infection is relatively common in neonates and children below the age of 2 years (160 per 100 000), the incidence falling sharply in adolescent and young adult years (5 per 100 000), to rise again in populations over the age of 65 years (70 per 100 000) (Breiman *et al.*, 1990). Rates of both colonisation and invasive infection show marked seasonal variation, with considerable increase in the colder months (Balakrishnan *et al.*, 2000).

Although pneumococci undoubtedly attack previously healthy people, several anatomical (dural tears and basal skull fracture) and physiological (mucociliary escalator dysfunction due to pollution, cigarette smoke or viral infection) defects predispose to pneumococcal infection. Defects of the reticuloendothelial system (hyposplenism due to any cause) and humoral immune system (hypogammaglobulinaemia and complement defects) and AIDS also greatly increase host susceptibility. Other conditions that predispose to pneumococcal infection include alcoholism, diabetes mellitus and chronic cardiac, respiratory, liver and renal disease.

Host-to-host transmission occurs from extensive, close contact. Daycare centre attendance and crowded living conditions (prisons, nursing homes and homeless shelters) are associated with an increased transmission rate, but casual contact is usually not (Rauch *et al.*, 1990; Hoge *et al.*, 1994).

IgG2 has a pivotal role in defence against pneumococcal infection. Human FcγRIIa has two codominantly expressed allotypes, which greatly differ in their ability to ligate IgG2, FcγRIIa-R131 binding only weakly. Studies have shown that half of all patients with bacteraemic pneumococcal pneumonia were homozygous for FcγRIIa-R131, which was significantly higher than in other groups. Moreover, all bacteraemic patients who died within 1 week of admission were homozygous for this allele (Yee *et al.*, 2000).

Serotype Distribution

More than 90 known serotypes of pneumococci vary in their distribution and propensity to cause different infections. Seven serotypes (6A, +6B, 7F, 14, 18C, 19F and 23F) account for 70% of isolates from blood and CSF amongst children in North America and Western Europe (Klein, 1981; Nielsen and Henrichsen, 1992). Together with these serotypes, type 3 is commonly implicated in otitis media in children.

CLINICAL SYNDROMES

Streptococcus pneumoniae causes infection of the bronchi, lungs, sinuses and middle ear by direct spread from the site of nasopharyngeal colonisation and of the CNS, peritoneal cavity, bones, joints and heart valves by haematogenous spread. Local extension to the CNS may also result in recurrent meningitis in patients who have a dural defect. Primary bacteraemia (i.e. one without identifiable source) is particularly common in children aged 6–24 months – patients with this syndrome are often only moderately ill and may recover swiftly and spontaneously; if left untreated, however, overt foci of infection may subsequently develop.

Pneumonia

Streptococcus pneumoniae is the most common cause of pneumonia worldwide, and pneumonia is the most common manifestation of pneumococcal infection, being present in 68% of cases of pneumococcal bacteraemia in a study by Balakrishnan *et al.* (2000). Pneumococcal pneumonia is estimated to affect 1 in 1000 adults each year (World Health Organization, 1999). Disease occurs when body defences fail to prevent pneumococcal access to and subsequent replication in the alveoli.

The most frequent clinical picture is an ill patient who reports sudden onset of fever in association with pleuritic chest pain and other nonspecific symptoms such as headache, vomiting and diarrhoea. Cough soon develops, which is initially dry but often followed by haemoptysis. The presentation may be much more subtle in elderly and immunocompromised patients. Physical examination reveals signs consistent with consolidation. Pleural effusion may also be detectable. These findings are confirmed by chest X-ray, which usually shows consolidation filling all or most of a lobe. *S. pneumoniae* is not a classic abscess-producing organism, and lung abscess should raise suspicion of other pathology such as bronchial obstruction or pulmonary infarction. Most patients with pneumococcal pneumonia have a leucocytosis. Some patients, however, have a low leucocyte count, which indicates a very poor prognosis (Balakrishnan *et al.*, 2000). Abnormal liver function tests are also a common finding.

The presence of abundant neutrophils together with lanceolate Gram-positive diplococci in sputum strongly suggests the diagnosis, which is usually confirmed by microbiological culture of respiratory tract specimens (most often sputum) and blood.

The case fatality of pneumococcal pneumonia approximates 5–10% and increases to 20% in the presence of bacteraemia. Besides the bloodstream, infection can rarely extend to involve the pericardial and pleural cavities, resulting in empyema.

Meningitis

Streptococcus pneumoniae causes meningitis in all age groups and is the most common cause of bacterial meningitis in middle-aged and elderly populations and in patients with dural defects. Meningitis accounts for about 10% of invasive pneumococcal infections. Its incidence in developed countries is about 1.5 per 100 000, rising to 8 per 100 000 in children below the age of 5 years (Spanjaard *et al.*, 2000).

Onset is usually over 1–2 days, although it may be more gradual. Meningism is usually obvious at presentation, and confusion and obtundation are not uncommon. Rash is not a typical feature and should prompt investigation for an alternative aetiology. A petechial rash may, however, be seen in overwhelming pneumococcal sepsis. The patient may have evidence of other foci of pneumococcal infection.

Peripheral neutrophil leucocytosis ($>20 \times 10^9/L$) is usual, a low white count being associated with a poor prognosis (Balakrishnan *et al.*, 2000). CSF examination reveals a high neutrophil count, accompanied by other features of bacterial meningitis (high CSF protein and low CSF: plasma glucose ratio). Pneumococci are often evident on Gram

stain examination of CSF (organisms are seen in 75–90% of culture-positive specimens) and are readily cultured from CSF and often from blood. Antigen detection in CSF provides a rapid adjunct to diagnosis and is of particular benefit in specimens taken after commencement of chemotherapy. Molecular amplification techniques may also be applied.

Pneumococcal meningitis is particularly prone to complications, common sequelae being subdural empyema, cranial nerve palsies and hydrocephalus. Seizures occur in about 30% of cases and are associated with higher mortality. Brain infarcts due to cortical thrombophlebitis or arteritis occur in about 15%. It carries a case fatality of about 30% (Immunization Practices Advisory Committee, 1981), although mortality may be much higher at the extremes of age.

Otitis Media

Streptococcus pneumoniae is recognised as being the most common cause of otitis media, being implicated in 30–40% of cases. Pneumococcal otitis media has a high prevalence the world over, nearly every child suffering at least one episode of this infection before the age of 5 years. Pneumococcal otitis media usually follows viral upper respiratory tract infection, which plays a contributory role by causing congestion of the meatus of the eustachian tube. Infection usually follows soon after the host is colonised with a novel serotype, serotypes 6, 14, 19F and 23F being predominant.

Sinusitis

Streptococcus pneumoniae is a leading cause of sinusitis. Pneumococcal sinusitis is usually secondary to mucosal congestion by viral infection or allergy, resulting in impaired bacterial clearance.

Other Syndromes

Streptococcus pneumoniae is recognised as the most common cause of primary bacterial peritonitis in prepubertal females. Pneumococcal endocarditis and osteomyelitis have been described rarely, pneumococci having a vertebral predilection. Pneumococcal septic arthritis is also well recognised. Unusual or recurrent pneumococcal infection without obvious predisposing cause should prompt exclusion of HIV infection.

LABORATORY DIAGNOSIS

Microscopy

Streptococcus pneumoniae is readily recognised in clinical specimens by its distinctive appearance. The presence of Gram-positive lanceolate diplococci (or short chains) in clinical specimens is, in most cases, diagnostic of pneumococcal infection – this diagnosis is supported by the presence of pus cells. An interesting adjunct to the Gram stain is the demonstration of capsular swelling (visible under phase-contrast or bright-field microscopy) on addition of polyvalent antisera – the quellung reaction.

Culture

Although a fastidious organism, pneumococci are readily cultured from appropriate clinical specimens on blood and chocolate agar, usually after overnight incubation at 37 °C. These organisms grow better under capnophilic (5% CO₂) and anaerobic conditions than they do aerobically. The typical draughtsman-shaped colonial appearance is often diagnostic. Confirmation may be obtained by demonstrating either inhibition of growth around a 5-µg optochin disc after overnight incubation or bile solubility.

Antigen Detection

Detection of antigen in body fluids enables rapid diagnosis of pneumococcal infection and is of particular advantage in patients who have received chemotherapy before specimens were obtained. Counter-immunoelectrophoresis was the earliest rapid antigen detection employed in clinical settings. This has now been largely replaced by latex agglutination and by immunochromatography.

Latex agglutination and coagglutination detect soluble pneumococcal capsular polysaccharide by using latex particles (or *Staphylococcus aureus* cells) coated with polyvalent antisera. These techniques are more sensitive and more rapid than counterimmuno-electrophoresis and have the added advantage of requiring no specialised equipment. Latex agglutination has a sensitivity of 90–100% and specificity of more than 98% in CSF but is considerably less reliable in other specimens such as sputum, urine (even after concentration) and pleural fluid. In sputum, sensitivity remains high (>90%), but specificity is considerably lower (80–85%).

The rapid diagnosis of pneumococcal infection has been greatly facilitated by immunochromatographic detection of C-polysaccharide in urine and CSF. This test takes only 15 min, requires no specialised equipment and is very reliable, producing sensitivities of 82% and 97% and specificities of 97% and 99% in urine and CSF, respectively (Smith *et al.*, 2003).

Nucleic Acid Amplification

Amplification of specific nucleic acid sequences by using the polymerase chain reaction (PCR) has provided a rapid and sensitive diagnostic technique for detecting pneumococcal infection that is virtually unaffected by prior chemotherapy. This technology has been applied to a variety of clinical samples, including CSF, blood and sputum. Several targets have been examined for suitability in this technique, the most popular being autolysin and pneumolysin. Studies using the autolysin gene as an amplification target in sputum samples have shown sensitivity and specificity of 95% and 100%, respectively (Gillespie *et al.*, 1994). Quantitative real-time PCR targeting the pneumolysin gene by using fluorescence resonance energy transfer (FRET) probes was shown to be highly sensitive and specific in CSF and whole-blood specimens – sensitivity was determined to be between one and ten target copies per reaction, and specificities of 97% and 100% were obtained for CSF and whole blood, respectively (van Haeften *et al.*, 2003). Another new development using molecular methodology is the evolution of molecular typing techniques such as multilocus sequence typing (MLST), field inversion gel electrophoresis, ribotyping, restriction fragment end labelling, BOX PCR and random amplification of polymorphic DNA, which surpass the quellung reaction in facilitating the analysis of the way in which this organism interacts with human populations (Enright and Spratt, 1998; Gillespie, 1999).

Susceptibility Testing

Disc Susceptibility Testing

Historically, clinical laboratories in the United Kingdom and Ireland have used a comparative method of disc testing to interpret susceptibility, rather than one based on a correlation between MIC and zone of inhibition (which is used widely in Europe). This latter methodology is now recommended by the British Society for Antimicrobial Chemotherapy (BSAC), which publish a standardised method of disc testing, together with zone limits that correlate with MIC breakpoints (Andrews, 2001). Testing is performed on Isosensitest agar supplemented with 5% defibrinated horse blood. Incubations are carried out for 18–20 h at 35–37 °C in air plus 4–6% CO₂. The inoculum used should match the density of the 0.5 McFarland standard. Susceptibility testing using penicillin discs is not a reliable indicator of resistance,

and it is recommended that penicillin resistance be detected with an oxacillin 1 µg disc.

MIC Determination

The method of MIC determination generally used in North America is National Committee for Clinical Laboratory Standards (NCCLS) broth microdilution, using cation-adjusted Mueller–Hinton broth supplemented with 5% defibrinated lysed horse blood and inoculated with standardised inocula of 5×10^4 CFU/mL (National Committee for Clinical Laboratory Standards, 2000). Incubations are carried out in air at 35–37 °C for 18–20 h. The BSAC recommend either broth or agar dilution. The latter methodology, which was employed in the BSAC Surveillance Programme, is carried out using Isosensitest agar supplemented with 5% defibrinated horse blood and inoculated with standardised inocula of 10^4 CFU/mL. Incubations are carried out for 18–20 h at 35–37 °C in air plus 4–6% CO₂. Reynolds *et al.* (2003a) reported very good agreement between BSAC agar dilution and NCCLS broth microdilution methodologies.

A more rapid method of MIC determination better suited to clinical laboratories is E-testing, which involves application of a calibrated, antibiotic-impregnated plastic strip to the surface of an inoculated plate.

Nucleic Acid Amplification Techniques

Molecular techniques for susceptibility testing are being developed. The effectiveness of a PCR-restriction fragment polymorphism strategy directed against the *pbp2b* gene in identifying penicillin-nonsusceptible pneumococci has been demonstrated (O'Neill, Gillespie and Whiting, 1999), and Kearns *et al.* (2002) have shown that a real-time PCR hybridisation assay directed against the same gene can be used to rapidly (<1 h) determine penicillin susceptibility in pneumococcal meningitis, even in culture-negative cases.

Susceptibility Profiles

Data obtained by the BSAC Respiratory Resistance Surveillance Programme in Great Britain, which collected 1154 pneumococcal isolates, are summarised in Table 3.3 (Reynolds *et al.*, 2003b). Penicillin susceptibility (MIC ≤ 0.06 mg/L) overall was 89.5%, there being 92.8% and 67.8% susceptibility rates in Great Britain and Ireland, respectively (Table 3.4). Clinically relevant penicillin

Table 3.3 Breakpoints, per cent susceptible (intermediate) and MIC₉₀ values for *S. pneumoniae* in Great Britain

Antibiotic	Low breakpoint (mg/L): (S≤)	High breakpoint (mg/L): (R≥)	%S (%I)	MIC ₉₀ (mg/L)
Penicillin	0.06	2	92.8 (7.0)	0.03 (MIC _{max} = 2)
Amoxicillin	1	2	99.2	0.03
Cefaclor	1	2	91.9	1
Cefuroxime	1	2	95.9	0.12
Cefotaxime	1	2	100	0.06
Erythromycin	0.5	1	89.2	4
Clindamycin	0.5	1	95.9	0.25
Ciprofloxacin	NA	4	0 (94.9)	2
Moxifloxacin	1	2	99.7	0.25

Clindamycin	95.9	87.9	0.25 (4)	≥4 (4)
Tetracycline	93.1	81.6	0.25 (32)	≥32 (32)

I, intermediate resistance to penicillin; MIC₉₀, minimum inhibitory concentration of 90% of isolates; MIC_{max}, maximum minimum inhibitory concentration; S, susceptibility to penicillin.

resistance (MIC ≥ 2 mg/L) remains very rare (0.3% overall). These rates mirror those reported from the European Antimicrobial Resistance Surveillance System (EARSS) and Nearchus programmes (<http://www.earss.rivm.nl>; Grüneberg *et al.*, 1998). The data show near-universal susceptibility to cefotaxime, moxifloxacin and levofloxacin and universal resistance to trimethoprim. This high level of susceptibility to fluoroquinolones contrasts with that seen in some other areas, notably in Hong Kong, where the prevalence of fluoroquinolone nonsusceptibility (MIC ≥ 4 mg/L) in 2000 was reported as 13.3% (Ho *et al.*, 2001). There was considerable regional variation in other β-lactams, erythromycin, clindamycin and tetracycline, as shown in Table 3.4.

As compared with British isolates, Irish isolates had MIC₉₀s that were five to six doubling dilutions higher for all β-lactams tested including cefotaxime, six doubling dilutions higher for tetracycline and at least three doubling dilutions higher for erythromycin and clindamycin. Logistic regression analysis of the data shows that for all agents tested except ciprofloxacin, isolates from Ireland were less likely to be susceptible than were those from England. The reasons for these differences remain unclear. Outpatient prescribing data do not suggest significant differences in prescribing practices (Cars, Molstad and Melander, 2001). For any given country and antibiotic, isolates from patients aged 20–49 years were more likely to be susceptible than those from patients aged 50–69 years.

All 17 amoxicillin-resistant isolates (1.3%) were nonsusceptible to penicillin; 123 isolates (9.3%) were resistant to two or more unrelated antimicrobials. The most common linked nonsusceptibilities were to erythromycin/tetracycline (6.1%), penicillin/tetracycline (5.3%) and penicillin/erythromycin (5.2%). Fifty-five isolates (4.1%) were resistant to three or more unrelated antimicrobials, 51 (3.8%) being nonsusceptible to penicillin, erythromycin and tetracycline. Three isolates (0.2%) were resistant to penicillin, erythromycin and ciprofloxacin, and one isolate (0.1%) was resistant to erythromycin, ciprofloxacin and tetracycline. No isolate was resistant to amoxicillin, erythromycin, tetracycline and ciprofloxacin. Resistance to amoxicillin, penicillin, erythromycin and tetracycline showed positive associations in all possible pairwise combinations. There was no evidence of association between ciprofloxacin resistance and resistance to any of these antibiotics.

Resistance to β-Lactams

Activity against pneumococci varies between β-lactams. Amoxicillin remains the most active oral agent, followed by cefditoren and cefpodoxime. Cefuroxime and ceftazidime are notably less active. Amongst parenteral cephalosporins, cefotaxime, ceftazidime, cefepime and ceftazidime have most activity. Other third-generation cephalosporins (ceftazidime and ceftizoxime) are much less active.

Table 3.5 Antimicrobial resistance rates for *S. pneumoniae* in the United States

Antibiotic	All strains	% Resistance		
		Susceptibility to penicillin (MIC ≤ 0.16 mg/L)	Intermediate resistance to penicillin (MIC = 0.12–0.1 mg/L)	Resistance to penicillin (MIC ≥ 2 mg/L)
Macrolides	25.7	5.6	42.3	77.8
Clindamycin	8.9	1.3	19.6	25.8
Tetracycline	16.3	3.1	31.4	48.0
Co-trimoxazole	30.3	7.6	39.2	94.5
Chloramphenicol	8.3	1.0	13.4	27.7

MIC, minimum inhibitory concentration.

The first clinical isolate with reduced susceptibility to penicillin was reported in 1967 (Hansman and Bullen, 1967). The prevalence of resistance increased sharply in the 1990s, and up to 34% of American isolates of the early 2000 have reduced susceptibility to penicillin (MIC ≥ 0.12 mg/L), between half and two-thirds of which are considered resistant (MIC ≥ 2 mg/L). The levels of reduced susceptibility and resistance to penicillin seen in several other countries (Hong Kong, Spain, Hungary and South Africa) are far greater, being in the range of 40–70%. As happens for several other pathogens, this situation is exacerbated by co-resistance to other antibiotics. Data from a large American survey conducted during 1999–2000 are summarised in Table 3.5 (Doern *et al.*, 2001).

Two factors have been identified as being strongly associated with the development of β -lactam resistance: β -lactam exposure and contact with carriers. Hence, treatment with β -lactams in the last 3 months, age, hospitalisation, institutionalisation, overcrowding, daycare attendance (or exposure to children in day care) and immunosuppression have all been associated with carriage of β -lactam-resistant strains (Clavo-Sanchez *et al.*, 1997).

β -Lactams kill pneumococci by binding and inhibiting the enzymes involved in peptidoglycan biosynthesis, namely the transpeptidases and carboxypeptidases, forming a serine ester-linked, enzymatically inactive penicilloyl complex. Six such enzymes [also called penicillin-binding proteins (PBPs)] have been identified: 1A, 1B, 2A, 2B, 2X and 3. Resistance is a consequence of minor alterations in the genes encoding PBPs, resulting in a decreased affinity of the PBP- β -lactam interaction. Genomic studies suggest that many of these alterations are the result of transformation and homologous recombination with *PBP* genes from related species, notably *Streptococcus oralis* and *Streptococcus mitis* in the oropharynx with which pneumococci share a niche, resulting in the formation of a mosaic gene structure (Dowson *et al.*, 1993). Point mutations have also contributed to the alterations in some strains (Coffey *et al.*, 1995). The altered PBPs seem to synthesise a chemically distinct cell wall characterised by abundant branched muropeptides in contrast to the linear muropeptide structure of penicillin-susceptible strains (Garcia-Bustos and Tomasz, 1990).

Stepwise accumulation of PBP genetic alterations leading to progressive loss of β -lactam affinity has meant that pneumococcal β -lactam susceptibility is concentration dependent and is not an all-or-none phenomenon. The efficacy of a given β -lactam in a particular infection therefore depends both on the MIC of the isolate and on the drug concentration that can be attained within the site of infection, antibacterial activity being maximal at four times MIC and being a function of the time above MIC (optimal efficacy being obtained when drug concentration exceeds MIC for 30%, 40% and 50% of the dosing interval for the carbapenems, penicillins and cephalosporins, respectively) (Craig, 1998). This has two important consequences. Firstly, the different permeabilities of different tissues mean that it is necessary to adjust breakpoints accordingly when interpreting MICs. Hence, the excellent lung penetration of intravenous benzylpenicillin (concentrations obtained are similar to those in serum) means that it remains an effective treatment for pneumococcal pneumonia caused by strains with MICs up to 4 mg/L. In contrast, its vastly inferior

CSF penetration makes it unsuitable for pneumococcal meningitis caused by strains with MICs ≥ 0.25 mg/L, and current British recommendations are that such CSF isolates be reported as resistant. In view of these considerations the NCCLS has published revised breakpoints for nonmeningeal pneumococcal infection (National Committee for Clinical Laboratory Standards, 2001a,b) (Table 3.6). Secondly, it is often possible to overcome loss of susceptibility either by increasing the dosage of the β -lactam or by choosing an agent with better penetration for the tissue concerned. This principle has led to an increased dosage of amoxicillin being recommended for empiric treatment of otitis media and third-generation cephalosporins being recommended as empiric treatment for pneumococcal meningitis.

The common target site for all β -lactams has resulted in cross-resistance to varying degrees within this group of antibiotics. MICs to second- and third-generation cephalosporins have been found to rise with that to penicillin for many strains (Doern *et al.*, 2001).

Resistance to Macrolides

Macrolide resistance has increased markedly in many areas over the 1990s and is particularly prevalent amongst penicillin-resistant isolates. Whereas in the United Kingdom resistance rates are only around 10%, Ireland and the United States have between two and three times this prevalence. In Spain, erythromycin resistance rose from 0% in 1979 to 9.4% in 1990. By 1997 one-third of isolates were macrolide resistant. Italian studies show a similar pattern (Lynch and Martinez, 2002). By the mid-1990s macrolide resistance rates in Greece, Slovakia, Bulgaria, Romania, Uruguay and some Asian countries were in excess of 20%. By the late 1990s 45% of isolates in southwest France and more than two-thirds of Chinese and Japanese isolates were macrolide resistant. Macrolide resistance has, however, remained low (0–7%) in many parts of the world, notably South Africa, Scandinavia, Germany, Austria, Portugal and Israel.

Previous macrolide exposure, in particular to the newer longer-acting agents that have protracted sub-MIC periods (notably azithromycin), is strongly associated with resistant isolates. Nasopharyngeal carriage allows dissemination of macrolide-resistant clones, children being the predominant reservoir. The pace of transmission is accelerated by selection pressure imposed by antibiotic use. An increased prevalence

Table 3.6 National Committee for Clinical Laboratory Standards (NCCLS) breakpoints for *S. pneumoniae* – nonmeningeal infection

	Old breakpoint (mg/L)			New breakpoint (mg/L)		
	S	I	R	S	I	R
Amoxicillin	<1	1	>1	<4	4	>4
Cefuroxime	<1	1	>1	<2	2	>2
Ceftriaxone or cefotaxime	<1	1	>1	<2	2	>2

I, intermediate resistance to penicillin; R, resistance to penicillin; S, susceptibility to penicillin.

of resistant isolates is also associated with day care, institutionalisation, penicillin resistance, a persistent source of infection (middle ear or sinus), age below 5 years or above 65 years and hospitalisation (Gay *et al.*, 2000).

Macrolides, lincosamides, streptogramins and ketolides exert their antimicrobial properties by binding bacterial ribosomal target sites, causing premature dissociation of the peptidyl tRNA from the 50S ribosome and inhibition of protein synthesis.

Target-site alteration disrupts the ribosomal tertiary structure, resulting in the loss of binding affinity and drug resistance. This alteration is most commonly mediated by a methyltransferase, which methylates a highly conserved region (A2058) of the peptidyl transferase loop in domain V of 23S mRNA. This enzyme is encoded by the *ermAM* (erythromycin ribosome methylation) gene, which may be either chromosomal or borne on plasmids or conjugative transposons. Expression may be either constitutive or inducible. The most common variant of *ermAM* in pneumococci is *ermB* – this gene is usually transposon-borne, allowing rapid dissemination. This mechanism, which is the predominant cause of macrolide resistance in Europe and South Africa, confers high-level resistance (MIC to erythromycin >64 mg/L) to macrolides, lincosamides and streptogramins – the MLS_B phenotype. Telithromycin, a new ketolide, retains activity against strains of the MLS_B phenotype where *ermB* expression is inducible because of higher affinity and weaker induction. Activity is reduced, however, when expression is constitutive. Less commonly, target-site alteration may occur by point mutation, either in ribosomal protein or in the 23S rRNA – this is responsible for only 1–3% of macrolide resistance but has led to the emergence of novel phenotypes including high-grade telithromycin resistance (Tait-Kamradt *et al.*, 2000). Fortunately, ketolides and oxazolidinones remain active against >99% of macrolide-resistant strains, and the glycopeptides remain universally active (Lynch and Martinez, 2002).

A very different mechanism by which resistance may occur is by active efflux of the antibiotic. Macrolide efflux is mediated by a 405-amino acid hydrophobic protein encoded by the chromosomal *mefE* (macrolide efflux) gene, which confers resistance to 14- and 15-membered macrolides (erythromycin, clarithromycin and azithromycin) but not to 16-membered macrolides (josamycin), lincosamides, streptogramins or ketolides – the so-called M phenotype. This is the predominant mechanism of resistance in North America and Japan, being detected in more than two-thirds of resistant strains. Resistance is relatively low level (MIC to erythromycin 1–32 mg/L) and transferable by conjugation (Bellido *et al.*, 2002). The M phenotype remains rare in Europe and South Africa, being found in <20% of macrolide-resistant isolates (Tait-Kamradt *et al.*, 2000).

Any combination of these various mechanisms of macrolide resistance may coexist, resulting in a wide range of MICs. The extent to which *in vitro* macrolide resistance translates into therapeutic failure may be significantly affected by the mechanism(s) of resistance involved.

Current NCCLS guidelines state that pneumococci with MICs to erythromycin and clarithromycin of 0.5 mg/L (1 mg/L for azithromycin) should be considered as being of intermediate sensitivity and be regarded as resistant above this MIC (National Committee for Clinical Laboratory Standards, 2001b). The most appropriate pharmacodynamic parameters that best correlate with efficacy remain controversial – it appears that, as for β -lactams, duration above MIC is the best correlate for erythromycin and clarithromycin (optimal when >40% of the dosing interval) and area under the curve (AUC)/MIC is the best correlate for azithromycin (optimal when >25%) (Craig, 2001).

The extent to which *in vitro* macrolide resistance translates into therapeutic failure is influenced by several pharmacokinetic and pharmacodynamic variables and remains poorly understood. Studies indicate that, as for β -lactams, an *in vivo*–*in vitro* paradox exists, owing largely to the excellent tissue-penetration properties and long tissue-elimination half-lives of these agents which allow target attainment despite relatively high MICs. As a result, good clinical outcomes are usually achieved in pneumococcal pneumonia and otitis

media caused by isolates with MIC values as high as 4 μ g/mL or even 8–16 μ g/mL. There are, however, increasing numbers of reports of treatment failure attributed to bacteraemic infection with macrolide-resistant pneumococci (where outcome is related to serum macrolide levels rather than pharmacodynamics) (Garau, 2002).

Resistance to Fluoroquinolones

The tide of fluoroquinolone resistance (MIC \geq 4 mg/L) in pneumococci began in Canada, with an increase in ciprofloxacin resistance from 0% in 1993 to 1.7% in 1997–1998. This sharp increase was preceded by an increase in the use of fluoroquinolones, principally ciprofloxacin, and was associated with older age (>65) and residence in Ontario, both of which correlated with increased fluoroquinolone use (Chen *et al.*, 1999). Resistance was also more common in penicillin-resistant isolates. A similar rate of resistance (1.4%) was reported in 2000, but there was now evidence of cross-resistance with the latest, most potent fluoroquinolones: 62% of ciprofloxacin-resistant isolates were cross-resistant to levofloxacin, 7% to gatifloxacin and 3% to moxifloxacin (Low *et al.*, 2002).

A survey of the UK isolates from pneumococcal invasive infections showed resistance rates of 1% to moxifloxacin (Johnson *et al.*, 2001). Similarly low rates of fluoroquinolone resistance have been found in the United States. However, increasing resistance to the newer drugs has been noted – levofloxacin resistance rates increased from 0.2% in 1999–2000 to 0.7% in 2000–2001 and gatifloxacin from 0.3% to 0.4% during the same period (Doern *et al.*, 2001). Studies also suggest an increase in the number of strains containing single *parC* mutations [from 0.4% in 1992–1996 to 4.5% in 1999–2000: these strains would be classified as susceptible by routine susceptibility testing but are the progenitors of fully resistant dual mutants (*parC* and *gyrA*) (Davies *et al.*, 2002)].

Higher rates of fluoroquinolone resistance have been reported in other areas. Hong Kong has witnessed a dramatic rise in levofloxacin resistance (<0.5% in 1995, 5.5% in 1998 and 13.3% in 2000) (Ho *et al.*, 2001). Typing studies (pulse-field gel electrophoresis and MLST) indicate that this increase is largely due to clonal dissemination of a newly emerged fluoroquinolone-resistant variant of the widely distributed multidrug-resistant Spanish 23F clone. Fluoroquinolone resistance rates of 5.3% have been reported from Spain. Most resistant isolates were polyclonal in origin, but 30% of strains were fluoroquinolone-resistant variants of the multiresistant internationally epidemic Spanish 23F and French 9V clones (Alou *et al.*, 2001).

Since paediatric fluoroquinolone use is exceptional, fluoroquinolone-resistant pneumococci are largely limited to adult populations. Besides older age, other risk factors for acquisition include chronic obstructive pulmonary disease, nosocomial acquisition, institutionalisation and prior fluoroquinolone exposure.

Fluoroquinolones inhibit pneumococcal DNA replication by binding vital enzymes, namely topoisomerase IV (which acts to separate interlocked DNA strands to allow segregation of daughter chromosomes) and DNA gyrase (which alters DNA supercoiling). Different fluoroquinolones have different affinities for the two enzymes, each of which is composed of two subunits: ParC and ParE in topoisomerase IV and Gyr A and GyrB in DNA gyrase. Ciprofloxacin, levofloxacin, norfloxacin and trovafloxacin preferentially target ParC, whereas GyrA seems to be the preferred target for moxifloxacin, gatifloxacin and gemifloxacin (Fukuda and Hiramatsu, 1999). The rank order of activity against pneumococci, from most to least active, is gemifloxacin, trovafloxacin, sparfloxacin, moxifloxacin, grepafloxacin, gatifloxacin, levofloxacin and ciprofloxacin (Jones *et al.*, 2000).

Resistance to fluoroquinolones may occur by two mechanisms. Target-site alteration most commonly occurs because of stepwise accumulation of chromosomal mutations, particularly in the quinolone-resistance-determining region (QRDRs) of *gyrA* or *parC*. Reports of mosaic genes in fluoroquinolone-resistant strains suggest that horizontal

transfer of altered type II topoisomerase genes from viridans-type streptococci by recombination and transformation also contributes significantly to resistance by target-site alteration (Janoir *et al.*, 1999). The second mechanism by which fluoroquinolone resistance occurs is active drug efflux from the bacterial cell by overexpression of the multidrug resistance efflux pump PmrA.

QRDR mutations occur at a rate of about 1 in 10^{-6} to 1 in 10^{-9} (Fukuda and Hiramatsu, 1999). The first QRDR mutation to confer a selective advantage has to occur in the preferred subunit of the quinolone, imposing a selection pressure. This has the effect of raising the MIC of the organism to all quinolones with the same preference by four- to eightfold. Given time, this population acquires a mutation in the second subunit, which further increases its MIC and also renders it resistant to quinolones that target either subunit (or both). Continued or repeated fluoroquinolone exposure augments the selective advantage, allowing further mutations and higher levels of resistance to build up. As the pulmonary bacterial load in a patient with pneumonia often exceeds 10^9 , the risks of QRDR mutants arising are great – fluoroquinolones further increase this risk because of their ability to damage bacterial DNA and trigger the error-prone SOS DNA repair system (Hooper, 2002).

MDR efflux pumps are normally present even in susceptible wildtype bacteria. Low-level resistance to fluoroquinolones (MIC 4–8 mg/L) can occur by increased expression of these pumps, usually because of mutations of the structural gene *pmrA*. Fluoroquinolones differ in the extents to which they are affected by efflux mechanisms. Studies suggest that sparfloxacin, levofloxacin, grepafloxacin, gatifloxacin and moxifloxacin are poorer substrates for PmrA than hydrophilic fluoroquinolones such as ciprofloxacin and norfloxacin and are hence less susceptible to this mechanism of resistance. There is also preliminary evidence of other as-yet-undefined fluoroquinolone efflux mechanisms (Pidcock *et al.*, 2002). Efflux-mediated resistance may be additive to that produced by target-site alteration.

Our understanding of the mechanism of action of fluoroquinolones and the mechanisms by which resistance arises can be extrapolated to devise strategies that minimise the risks of resistance. A fluoroquinolone with equal affinities for both topoisomerase II enzymes should confer no selective advantage on single mutants – double mutants, which are much less frequent (1 in 10^{12}), would be needed before resistance could emerge. Gemifloxacin, a new fluoroquinolone, is active against both single mutants (either *gyrA* or *parC*) and efflux mutants. There is some evidence that it remains effective even against double mutants (Nagai *et al.*, 2000). An alternative strategy is to design drugs and dosing regimens to achieve a tissue antibiotic concentration that is inhibitory to single mutants [so that mutant prevention concentration (MPC) about $8 \times$ MIC is achieved]. MPC can be safely achieved with moxifloxacin and gatifloxacin and high-dose levofloxacin regimens. Conversely, the use of weaker fluoroquinolones may facilitate the stepwise selection of mutants and, therefore, should be avoided.

The susceptibility breakpoints for pneumococci in accordance with current NCCLS guidelines are summarised in Table 3.7 (National Committee for Clinical Laboratory Standards, 2001b).

Table 3.7 National Committee for Clinical Laboratory Standards (NCCLS) breakpoints for *S. pneumoniae*

Antibiotic	Breakpoint (mg/L)		
	S	I	R
Levofloxacin	≤2	4	≥8
Moxifloxacin or gatifloxacin	≤1	2	≥4

I, intermediate resistance to penicillin; R, resistance to penicillin; S, susceptibility to penicillin.

The bactericidal activity of fluoroquinolones is related to AUC: MIC, being maximal when the ratio exceeds 25–40 (Wright *et al.*, 2000). Target attainment is more easily achieved with moxifloxacin and gatifloxacin than with levofloxacin (Nuermberger and Bishai, 2004). Moxifloxacin and gatifloxacin have the added advantage of requiring mutations in both *parC* and *gyrA* before resistance becomes clinically significant, because their peak serum levels exceed the MICs produced by single-step mutants (Blondeau *et al.*, 2001). Hence, these newer agents have lower MPCs (1 mg/L) as compared with levofloxacin (4 mg/L) and ciprofloxacin (8 mg/L). One should, however, be wary of using these agents to treat a population of single-step mutants (such as might be present in the alveoli of a patient with pneumonia who has been recently exposed to ciprofloxacin), as dual mutants will emerge at a much higher frequency (1 in 10^6) than in a wildtype population and could lead to clinical failure (Gillespie *et al.*, 2002, 2003).

Resistance to Rifampicin

The incidence of rifampicin nonsusceptibility remains low, at <3%. Rifampicin exerts its bactericidal action by binding the β -subunit of DNA-dependent RNA polymerase, hence preventing chain initiation. Highly resistant isolates result from mutations within the *rpoB* gene.

Resistance to Vancomycin

Vancomycin resistance remains almost entirely a hypothetical issue; 99.7–100% of isolates remain susceptible. However, vancomycin tolerance (MBC: MIC > 32) was described in a survey of clinical isolates – all these strains were serotype 9V, penicillin resistant and had a unique valine-for-alanine substitution at position 440 of the *vncS* gene (Novak *et al.*, 1999). This mutation results in the loss of function of the *vncS* histidine kinase, producing a reduction in autolytic activity. Tolerance could lead to clinical failure; however, there are no human data to support this. By allowing survival in the presence of the drug, tolerance could also facilitate the acquisition of resistance-mutations and hence accelerate the development of resistance.

Resistance to Other Drugs

Tetracycline resistance in *S. pneumoniae* is recognised in about 7% of isolates in the United Kingdom. It is mediated by a soluble protein encoded by the *tetM* gene, which shares N-terminal homology with elongation factors involved in translation. The tetM protein is hence able to bind to the ribosome, thereby protecting it from the inhibitory activity of tetracycline. Chloramphenicol resistance is found in about 8% of UK isolates. It is mediated by an inducible chloramphenicol acetyltransferase (CAT). Both tetM and CAT are most commonly encoded by genes on conjugative transposon Tn1545. Other conjugative elements bearing these resistance genes have also been described.

Multidrug-Resistant *S. pneumoniae*

Multidrug-resistant *S. pneumoniae* (MDRSP) (defined as resistance to penicillin and at least two other antibiotic classes) was first reported from South Africa in 1978. The isolate was reported to be resistant to penicillin, erythromycin, tetracycline, clindamycin, co-trimoxazole and chloramphenicol (Jacobs *et al.*, 1978). Global dissemination has since occurred, and multidrug-resistant isolates are now recognised in every continent. Their prevalence in the United States has been estimated at 14–16% (Whitney *et al.*, 2000). Most of these strains are derived from a few clones, notably the Spanish clone (serotype 23F) and its variants (serotypes 19A, 19B and 19F) that are associated with resistance to penicillins, chloramphenicol (cat+), tetracycline (tetM+), co-trimoxazole and macrolides (75% are *mefE*+ or *ermB*+) and the

more sensitive Spanish–French clones (serotypes 6B, 9 and 14) that are resistant to penicillin and co-trimoxazole but only occasionally show resistance to macrolides, tetracycline and chloramphenicol (Corso *et al.*, 1998). The French clone is prevalent in Europe and South America. The Spanish clone has a broader distribution, being prevalent in North America, Europe, Asia, South America and South Africa. Patterns of drug resistance and the relative prevalences of different clones show considerable regional and international variation.

Fluoroquinolone-resistant variants of both the Spanish 23F and French 9V clones have emerged. Selection pressures imposed by a variety of unrelated antibiotics could fuel a rapid increase in fluoroquinolone resistance, rendering useless the agents that are currently most active against MDRSP (Doern, 2001).

MANAGEMENT

The treatment of choice for severe penicillin-susceptible pneumococcal infection is benzylpenicillin. The major reasons for departure from this therapy are allergy and possible or confirmed resistance. The treatment approaches in the face of these issues and the nuances of different infections are addressed below.

Pneumonia

The incidence of pneumococci that are highly resistant to penicillin ($\text{MIC} \geq 4 \mu\text{g/mL}$) in the United Kingdom remains low, and documented clinical failures among penicillin-resistant pneumococcal pneumonia treated with adequate doses of penicillin are rare.

The optimal duration of therapy for pneumococcal pneumonia is uncertain. Most physicians now treat for 10–14 days.

Oral Therapy

Amoxicillin is the preferred agent, at a dose of 0.5–1 g three times daily. Clarithromycin 500 mg twice daily or the newer fluoroquinolones (e.g. levofloxacin 500 mg once daily) are alternatives for β -lactam-intolerant patients or, much more rarely, those infected with strains that are highly resistant to penicillin.

Intravenous Therapy

Amoxicillin 0.5–1 g three times daily or benzylpenicillin 1.2 g 4–6 hourly is the treatment of choice for pneumococcal pneumonia caused by strains that are either sensitive or intermediately resistant to penicillin. Third-generation cephalosporins (ceftriaxone 1 g once daily or cefotaxime 1 g three times daily) are suitable alternatives in 90% of penicillin-intolerant patients. There are few data on whether treatment should be altered in infection with penicillin-resistant strains. Benzylpenicillin at a dose of 18–24 MU per day in four to six divided doses remains a viable option for isolates with MICs up to 4 mg/L. At the time of writing, levels of cefotaxime or ceftriaxone achievable in the pulmonary tissues are adequate in most cases, and even critically ill patients are treated with ceftriaxone 1–2 g 12–24 hourly. However, the macrolides, newer fluoroquinolones, glycopeptides, linezolid and carbapenems present alternatives in the rare cases of exceptional resistance. All these agents except the carbapenems could also be used when faced with β -lactam intolerance.

Meningitis

Pneumococcal meningitis caused by penicillin-susceptible strains should ideally be treated with benzylpenicillin 1.2 g 4 hourly for 10–14 days. The preferred treatment for infection caused by strains in which penicillin MIC levels are $\geq 0.25 \text{ mg/L}$ is ceftriaxone 2–4 g

once daily. Penicillin is ineffective against these resistant strains because CSF concentrations are unlikely to exceed 2–10% of serum levels.

The efficacy of third-generation cephalosporins in pneumococcal meningitis diminishes once their $\text{MIC} \geq 0.5 \text{ mg/L}$, and isolates with $\text{MIC} 1 \text{ mg/L}$ are defined as partially resistant (highly resistant if $\text{MIC} > 1 \text{ mg/L}$). However, there have been several reports of success in using cefotaxime therapy in partially cefotaxime-resistant pneumococcal meningitis (Viladrich *et al.*, 1988; Tan *et al.*, 1994). High-dose regimens (300–350 mg/kg/day to a maximum of 24 g) have been found to be safe and effective for meningitis caused by cefotaxime-resistant strains (MICs of cefotaxime up to 2 mg/L) (Viladrich, 2004).

However, high-dose cefotaxime therapy might sometimes fail, either because the isolate is particularly resistant ($\text{MIC} \geq 4 \text{ mg/L}$) or because CSF penetration is particularly low. In these cases, several possible antibiotic regimens may be employed:

1. Third-generation cephalosporin plus vancomycin: The main disadvantage of this regimen is that vancomycin penetration into the CSF is unreliable, particularly if dexamethasone is co-administered. Clinical experience is lacking.
2. Third-generation cephalosporin plus rifampicin: CSF penetration of rifampicin is unaffected by dexamethasone administration, and CSF levels of 1 mg/L can be attained. Nearly all pneumococcal isolates remain susceptible, with MICs of about 0.12 mg/L. However, clinical experience with this regimen is lacking, and concerns have been raised that rifampicin might antagonise the β -lactam.
3. Vancomycin plus rifampicin.
4. Addition of intrathecal vancomycin to the intravenous regimen (10–20 mg every 24–48 h).
5. Imipenem \pm rifampicin: Imipenem MICs of penicillin-resistant pneumococci tend to be lower than those of third-generation cephalosporins, and there are documented cases of cure (Asensi *et al.*, 1989; Guibert *et al.*, 1995). Imipenem-induced neurotoxicity is an obvious hazard in this setting. MICs to meropenem tend to be two- to fourfold higher, and this agent is therefore unlikely to confer any significant advantage.
6. New antibiotics, such as levofloxacin and linezolid, present hope for the future.

It has been shown that early treatment with dexamethasone (i.e. before or with the first dose of antibiotic, and then continued for 2–4 days) improves outcome in pneumococcal meningitis (de Gans and van de Beek, 2002). This adjuvant therapy is now unequivocally recommended in both adults and children (Chaudhuri, 2004).

Otitis Media and Sinusitis

In a report from the Drug-resistant *S. pneumoniae* Therapeutic Working Group it was recommended that oral amoxicillin should remain the first-line antimicrobial agent for treating pneumococcal otitis media (Dowell *et al.*, 1999). However, in view of the increasing prevalence of penicillin resistance, a higher dose (an increase from 40–45 mg/kg/day to 80–90 mg/kg/day) was recommended for empiric treatment. For patients with defined treatment failure after 3 days, alternative regimens such as oral cefpodoxime, a single parenteral dose of ceftriaxone followed by oral cefpodoxime for 5 days or co-amoxiclav are recommended to cover infection caused either by a penicillin-resistant pneumococcus or by a β -lactamase-producing organism such as *Moraxella catarrhalis* or *Haemophilus influenzae*. The macrolides provide a viable alternative for the β -lactam-allergic patient.

The same therapeutic considerations apply for sinusitis, which has a similar pathogenesis to otitis media.

PREVENTION AND CONTROL

Pneumococcal Vaccines

There are two types of pneumococcal vaccines: a 23-valent pneumococcal polysaccharide vaccine (PPV) and a 7-valent pneumococcal conjugate vaccine (PCV).

Pneumococcal Polysaccharide Vaccine

This is a polyvalent vaccine containing 25 µg of purified capsular polysaccharide from each of 23 capsular types of pneumococci that together account for about 96% of the pneumococcal isolates causing serious infection in Great Britain (World Health Organization, 1999).

Most healthy adults develop a good antibody response to a single dose of the vaccine by the third week following immunisation. Protection is much less reliable in the immunocompromised and in children below the age of 2 years.

Pneumococcal Conjugate Vaccine

This vaccine contains polysaccharide antigens from seven common serotypes (4, 6B, 9V, 14, 18C, 19F and 23F) conjugated to a protein carrier (currently CRM197 protein). The selected serotypes accounted for 65.6% of pneumococcal invasive infections in England and Wales in 2000 (82.3% in children <5 years) (World Health Organization, 1999). The main advantage of this vaccine is that it is protective in children over 2 months of age. Conjugation of polysaccharide antigen to a protein carrier has the effect of converting a T-independent immune response to a T-dependent one, hence achieving better immunogenicity.

Vaccine Effectiveness

Studies on the polysaccharide vaccine have produced variable results, but overall protective efficacy in preventing bacteraemic infection ranges from 50% to 70% (Mangtani, Cutts and Hall, 2003). The main drawbacks of this vaccine are its ineffectiveness at preventing nonbacteraemic pneumococcal pneumonia, otitis media and exacerbations of chronic bronchitis and inability to protect children below the age of 2 years and the immunocompromised. In addition, data from several Asian countries suggest that the 23 vaccine serotypes account for only 63% of infections, and serotype data from many parts of the world are scarce (Lee, Banks and Li, 1991).

The PCV has been shown to protect against meningitis, pneumonia, bacteraemia and otitis media in children vaccinated at 2, 4, 6 and 15 months of age. Serotype-specific efficacy was 94% after the first dose of vaccine and 97% after the fourth (Black *et al.*, 2000).

The potential of pneumococcal proteins, such as pneumolysin, PspA and CbpA, as vaccine candidates is being examined. These antigens should circumvent the issues of serotype-specific immunity and low immunogenicity that hamper polysaccharide-based vaccines, but many factors require further study, including allelic variation and its effects on cross-reactivity.

Recommendations

Vaccination is recommended for all those in whom pneumococcal infection is likely to be common and/or serious, i.e.

1. all adults aged 65 and over;
2. asplenia and severe splenic dysfunction [ideally 4–6 weeks (no less than 2 weeks) before splenectomy. If not possible, vaccination

should be delayed until after recovery. Vaccination against *H. influenzae* type b, influenza and *Neisseria meningitidis* group C is additionally recommended, together with antibiotic prophylaxis (usually with phenoxymethyl penicillin) until at least age 16 years];

3. chronic renal disease;
4. chronic heart disease;
5. chronic liver disease including cirrhosis;
6. diabetes mellitus;
7. immunodeficiency or immunosuppression [ideally 4–6 weeks (no less than 2 weeks) before chemotherapy or radiotherapy. If not given, vaccination should be delayed until at least 3 months after treatment];
8. HIV infection at all stages. A report of increased risk of pneumococcal disease in severely immunocompromised HIV-infected Ugandan adult vaccinees requires further confirmatory studies and additional studies to assess its relevance to the United Kingdom (French *et al.*, 2000). However, current UK recommendations are to vaccinate all HIV-infected individuals;
9. patients with cochlear implants.

The vaccine routinely used is the 23-valent polysaccharide vaccine, the conjugate vaccine only being recommended in children belonging to the groups above, who are below the age of 2 years. These children should be subsequently vaccinated with the polysaccharide vaccine after they reach the age of 2 years, to broaden the spectrum of serotype coverage.

Dosage and Administration

The polysaccharide vaccine may be administered either subcutaneously or intramuscularly as a single dose. It may be given simultaneously with the influenza vaccine, at a different site. Revaccination is not routinely recommended, except at 5-yearly intervals in patients in whom antibody levels are more likely to have declined rapidly, such as those with nephrotic syndrome, asplenia or splenic dysfunction.

The conjugate vaccine is given intramuscularly. It may be administered at the same time as other childhood immunisations but must be given at a separate site in a separate limb. The dosage regimen varies depending on the age of the child (Table 3.8).

The polysaccharide vaccine should be administered at least 2 months following the last dose of conjugate vaccine.

Adverse Reactions

Both vaccines are generally well tolerated but have been associated with mild erythema and induration that last 1–3 days at the site of injection. Systemic reactions are rare.

A transient increase in viral load usually follows vaccination in HIV-infected patients, the clinical significance of which remains to be ascertained.

Table 3.8 Dosage regimen for pneumococcal conjugate vaccine

Age	Regimen
<6 months	Three doses separated by at least 1 month Fourth dose after first birthday
7–11 months	Two doses separated by at least 1 month Third dose after first birthday
12–23 months	Two doses separated by at least 2 months

Contraindications

1. hypersensitivity to any component of vaccine – an allergic reaction following administration of diphtheria toxoid or CRM197-containing vaccines is a contraindication to vaccination with PCV;
2. acute infection;
3. pregnancy/breastfeeding – safety not assessed;
4. revaccination with PPV within 3 years of a previous dose of polysaccharide vaccine.

Enterococcus spp.

Esteban C. Nannini^{1,2} and Barbara E. Murray²

¹Department of Infectious Diseases, Sanatorio Parque, Rosario, Argentina; and ²University of Texas Health Science Center, Houston Medical School, Houston, TX, USA

INTRODUCTION

The term enterococque, emphasizing the intestinal origin of a newly recognized Gram-positive coccus, was encountered in a French paper published in 1899 (Murray, 1990). Because of their cell shape, staining characteristics and lack of catalase, enterococci were considered members of the genus *Streptococcus* until the early 1990s. The name *Streptococcus faecalis*, which came to be used for the most common species, emphasized the relationship of these organisms to feces. In Sherman's classification scheme of streptococci proposed in 1937, the term enterococcus was used for those streptococci that had the ability to grow at 10 °C and 45 °C, in sodium chloride concentrations of 6.5% and at pH 9.6, to resist 60 °C for 30 min and to split esculin (Sherman, 1937). Some enterococci were also noted to be β-hemolytic, at least on some types of blood. Based on Lancefield's serological classification, enterococci were considered salt-tolerant group D streptococci. Biochemical characteristics that distinguished *Streptococcus faecium* from *S. faecalis* were clarified in the 1940s, and the species status of *S. faecium* was formally accepted in the mid-1960s. In 1984 the genus *Enterococcus*, with inclusion of the species *Enterococcus (S.) faecalis*, *Enterococcus (S.) faecium* and others, was proposed based on the low nucleic acid homology between enterococci and streptococci (Schleifer and Kilpper-Bälz, 1984). Many new species of *Enterococcus* have also been described in recent years.

DESCRIPTION OF THE GENUS

Biochemical Characteristics

Enterococci are Gram-positive, facultatively anaerobic cocci that typically grow in pairs or short chains. They are catalase negative, although a weak pseudocatalase is occasionally seen. Most strains have the ability to grow in the presence of 6.5% sodium chloride, at 10 °C and at 45 °C and at pH 9.6 and can survive at 60 °C for 30 min. Enterococci are capable of hydrolyzing esculin in the presence of bile, and most strains react with group D antisera. Some react also with group Q antisera. Detection of the group D antigen, which is a cell-wall-associated glycerol teichoic acid antigen, is not specific to enterococci, and group D antigen may be found in other Gram-positive bacteria such as *Streptococcus bovis*, *Streptococcus equines*, *Streptococcus suis*, *Pediococcus* spp. and *Leuconostoc* spp. Genera of Gram-positive, catalase-negative, facultatively anaerobic bacteria whose members may also show some of the other phenotypic characteristics of enterococci include *Aerococcus*, *Gemella*, *Streptococcus*, *Lactococcus*, *Pediococcus* and *Leuconostoc* (Table 4.1). The emergence of vancomycin resistance in enterococci has increased the importance and difficulty of differentiating enterococci from intrinsically vancomycin-resistant Gram-positive cocci, for example, *Leuconostoc* spp. or *Pediococcus* spp., which also may be isolated from human specimens. Most enterococci possess the enzyme

Table 4.1 Useful tests to differentiate selected Gram-positive organisms from enterococci

	Gas	Vancomycin resistance	Group D antigen	Bile–esculin	PYR	Leucine aminopeptidase	Hemolysis ^a	Growth in		
								6.5% NaCl	45 °C	10 °C
Enterococci	– ^a	± ^b	V+	+	+	+	α/γ	+	+	V+

Lactobacilli	V+	V+	V–	V+	–	–	α/γ	V–	V+	+
<i>Gemella</i>	–	–	–	–	+	+	γ	–	–	–

–, most (>90%) strains negative; +, most (>90%) strains positive; ±^b, depending on the species could be intrinsic or acquired vancomycin resistance (see *Glycopeptide Resistance*); –^a, occasionally positive; Gas, gas production from glucose; PYR, L-pyrrolidonyl-β-naphthylamide; V–, more than half of the strains negative; V+, more than half of the strains positive. Adapted from Facklam and Collins (1989) and Facklam, Carvalho and Teixeira (2002).

^a Hemolysis on 5% sheep blood agar.

pyrrolidonylamidase and are able to hydrolyze L-pyrrolidonyl- β -naphthylamide (Pyr) (Facklam, Hollis and Collins, 1989), although some species are negative (*Enterococcus cecorum*, *Enterococcus columbae*, *Enterococcus pallens* and *Enterococcus saccharolyticus*) (Facklam, Carvalho and Teixeira, 2002). This reaction is very useful for differentiating enterococci from most streptococci, *Leuconostoc* spp. and pediococci. Other Gram-positive, catalase-negative cocci that test positive for Pyr include group A streptococci, *Abiotrophia* and *Granulicatella* (both formerly known as nutritionally variant streptococci), *Helcococcus*, *Aerococcus* spp. and *Gemella*. *Leuconostoc* spp. and pediococci can be group D positive, but both are Pyr negative, and *Leuconostoc* produce gas from glucose in Mann-Rogosa-Sharpe (MRS) *Lactobacillus* broth and do not produce leucine aminopeptidase (Facklam and Collins, 1989). The ability to grow on bile-containing media and hydrolyze esculin [bile-esculin (BE) test] is characteristic of group D streptococci, but growth in 6.5% sodium chloride broth distinguishes enterococci from the other group D-reactive species (Facklam *et al.*, 1974). Table 4.1 summarizes the reactions useful for differentiating selected Gram-positive organisms. Some investigators have used molecular methods to differentiate enterococci from other genera (see *Laboratory Diagnosis*).

Growth Characteristics

It has been known for decades that enterococci have complex growth requirements. *E. faecalis* has been shown to grow well on Davis minimal medium (consisting of salts, citrate, thiamine, glucose and agar) supplemented with additional vitamins (biotin, calcium pantothenic acid, pyridoxine, nicotinic acid, riboflavin and folic acid) plus 20 amino acids (Murray *et al.*, 1993). By deleting individual amino acids from this medium, it was shown that most of 23 *E. faecalis* strains tested were prototrophic for purines and pyrimidines and eight amino acids (Ala, Asn, Asp, Gln, Lys, Phe, Pro and Tyr) and auxotrophic (or almost so) for Arg, Glu, Gly, His, Ile, Leu, Met, Trp and Val. Cys, Ser and Thr were stimulatory for the growth of some *E. faecalis* strains (Murray *et al.*, 1993). Availability of the genome sequence from a clinical isolate of vancomycin-resistant *E. faecalis* (V583) has allowed the determination of the location of purine, pyrimidine and other biosynthesis genes (Paulsen *et al.*, 2003).

Habitat

Enterococci are usual inhabitants of the gastrointestinal (GI) tracts of warm-blooded animals and are also found in insects and plants. *E. faecalis* is usually more common in human feces than *E. faecium*, averaging 10^5 – 10^7 and 10^4 – 10^5 colony-forming units (CFU) per gram, respectively, but *E. faecium* predominates especially in the hospital setting (Murray, 1990; Suppola *et al.*, 1996). Enterococci are less frequently found at other sites such as vagina, skin, oral cavity and dental plaque. Enterococci are also found routinely in sewage, and their presence has been used to monitor fecal contamination. Because of their production of lactic acid, enterococci have been used as starters in the manufacture of cheese, and they have been isolated from cheese products as well as from certain meats and other foods.

PATHOGENICITY

Virulence Factors in Enterococci

It was recognized early on that enterococci were less virulent than staphylococci, pneumococci and group A streptococci and were even called facultative parasites. The introduction and widespread use of antibiotics, many of which had no or poor activity against enterococci (i.e. cephalosporins), was soon followed by an increase in the incidence of enterococcal infections. However, there were many reports of

infections before the antibiotic era, which illustrates that these organisms are able to produce infection in normal hosts, particularly endocarditis and pelvic, intra-abdominal and urinary infections.

Virulence factors associated with the pathogenesis of enterococcal infections in humans are currently under active investigation. Some have been identified, and their role has been tested in diverse animal models of enterococcal infection, although the degree of correlation with human disease is uncertain for most of the models. These virulence factors may be divided into secreted factors (cytolysin/hemolysin, gelatinase and serine protease), cell-surface-located proteins or adhesins [aggregation substance, enterococcal surface protein (Esp) and the adhesin of collagen from *E. faecalis* (Ace)] and cell-wall polysaccharides.

Secreted Factors

Cytolysin is a bacterial toxin produced by some strains of *E. faecalis* that is often encoded within pheromone-responsive plasmids (Ike *et al.*, 1990) and also the chromosome (Ike and Clewell, 1992). It has β -hemolytic activity against some types of blood, including human, rabbit and horse blood. Diverse animal studies have shown that cytolysin-producing strains are associated with higher lethality rates (or increased organ destruction in the rabbit endophthalmitis model) than nonproducing isogenic strains; however, the exact mechanism by which this enzyme contributes to the pathogenesis of *E. faecalis* is still unknown.

Early studies identified certain enterococcal strains with the ability to liquefy gelatin, therefore called *S. faecalis* var. *liquefaciens* or *S. faecalis* var. *zymogenes*, if they were also hemolytic strains. The enzyme thought to be responsible for this reaction was named gelatinase, a metalloprotease which hydrolyzes gelatin, collagen, casein, lactoglobulin and other peptides, although it is now known that gelatinase producers also produce a co-transcribed serine protease, and both are regulated by the *fsr* system, a homologue of the very-well-studied *agr* system of *Staphylococcus aureus*. An experimental endocarditis model from the late 1970s reported a more aggressive course of disease (higher degree of bacteremia, earlier mortality and more embolic phenomena) in animals infected with proteolytic strains than in those infected with the nonproteolytic ones; however, these were not isogenic strains, which limits conclusions from this study (Gutschik, Moller and Christensen, 1979). Using a mouse peritonitis model, a lower lethal dose 50% (LD₅₀) and a delayed mortality were observed when isogenic strains not producing the proteases were compared with gelatinase- and serine protease-producing parental strains (Singh *et al.*, 1998b), and other models have reported similar findings.

Surface-Located Proteins

Aggregation substance is a surface-located protein encoded by pheromone-responsive plasmids that may play a role in binding to human cells, in resistance to neutrophil-mediated killing and in promoting internalization by intestinal cells. It is proposed that aggregation substance, by mediating clumping and/or binding between enterococcal cells and target cells, leads to increased local density of cells, necessary to induce cytolysin/hemolysin production and protease expression via quorum-sensing mechanisms.

The Esp is another surface protein and has been shown to promote colonization and persistence in bladder (but not kidneys) of mice (Shankar *et al.*, 2001). Esp also influences, at least in some strains, biofilm formation *in vitro* (Toledo-Arana *et al.*, 2001). A collagen adhesin called Ace has also been described, which has significant similarity to the A domain of the collagen-binding protein (Cna) of *S. aureus* and the *E. faecium* adhesin Acm (Nallapareddy *et al.*, 2000). The *ace* gene is apparently well conserved and specifically present in *E. faecalis* isolates (Duh *et al.*, 2001).

Another factor that seems to be specific to *E. faecalis* isolates is the *E. faecalis* antigen A (EfaA), which encodes a putative ABC transporter that is regulated by manganese and appears to be important for full virulence (Singh *et al.*, 1998a; Low *et al.*, 2003).

Cell-Wall Polysaccharides

Polysaccharides on the surface of enterococci may represent an effective way to prevent phagocytosis. Some of these appear to be variable capsular carbohydrates, and several have been described in *E. faecalis* and *E. faecium* (Arduino *et al.*, 1994; Huebner *et al.*, 1999; Rakita *et al.*, 2000; Hancock and Gilmore, 2002). The Epa, enterococcal polysaccharide antigen, is a common *E. faecalis* cell-wall polysaccharide, and mutants with an insertion in genes of the *epa* cluster showed attenuation in the mouse peritonitis model and reduced biofilm formation and are more susceptible to neutrophil killing (Teng *et al.*, 2002).

Although adhesins (Acm and SagA) and a variant of Esp have been described in *E. faecium*, virulence factors of this species remain poorly understood, and the traits typically described in *E. faecalis*, such as cytolysin, gelatinase, serine protease and aggregation substance, are rarely, if ever, found in *E. faecium*. The availability of the genome sequence of an *E. faecium* strain (partial sequence available at <http://www.hgsc.bcm.edu/microbial/efaecium>) should aid in the study of enterococcal pathogenesis.

CLINICAL INFECTIONS

Historically, *E. faecalis*, *E. faecium* and other species (e.g. *Enterococcus gallinarum*, *Enterococcus avium*, *Enterococcus casseliflavus* and *Enterococcus raffinosus*) accounted for 80–90%, 5–20% and 2–4% of all enterococcal infections, respectively (Maki and Agger, 1988; Lewis and Zervos, 1990; Patterson *et al.*, 1995). However, in the 1990s, a shift to a higher incidence of *E. faecium* infections has been observed in the United States, coincident with increased antibiotic pressure and development of vancomycin resistance by this species.

Urinary Tract Infections

Since the early 1900s enterococci have been known to cause urinary tract infections (UTIs). Elderly men, the presence of an indwelling bladder catheter, structural abnormalities of the urinary tract and recent urologic instrumentation are recognized risk factors for the isolation of enterococci from UTIs, which has been reported in ~15% of nosocomial cases (Murray, 1990). In contrast, enterococci cause less than 5% of uncomplicated UTIs in young women. Despite the associated low morbidity and mortality, enterococcal UTIs have clinical importance because of additional costs of hospitalization and therapy.

Intra-abdominal and Pelvic Infections

Enterococci are frequently found in intra-abdominal and pelvic infections, including salpingitis, endometritis and abscesses after cesarean section, but very rarely as the sole agent. The role of enterococci in the early phases of these infections remains controversial, since most of these resolve with antibiotics that do not specifically target enterococci, although occasionally breakthrough enterococcal bacteremia does occur. Animal experiments show that enterococci act synergistically with other bacteria in polymicrobial intra-abdominal infections (Montravers *et al.*, 1997). Enterococci are also a cause of spontaneous bacterial peritonitis in cirrhotic and nephrotic patients and peritonitis in patients on continuous ambulatory peritoneal dialysis.

Endocarditis

Enterococci are the third most common cause of infective endocarditis, following viridans streptococci and *S. aureus*, and account for 5–20% of cases (Megran, 1992). *E. faecalis* is most often the species isolated, but other enterococcal species also cause endocarditis. Enterococcal endocarditis has an acute or, more frequently, subacute onset, affects men (especially elderly men) more frequently than women and often has a genitourinary origin, although GI or biliary tract sources are also probable sources. A high percentage of women with enterococcal endocarditis have a recent history of abortion, cesarean section or genitourinary manipulation. Even though subjects with prior valvular heart disease are common in the series of enterococcal endocarditis, enterococci also affect normal valves (mainly aortic and mitral valves) and prosthetic valves, for which enterococci have been implicated in ~7% of the cases (Rice *et al.*, 1991; Megran, 1992). Enterococci are also among the organisms to consider in intravenous drug users with endocarditis, although, interestingly, they usually do not affect the tricuspid valve. Studies have shown the relatively high propensity of enterococci to adhere to normal and damaged valvular endothelium, comparable to that observed with viridans streptococci and *S. aureus* (Gould *et al.*, 1975). As with other enterococcal infections, the mortality rate (15–20%) is probably affected by the seriousness of the underlying disease present in most of these patients (Megran, 1992).

Bacteremia

Enterococcal bacteremia without endocarditis is a much more common event than endocarditis. The source of the bacteremia in the absence of endocarditis is often the urinary tract, the biliary tract, intra-abdominal or pelvic collections, intravascular catheters or wound infections, situations in which the finding of polymicrobial bacteremia is not uncommon (Maki and Agger, 1988). The features of enterococcal bacteremia that are associated with endocarditis include community-onset, the presence of preexisting valvular heart disease or audible heart murmur and no primary site of infection to explain the bacteremia. On the other hand, nosocomial and/or polymicrobial bacteremia is typically observed in the absence of endocarditis (Maki and Agger, 1988). When there are no signs of intra-abdominal, genitourinary tract or intravascular catheter-related infections, the source of the bacteremia is usually presumed to be translocation of enterococci from the GI tract. Enterococcal bacteremia is frequently observed in patients with serious underlying disease and in those who have undergone major surgery, have received antibiotic therapy or have urethral or intravascular catheters (Wells and von Graevenitz, 1980; Shlaes, Levy and Wolinsky, 1981; Maki and Agger, 1988; Pallares *et al.*, 1993). The severity of the underlying disease, the invasiveness of in-hospital procedures (surgeries, intravascular and bladder catheter placements, etc.), the length of intensive care unit (ICU) stay and the suppression of the normal gut flora by antibiotic pressure (especially antibiotics with antianaerobic effect) are factors that have been associated with enterococcal infections, particularly with *E. faecium* strains. When these factors are prolonged, resistant strains acquired from the hospital environment [i.e. ampicillin-resistant *E. faecium*, *E. faecalis* with high-level resistance (HLR) to gentamicin, vancomycin-resistant enterococci (VRE) and, possibly, in the future, linezolid- and quinupristin-dalfopristin-resistant *E. faecium* strains] are allowed to persist and proliferate in the GI tract, predisposing to subsequent disseminated enterococcal infection.

It has been speculated that the presence of enterococcal bacteremia by itself is a marker of a serious underlying condition. Of note, patients with bacteremia due to *E. faecium* are more often seriously ill or are receiving immunosuppressors or had been previously treated with antibiotics than patients with *E. faecalis* bacteremia (Noskin, Peterson and Warren, 1995; Suppola *et al.*, 1998), which may explain,

at least in part, the higher mortality associated with *E. faecium* observed in some series (up to 50%) (Noskin, Peterson and Warren, 1995). Thus, the difference in mortality rates observed in infections caused by these two species may be related to host factors (and, perhaps, resistance) rather than to existing differences in virulence.

Nosocomial Infections

In the United States, enterococci have been ranked as the third most common agent recovered from nosocomial bloodstream infections (Edmond *et al.*, 1999). The high incidence of enterococcal infections has been attributed to the widespread use of antimicrobial agents to which enterococci are resistant, the high proportion of patients who are immunocompromised and with invasive devices and the nosocomial spread of resistant strains. Of note, a dramatic increase in the proportion of VRE among nosocomial isolates has been observed over the past 15 years, reaching 26% of the ICU isolates collected in 2000 (NNIS, 2001). Enterococci are important pathogens in nosocomial-acquired UTIs and are the second most common agent isolated, both in Europe (Bouza *et al.*, 2001) and in US hospitals (Mathai, Jones and Pfaller, 2001). Enterococci are also increasingly reported as a cause of catheter-related bloodstream infection (Sandoe *et al.*, 2002).

Neonatal Infections

Enterococci cause neonatal sepsis and/or meningitis, and it was reported as the second most common isolate in a point prevalence study of nosocomial infections in neonatal ICUs in the United States (Sohn *et al.*, 2001). Although this may occur in normal-term infants, low-birth-weight infants and premature infants with severe underlying conditions are a high-risk group for enterococcal infections (Das and Gray, 1998). Use of a central catheter, the time the central line was in place, GI surgery, prior antibiotic use and intubation have been identified as risk factors for neonatal enterococcal disease (Luginbuhl *et al.*, 1987; Sohn *et al.*, 2001). As with adults, VRE may also spread rapidly among hospitalized neonates (Malik *et al.*, 1999).

Other Less Common Infections

Besides neonatal meningitis, enterococci have also been cited as a cause of shunt infections and meningitis in older children and adults (Durand *et al.*, 1993). In most of these patients, invasive procedures of the central nervous system, underlying diseases, previous antibiotic therapy and even disseminated strongyloidiasis were the predisposing factors for infection. Enterococci have also been found, usually with other microorganisms, in diabetic foot infections, decubitus ulcers, burns and postsurgical abdominal wounds (Lewis and Zervos, 1990).

LABORATORY DIAGNOSIS

Isolation Procedures

Enterococci grow well on blood agar base media containing 5% animal blood and on many other media [e.g., Mueller–Hinton, brain–heart infusion (BHI), dextrose phosphate, chocolate] that are not selective for Gram-negative bacteria. Some strains of *E. faecalis* produce β -hemolysis on media containing rabbit, human or horse blood but not sheep blood. Bile–esculin azide (Enterococcosel agar) or other commercially available azide-containing media, Columbia colistin–nalidixic acid (CNA) agar, phenylethyl alcohol (PEA) agar, SF agar, triphenyl tetrazolium chloride azide agar (m-Enterococcus agar), among others, may be used to isolate enterococci from mixed samples containing Gram-negative bacteria.

Species Identification

Enterococcus faecalis accounts for more than 80% of the clinical isolates, followed by *E. faecium* and then by other enterococcal species (e.g. *E. gallinarum*, *E. avium*, *E. casseliflavus* and *E. raffinosus*), although in settings with a high rate of VRE an increased proportion of *E. faecium* strains is usually found. Some other species are encountered less often (*Enterococcus mundtii*, *Enterococcus durans* and *Enterococcus hirae*), and some are mainly isolated from non-human sources (*Enterococcus malodoratus*, *Enterococcus pseudoavium*, *Enterococcus sulfureus*, *E. cecorum*, *E. columbae*, *E. saccharolyticus*, *Enterococcus asini*, *Enterococcus ratti* and *Enterococcus phoeniculicola*). Differentiation of non-faecalis enterococci may be helpful in serious infections for therapeutic (differences in susceptibilities to antibiotics exist) and epidemiological purposes. The genus *Enterococcus* now contains over 20 species, some of which have been isolated only from plants and animals (Facklam, Carvalho and Teixeira, 2002). Based on DNA reassociation and/or 16S rRNA sequencing studies, the proposed species *Enterococcus solitarius* and *Enterococcus seriolicida* no longer belong to the *Enterococcus* genus (Williams, Rodrigues and Collins, 1991) and *Enterococcus flavescens* and *E. casseliflavus* constitute a single species (hereafter called *E. casseliflavus*). New species have been recently described, namely, *Enterococcus haemoperoxidus* and *Enterococcus moraviensis* from surface waters (Svec *et al.*, 2001), *Enterococcus villorum* (also named *Enterococcus porcinus*) (Vancanneyt *et al.*, 2001), *E. phoeniculicola* (Law-Brown and Meyers, 2003) and *E. ratti* (Teixeira *et al.*, 2001) from animals and the pigmented *E. pallens* and *Enterococcus gilvus* from human clinical specimens (Tyrrell *et al.*, 2002).

Conventional Tests

Historically, enterococci have been separated into three groups on the basis of acid formation in conventional tubes of mannitol, sorbitol and sorbose broths and hydrolysis of arginine (Facklam and Collins, 1989). According to this scheme, group I species (*E. avium*, *E. malodoratus*, *E. raffinosus*, *E. pseudoavium*, *E. saccharolyticus*, *E. pallens* and *E. gilvus*) form acid in mannitol, sorbitol and sorbose broths but do not hydrolyze arginine. Group II species (*E. faecalis*, *E. faecium*, *E. casseliflavus*, *E. mundtii* and *E. gallinarum* as well as lactococci) produce acid in mannitol broth but not in sorbose broth and are able to hydrolyze arginine. Variable reactions are seen in sorbitol broth. Group III species (*E. durans*, *E. hirae*, *Enterococcus dispar*, *E. ratti* and asaccharolytic variants of *E. faecium* and *E. faecalis*) hydrolyze arginine but fail to form acid in these three carbohydrate broths. More recently, two groups have been added: group IV (*E. asini*, *E. sulfureus* and *E. cecorum*), which do not produce acid in mannitol and sorbose broths and fail to hydrolyze arginine, and group V (mostly variant strains of *E. faecalis*, *E. casseliflavus* and *E. gallinarum*), which are not able to hydrolyze arginine (Facklam, Carvalho and Teixeira, 2002). The species within each group may be identified by the reactions summarized in Table 4.2. *Enterococcus faecalis* strains are usually tellurite tolerant when tested on agar medium containing 0.04% potassium tellurite and form black colonies. A few *E. gallinarum*, *E. casseliflavus* and *E. mundtii* strains may also be tellurite tolerant. Motility and yellow pigmentation are helpful for differentiating three species in the group II. *Enterococcus casseliflavus* is motile and produces yellow pigment; *E. mundtii* produces yellow pigment, but it is not motile; *E. gallinarum* is motile but does not produce yellow pigment. Occasionally, pigment production and motility are unreliable features on which to base identification of *E. gallinarum* and *E. casseliflavus* (Vincent *et al.*, 1991). Other investigators found discrepancies in conventional tube test results described by Facklam and Collins, particularly in arginine and sorbitol tests (Knudtson and Hartman, 1992). *Enterococcus sulfureus* belongs to group IV and is a nonmotile pigment producer that does not possess

Table 4.2 Tests for identifying *Enterococcus* species

+, most (>90%) strains positive; -, most (>90%) strains negative; V, variable. Adapted from Facklam and Collins (1989) and Facklam, Carvalho and Teixeira (2002).

^a Occasional exceptions reported.

group D antigen, and mannitol, inulin, arabinose and arginine tests are negative (Martinez-Murcia and Collins, 1991). The two recently recognized nonmotile pigmented species, *E. pallens* and *E. gilvus*, may be differentiated from other pigmented species because they fit into group I, and therefore, mannitol, sorbitol and sorbose tests are positive and arginine hydrolysis is negative. PYR and methyl- α -D-glucopyranoside (MGP) reactions are negative for *E. pallens* and positive for *E. gilvus*. Owing to phenotypic similarities to enterococci, some authors have incorporated *Lactococcus* spp. and *Vagococcus* spp. into groups II and V, respectively (Facklam, Carvalho and Teixeira, 2002).

Because of the increased prevalence of VRE and its epidemiological and probably clinical implications, proper identification of these enterococci is important. The presence of Gram-positive cocci obtained from the growth of organisms on agars containing vancomycin (usually 6 μ g/ml), used for surveillance of VRE strains, must be confirmed, and then, the organisms should be subcultured onto blood agar (Willey *et al.*, 1999). The presence of yellow pigment (observed after picking up some colonies with a cotton swab) and the negative PYR reaction confirms the presence of *E. casseliflavus* and *Leuconostoc* or *Pediococcus* spp., respectively. If the strain is nonpigmented and PYR positive, then *E. gallinarum* may be identified by the motility test (although ~8% of the strains may test negative) or, more specifically, by the xylose test, which can be performed in 2 h (Willey *et al.*, 1999). Overnight fermentation tests using arabinose, pyruvate and sorbitol may further differentiate between *E. faecalis* and *E. faecium*. The results of the vancomycin minimal inhibitory concentration (MIC) might also be considered since the intrinsically vancomycin-resistant strains *E. casseliflavus* and *E. gallinarum* display intermediate-to-low level of resistance, whereas VanA or VanB type of VRE usually shows high-level vancomycin resistance.

Other Laboratory Tests

A method that has been used by several laboratories involves whole-cell protein analysis, which compares patterns generated by different

species (Teixeira *et al.*, 2001; Devriese *et al.*, 2002). Several methods based on genotypic rather than phenotypic characteristics have been useful for discriminating enterococcal species. Some of these tests include sequencing of *ddl* genes encoding D-alanine:D-alanine ligases (Ozawa, Courvalin and Gaiimand, 2000), the *sodA* gene coding for manganese-dependent superoxide dismutase (Poyart, Quesnes and Trieu-Cuot, 2000), the *tuf* gene (Ke *et al.*, 1999), PCR amplification of the intergenic spacer between 16S and 23S rRNA (Tyrrell *et al.*, 1997) and 16S rRNA sequencing (Angeletti *et al.*, 2001; Devriese *et al.*, 2002; Facklam, Carvalho and Teixeira, 2002; Ennahar, Cai and Fujita, 2003). Other methods have focused on the rapid identification of *E. faecium* strains with a PCR assay using specific inserts (Cheng *et al.*, 1997) or through amplification of or hybridization to species-specific genes, such as the *aac(6')Ii* gene (encoding the *E. faecium*-specific aminoglycoside-modifying enzyme 6'-N-acetyltransferase) (Costa *et al.*, 1993), the *msrC* gene (associated with low-level macrolide resistance of *E. faecium*) (Singh, Malathum and Murray, 2001), or detection using hybridization for 16S rDNA (Manero and Blanch, 2002), *efaA*, *ace* (Duh *et al.*, 2001) and *acm* genes (Nallapareddy *et al.*, 2000). The *lsa* gene [responsible for the natural resistance of *E. faecalis* to quinupristin-dalfopristin (Singh, Weinstock and Murray, 2002)] has also been used for identification of *E. faecalis* strains.

Commercial Identification Systems

Several commercially available devices are available for identifying *Enterococcus* species. The API 20S and the API Rapid ID 32 systems appear to work relatively well for *E. faecalis*, but supplemental tests are frequently needed for proper identification of *E. faecium*, *E. gallinarum*, *E. casseliflavus* and *E. durans* (Sader, Biedenbach and Jones, 1995; Hamilton-Miller and Shah, 1999). The Vitek 2 system shows better identification of enterococci than previous a version, although motility and pigmentation tests are frequently required to avoid misidentification of *E. gallinarum* or *E. casseliflavus* as *E. faecium* (Garcia-Garrote, Cercenado and Bouza, 2000; Ligozzi

et al., 2002). Similar findings were reported when the automated MicroScan WalkAway 96 system was evaluated (d'Azevedo *et al.*, 2001).

Susceptibility Testing

Routine Testing (Kirby–Bauer)

Since enterococcal susceptibility to antimicrobial agents is unpredictable, the site of infection and/or the significance of a particular isolate determines which antimicrobials should be included in susceptibility testing. Drugs to which enterococci are intrinsically resistant, such as cephalosporins, oxacillin, trimethoprim–sulfamethoxazole (TMP–SMX) (*in vivo* resistance), clindamycin and aminoglycosides (when used as monotherapy), should not be tested. On the other hand, susceptibility to penicillin or ampicillin and vancomycin should be determined routinely. For urine isolates, fluoroquinolones, nitrofurantoin and fosfomicin may be added. Using the Kirby–Bauer technique, a 16 mm or less zone diameter of inhibition around ampicillin 10 µg disks and a zone of 14 mm or less around penicillin 10 unit disks are considered resistant. A vancomycin (30 g disk) zone of inhibition of 14 mm or less is reported as resistant, 15–16 mm as intermediate and 17 mm or more as susceptible (plates should be held for a full 24-h period). It is recommended that any haze or colonies within the zone should be taken into account and that an MIC test be performed for strains with intermediate-susceptibility zones if vancomycin is to be used for treatment (Swenson *et al.*, 1992).

Agar Dilution MICs

For agar dilution testing, interpretative criteria of the National Committee for Clinical Laboratory Standards (NCCLS) for ampicillin and penicillin are the following: MIC ≤ 8 µg/ml, susceptible; MIC ≥ 16 µg/ml, resistant (NCCLS, 2003). For vancomycin, MICs of ≤ 4 µg/ml and 8–16 µg/ml are considered susceptible and intermediate, respectively (the latter are considered resistant in some countries), whereas an MIC of vancomycin of ≥ 32 µg/ml is considered resistant (NCCLS, 2003). For the screening of VRE, NCCLS recommends the use of a BHI agar with 6 µg/ml of vancomycin and an inoculum of 1–10 µl of a 0.5 McFarland standard suspension. Growth after 24 h of incubation at 35 °C is interpreted as resistant.

Aminoglycoside HLR and β-Lactamase Screening

For serious infections, particularly endocarditis and possibly for meningitis and deep-seated infections in immunocompromised patients, HLR to aminoglycosides and β-lactamase testing should be performed. HLR to gentamicin indicates resistance to synergism with all currently available aminoglycosides except streptomycin and, occasionally, arbekacin. MICs of arbekacin (available in Japan) are variable for strains with HLR to gentamicin. High-level aminoglycoside resistance can be detected by agar or single-tube broth screening with 500 µg/ml of gentamicin. For streptomycin, 2000 µg/ml and 1000 µg/ml is used for agar and broth screening, respectively. Disks containing 300 µg of streptomycin and 120 µg of gentamicin may also be used to predict synergy or the lack of synergy. E-Test also demonstrates concordance in the detection of HLR to aminoglycosides among enterococci when compared with agar dilution screening. Broth microdilution systems appear reliable for HLR to gentamicin, but they have missed some strains with HLR to streptomycin in the past. New versions of automated systems for susceptibility testing of enterococci display a high degree of correlation with standard methods, including VRE strains and strains with HLR to aminoglycosides (d'Azevedo *et al.*, 2001; Ligozzi *et al.*, 2002).

Molecular Typing Systems

Among various methods used for molecular epidemiology studies, total plasmid content, plasmid DNA digestion patterns, amplified fragment length polymorphism, ribotyping and conventional as well as pulsed-field gel electrophoresis (PFGE) of chromosomal DNA have been used to evaluate nosocomial enterococcal infections. PFGE is considered the gold standard and performs better at identifying clonality, at least during prolonged outbreaks. It is reproducible and generally available. A pilot study using multilocus sequence typing suggests that this method may also be used.

MECHANISMS OF RESISTANCE TO ANTIMICROBIAL AGENTS

The presence of tolerance and/or resistance to different classes of antibiotics is one of the typical characteristics of enterococci. Antimicrobial resistance among enterococci may be divided into two types: intrinsic (or inherent) and acquired (Table 4.3). Intrinsic resistance refers to naturally occurring, chromosomally encoded characteristics encountered in all or almost all of the strains of a particular species. Acquired resistance is caused by acquisition of new DNA or mutations in the existing DNA.

Intrinsic Resistance

Inherent resistance characteristics include resistance to semisynthetic penicillinase-resistant penicillins (e.g., methicillin), cephalosporins, monobactams, quinupristin–dalfopristin (*E. faecalis*), low levels of aminoglycosides and clindamycin and TMP–SMX (*in vivo*) and only moderate susceptibility to most fluoroquinolones. Vancomycin resistance in *E. gallinarum* and *E. casseliflavus* is also intrinsic and is discussed in the *Glycopeptide Resistance* section. Relative intrinsic resistance of enterococci to β-lactams is a characteristic feature of these organisms because of the presence of penicillin-binding proteins (PBPs) with low affinity for penicillin (Fontana *et al.*, 1983). MICs of penicillin for *E. faecalis* are generally between 1 µg/ml and 4 µg/ml, approximately 10–1000 times greater than those for streptococci such as *Streptococcus pyogenes*. Generally, MICs of ampicillin and ureidopenicillins are one dilution lower than those of penicillin. *Enterococcus faecium* is even more resistant to β-lactams with typical MICs of penicillin of ≥ 8 µg/ml. *Enterococcus faecium* strains with higher MICs of penicillin (64 to >256 µg/ml) are increasingly reported in recent years and are discussed in the section *Acquired Resistance*. None of the available cephalosporins inhibits enterococci sufficiently to be used clinically, and enterococcal superinfection may in fact occur in patients receiving cephalosporins. As with the penicillins, carbapenems are more active against *E. faecalis* than *E. faecium*. Low-level resistance to clindamycin is another characteristic feature of enterococci, particularly *E. faecalis*. A gene called *lsa*, which encodes a putative ABC transporter, accounts for the intrinsic resistance of *E. faecalis* to both clindamycin and quinupristin–dalfopristin (Singh, Weinstock and Murray, 2002). As a corollary, superinfection with *E. faecalis* isolates has occurred in patients receiving quinupristin–dalfopristin (Moellering *et al.*, 1999), and acquired resistance also occurs in *E. faecium*. Another example of intrinsic resistance is the low-level resistance to aminoglycosides (4–64 µg/ml for gentamicin and 32–500 µg/ml for streptomycin). This resistance appears to be related to limited drug uptake. Combining aminoglycosides with cell-wall-active agents such as penicillins or vancomycin results in markedly enhanced uptake of the aminoglycoside, leading to the well-known synergistic effect of cell-wall synthesis inhibitors plus aminoglycosides (defined as ≥ 2 log₁₀ enhanced killing relative to the effect of the cell-wall-active agent alone when the aminoglycoside effect is subinhibitory). Strains of *E. faecium* normally contain a chromosomally located gene, named *aac(6')Ii*, encoding the aminoglycoside-modifying enzyme

Table 4.3 Common resistances in enterococci

Pattern of resistance	Mechanisms/Comments
<i>Intrinsic resistances</i>	
Aminoglycosides (low level)	Limited drug uptake
Aminoglycosides (tobramycin, kanamycin, netilmicin and sisomicin) (MICs usually $\leq 2000 \mu\text{g/ml}$, but synergism with penicillin is abolished)	Chromosomally encoded AAC(6')-II enzyme present in <i>E. faecium</i> strains
β -Lactams (semisynthetic penicillinase-resistant penicillins, cephalosporins and aztreonam)	Low-affinity PBPs (<i>E. faecium</i> more so than <i>E. faecalis</i>)
Trimethoprim-sulfamethoxazole	<i>In vivo</i> resistance (MIC may fall within the susceptible range)
Quinupristin-dalfopristin	ABC transporter for lincosamides, and dalfopristin present in <i>E. faecalis</i> strains
Glycopeptides	VanC-type in <i>E. casseliflavus</i> and <i>E. gallinarum</i> isolates (peptidoglycan precursor ending in D-Ala-D-serine)
<i>Acquired resistances</i>	
Aminoglycosides (high level, MICs usually $\geq 2000 \mu\text{g/ml}$)	Aminoglycoside-modifying enzymes (AAC, ANT and APH) Ribosomal subunit mutation (described for streptomycin)
Chloramphenicol	Chloramphenicol acetyltransferase
Tetracyclines	Efflux system and ribosomal protection
Penicillins	Overproduction of low-affinity PBPs Mutations in low-affinity PBPs (<i>E. faecium</i> isolates)
Quinolones	Production of β -lactamase (<i>E. faecalis</i> isolates) Mutations in <i>gyrA</i> and <i>parC</i> genes, coding for submit of DNA gyrase and topoisomerase IV, respectively
Macrolides, lincosamides and streptogramins B (MLS _B group)	Reduced drug binding through methylation of an adenine residue of the 23S rRNA (most common is ErmB)
Glycopeptides	Production of low-affinity peptidoglycan precursors ending in D-Ala-D-lactate (VanA, VanB and VanD) or D-Ala-D-serine (VanC and VanE) instead of the normal D-Ala-D-alanine
Oxazolidinones (linezolid)	Mutations in the 23S rRNA

AAC, aminoglycoside acetyltransferase; ANT, aminoglycoside nucleotidyltransferase; APH, aminoglycoside phosphotransferase; MIC, minimum inhibitory concentration; PBP, penicillin-binding protein.

6'-N-acetyltransferase, which is specific to this species (Costa *et al.*, 1993). Although the low-level production of this enzyme does not confer HLR to aminoglycosides, MICs are higher than those of *E. faecalis* and synergism between cell-wall-active agents and the aminoglycosides carrying an unprotected amino group at the 6' position (tobramycin, kanamycin, netilmicin and sisomicin) is not observed. Another apparently intrinsic property of enterococci is that of *in vivo* resistance to TMP-SMX. Even though TMP-SMX may test active *in vitro*, it has been found to be ineffective as monotherapy in both animal and clinical case report studies.

Acquired Resistance

Enterococci possess several different types of mobile genetic elements that may be transferred from one strain to another. One class consists of broad-host-range plasmids, which may be transferred between enterococci and to various other Gram-positive bacteria such as staphylococci, streptococci, *Bacillus* spp. and lactobacilli. These plasmids transfer during filter mating but not usually in broth. Another type of plasmid, referred to as narrow-host-range plasmids because they appear to transfer primarily to *E. faecalis*, responds to sex pheromones produced by the recipient cells. There are many different known pheromones that act on specific pheromone-responsive plasmids. In response to pheromones, these plasmids initiate the production of aggregation substance (clumping factor) which leads to sticking together of donor and recipient cells. The transfer frequency of plasmids is markedly increased by this mechanism, and transfer occurs in broth as well as during filter matings (Clewel and Weaver, 1989). Transposons are also common in enterococci.

Macrolide, Lincosamide and Streptogramin Resistance

The erythromycin resistance determinant (*ermB*), which is commonly found in human enterococcal isolates, is often encoded on a transposon,

exemplified by the well-studied Tn917. This gene codes for an enzyme that methylates a specific adenine residue in the 23S ribosomal RNA within the 50S ribosomal subunit (Roberts *et al.*, 1999), resulting in reduced binding affinity of macrolides, lincosamides (clindamycin) and streptogramins B (quinupristin), the so called MLS_B-type resistance. This same determinant also reduces the bactericidal activity of quinupristin-dalfopristin (Synercid®). A gene, *vgb(A)*, responsible for the hydrolysis of streptogramins B has also been identified in enterococci (*E. faecium* isolates) (Jensen *et al.*, 1998), as have acetyltransferases encoded by the genes *vat(D)* and *vat(E)* that inactivate streptogramin compounds (Soltani *et al.*, 2000). It generally appears that high MICs of quinupristin-dalfopristin require the presence of more than one gene conferring resistance to the individual components (Bozdogan and Leclercq, 1999).

Chloramphenicol, Tetracycline and Fluoroquinolone Resistance

Chloramphenicol resistance, found in 20–40% of enterococci, is often mediated by chloramphenicol acetyltransferase (Murray, 1990). Tetracycline resistance, which is found in 60–80% of enterococci, is mediated by different genes that code for energy-dependent efflux proteins, including *tet(K)*, *tet(L)* or *tet(A)*. Other genes associated with tetracycline resistance include *tet(M)*, *tet(O)*, *tet(Q)* and *tet(S)* [with *tet(M)* by far the most common], which encode cytoplasmic proteins known as ribosomal protection proteins that confer cross-resistance to all currently available agents of this class (Roberts, 1996). The well-studied conjugative transposon Tn916 carries the tetracycline resistance gene *tet(M)*, the same gene found in tetracycline-resistant *Neisseria gonorrhoeae*. This and other conjugative transposons differ from ordinary or nonconjugative transposons (e.g., Tn917) because they initiate bacterial mating (conjugation), which allows them to self-transfer from one bacterial cell to another. Of note, the recently developed derivatives of minocycline, called glycylicylines, remain active against tetracycline- and

minocycline-resistant enterococcal isolates (Rasmussen, Gluzman and Tally, 1994).

Fluoroquinolones are considered agents with rather poor intrinsic activity against enterococci. Mutations in the *gyrA* and the *parC* genes, coding for subunits of DNA gyrase and topoisomerase IV, respectively, have been related to increasing quinolone MICs (Korten, Huang and Murray, 1994; Kanematsu *et al.*, 1998). Most of the quinolone-resistant enterococcal isolates studied had mutation in both genes.

HLR to Aminoglycosides

Besides intrinsic low-level resistance to aminoglycosides, many enterococcal strains have acquired HLR (MIC > 2000 µg/ml) to an aminoglycoside, which causes resistance to the synergism otherwise seen between cell-wall-active agents and the involved aminoglycoside. HLR to aminoglycosides is most often due to the production of one or more aminoglycoside-modifying enzymes: aminoglycoside phosphotransferases (APH), aminoglycoside nucleotidyltransferases (ANT) or aminoglycoside acetyltransferases (AAC). *Enterococcus faecalis* strains with HLR to gentamicin were first reported in 1979, and strains highly resistant to all aminoglycosides (including gentamicin and streptomycin) were first reported in 1983 (Murray, 1990; Patterson and Zervos, 1990). Such strains have now been reported around the world, and other enterococcal species with this trait have been increasingly reported in recent years. In some tertiary centers, most of the enterococci are resistant to penicillin and gentamicin synergism. More than 90% of the enterococci with HLR to gentamicin contain plasmids with a gene coding for a bifunctional enzyme 2''-phosphotransferase-6'-acetyltransferase (APH(2'')-AAC(6')) activity, identical to the gene found in gentamicin-resistant staphylococci (Ferretti, Gilmore and Courvalin, 1986). This gene may be located on a transposon probably inherited from *S. aureus* (Hodel-Christian and Murray, 1991). This enzyme causes resistance to synergy between cell-wall-active agents and all currently available aminoglycosides, except streptomycin (and occasionally arbekacin). More recently, other genes such as *aph(2'')Ib*, *aph(2'')Ic* and *aph(2'')Id* encoding phosphotransferases that confer HLR to gentamicin and some, but not all, other aminoglycosides have been reported (Chow, 2000). However, because the bifunctional APH(2'')-AAC(6') enzyme accounts for the vast majority of HLR to gentamicin and confers cross-resistance to all clinically available aminoglycosides except streptomycin, screening using high concentrations of gentamicin and streptomycin is still recommended. A different approach may arise if other genes conferring resistance to gentamicin, but not to other aminoglycosides, are found more frequently in clinical isolates (Chow, 2000).

HLR to streptomycin may result by enzymatic modification or secondary to mutations in the 30S ribosomal subunit. Strains with ribosomal resistance have very high MICs of streptomycin (>32 000 µg/ml), whereas the ANT(6') enzyme producers usually have MICs of streptomycin between 4000 µg/ml and 16 000 µg/ml. HLR to kanamycin without HLR to gentamicin is caused by the production of the widespread APH(3') or, rarely, ANT(4'). The latter enzyme also causes HLR to tobramycin. These enzymes are important because they also prevent penicillin-amikacin synergy, even though they do not confer HLR to amikacin (Leclercq *et al.*, 1992).

β-Lactamase Production and High-Level Penicillin Resistance due to Other Mechanisms

The first β-lactamase-producing enterococcus was an *E. faecalis* isolate recovered from a urine culture in 1981. Since then, such strains have been isolated from different geographical locations across the United States and several other countries (Murray, 1992). The *blaZ* gene in enterococci is identical to that of the type A β-lactamase found in *S. aureus* (Murray, 1992) and usually has been found on conjugative

plasmids, although a chromosomal location has also been described. In one instance, the gene appears to be incorporated into a transposon-like element derived from staphylococci (Rice and Marshall, 1992). Since the amount of enzyme produced by enterococci is lower than that produced by *S. aureus*, β-lactamase-producing strains may be missed by routine susceptibility-testing methods unless a high inoculum or a detection system such as the chromogenic cephalosporin nitrocefin is used. Although β-lactamase-producing enterococci are still rare among clinical isolates, they may cause outbreaks and severe infections. For this reason, it is advisable to test enterococci isolated from severe infections, particularly endocarditis, for β-lactamase production. With few exceptions, β-lactamase-producing enterococci are also highly resistant to gentamicin. The only β-lactamase-producing *E. faecium* reported was isolated in a hospital having an outbreak due to β-lactamase-producing *E. faecalis*, suggesting interspecies spread of this resistance determinant (Coudron, Markowitz and Wong, 1992).

Although it has been known for many years that strains of *E. faecium* are more resistant to β-lactams than *E. faecalis*, strains of *E. faecium* with much higher penicillin MICs (>64 µg/ml) have become increasingly common. Mechanisms that have been implicated in causing high levels of penicillin resistance include overproduction of PBPs with low affinity for β-lactams and mutations in the penicillin-binding domain of the PBP, resulting in further reduction in the affinity for β-lactams (Fontana *et al.*, 1996).

Glycopeptide Resistance

Glycopeptide resistance, the most worrisome acquired resistance in enterococci, was first described in England and France in the mid-late 1980s, with a rapidly increasing number of reports from the United States and other countries. In recent years, horizontal transfer of the enterococcal *vanA* gene associated with this type of resistance to *S. aureus* has been reported (CDC, 2002a,b).

Six types of glycopeptide resistances in enterococci have been described, named for their specific ligase genes (e.g., *vanA*, *vanB*), which may be intrinsic (e.g., *vanC*, as a species characteristic) or acquired. Within the acquired types of glycopeptide resistance, *E. faecium* accounts for most of the isolates, followed by *E. faecalis* and, less often, by other enterococcal species. These types of glycopeptide resistances share the capability of producing a peptidoglycan precursor with decreased affinity for glycopeptides. These peptidoglycan precursors end in the depsipeptide D-alanyl-D-lactate in VanA, VanB and VanD strains and in the dipeptide D-alanyl-D-serine in VanC and VanE isolates, instead of the normal D-alanyl-D-alanine ending. The VanA and VanB types are the most commonly found. High MICs of vancomycin and teicoplanin are usually observed in VanA isolates, whereas VanB strains typically display low teicoplanin MICs and intermediate-to-high MICs of vancomycin.

The *vanA* gene cluster is typically found on the transposon Tn1546 or related elements (e.g., Tn5482) (Arthur *et al.*, 1993; Handwerger and Skoble, 1995), which in turn may be carried on plasmids as well as on bacterial chromosomes. The three main, necessary and co-transcribed, genes of the *vanA* gene cluster are *vanH*, *vanA* and *vanX* (Arthur, Molinas and Courvalin, 1992), which encode a dehydrogenase (VanH), a ligase (VanA) and a D,D-dipeptidase (VanX), respectively. The ligase synthesizes D-Ala-D-Lac using D-Lac obtained from the reduction of the pyruvate by the dehydrogenase (VanH) (Arthur and Courvalin, 1993), which is then incorporated into cell-wall precursors. These D-Ala-D-Lac-ending precursors have less affinity for glycopeptides than D-Ala-D-Ala precursors; therefore, cell-wall synthesis continues in the presence of vancomycin. The D,D-dipeptidase VanX hydrolyzes free D-Ala-D-Ala dipeptides, decreasing the production of the normal D-Ala-D-Ala-containing precursor. Two-component regulatory systems composed of a membrane-associated sensor kinase (e.g., VanS) and a cytoplasmic regulator (e.g., VanR) regulate the expression of the *vanA* and *vanB* gene clusters. The presence of

glycopeptides is sensed by VanS, which activates VanR in the cytoplasm, leading to the transcriptional activation of the resistance genes and regulatory genes (Arthur and Quintiliani, 2001). The sensor kinase in VanB strains (VanS_B) does not recognize teicoplanin in the medium, which may explain the low teicoplanin MIC usually expressed by these strains (Evers and Courvalin, 1996).

The motile species *E. gallinarum* and *E. casseliflavus* have, as an intrinsic characteristic, the genes *vanC-1* and *vanC-2*, respectively (Navarro and Courvalin, 1994). Since these species synthesize both normal ending precursors (D-Ala-D-Ala) and low-glycopeptide-affinity precursors (D-Ala-D-Ser), variable MICs of vancomycin, even within the susceptible range, are usually observed in these enterococcal species (Dutka-Malen *et al.*, 1992).

The overall epidemiological impact of VRE strains is different in Europe and the United States. In the former, VRE strains that generally have low MICs of ampicillin are found relatively often in food animals and healthy volunteers, probably secondary to the prior use of the glycopeptide avoparcin as a growth enhancer to feed animals. In the United States, avoparcin was never approved for use in animals and, instead, a high prevalence of VRE is typically observed in hospitalized patients, probably because of the widespread use of vancomycin within the hospital setting.

Some isolates of vancomycin-resistant *E. faecalis* and *E. faecium* show growth only in the presence of vancomycin, thereby called vancomycin-dependent enterococci (VDE) (Framow *et al.*, 1994). These strains cannot produce D-Ala-D-Ala-ending precursors because they carry an inactive D-alanyl:D-alanine ligase, but they can continue cell-wall synthesis using products from their *vanA* or *vanB* gene cluster if they are under vancomycin-inducing conditions. Spontaneous revertants (vancomycin resistant but not dependent) arise because of restoration of endogenous D-alanyl:D-alanine ligase or mutations that cause constitutive (rather than inducible) expression of *van* resistance genes.

Linezolid Resistance

In vitro studies have indicated that the presence of a mutation in multiple copies of the 23S rRNA genes in *E. faecalis* and *E. faecium* strains is needed to cause linezolid resistance (Prystowsky *et al.*, 2001; Marshall *et al.*, 2002). Some patients receiving linezolid for infections caused by VRE (*E. faecium*) have failed treatment because of the development of resistance to linezolid (Gonzales *et al.*, 2001). These patients have had infections associated with high bacterial inoculum, such as empyema and liver abscesses, and usually received prolonged courses of linezolid therapy (Gonzales *et al.*, 2001).

MANAGEMENT OF ENTEROCOCCAL INFECTIONS

Most of the infections caused by enterococci in non-immunocompromised patients, such as UTIs, soft-tissue infections and intra-abdominal abscesses, do not require therapy using a regimen with bactericidal activity. Single-drug treatment with ampicillin, penicillin or vancomycin (in case of allergy to β -lactams) is usually sufficient. Ureidopenicillins, such as piperacillin and mezlocillin, with broader spectrum might also be used, especially when mixed infection is suspected. Ticarcillin and carbenicillin are not regarded as active anti-enterococcal agents and should not be prescribed for that purpose. Fluoroquinolones and nitrofurantoin alone are only marginally active against enterococci and have been successfully used only in lower UTIs (Lefort *et al.*, 2000). Erythromycin and rifampin have had little clinical use against enterococci, whereas tetracyclines and chloramphenicol had some use for VRE before the approval of quinupristin-dalfopristin and linezolid. Despite the fact that enterococci are frequently isolated from mixed intra-abdominal infections, most clinical trials with antibiotics without specific anti-enterococcal coverage do not show clinical failure or persistent isolation of these organisms. For this reason, many authorities do not recommend specific

anti-enterococcal therapy initially (Gorbach, 1993). However, in some cases, enterococci may be important pathogens and patients with persistent positive cultures in the absence of clinical improvement should be treated with specific anti-enterococcal therapy.

Endocarditis

Therapy of endocarditis and other serious systemic infections has been a challenge to clinicians since the beginning of the antibiotic era. Many patients with enterococcal endocarditis failed even with high doses of penicillin, presumably because a bactericidal effect is required in the treatment of such infections and because cell-wall agents alone are often not bactericidal for enterococci. With the introduction of streptomycin, successful outcome with penicillin-streptomycin therapy was reported and bactericidal synergism between penicillin and streptomycin could be demonstrated by time-kill techniques. The usual choices for the aminoglycoside component of combined therapy are streptomycin and gentamicin. The traditional treatment of enterococcal endocarditis has consisted of penicillin or ampicillin (or vancomycin for patients with β -lactam intolerance) combined with gentamicin or streptomycin administered for 4–6 weeks. (Because of its safety profile and the ability to monitor serum concentrations, gentamicin is preferred by many to streptomycin.) A recent study from Sweden suggested that shorter courses may suffice for some patients (Olaison *et al.*, 2002). Low-dose gentamicin (3 mg/kg/day, divided in three doses) plus high-dose penicillin (20×10^6 U/day divided in six doses) or ampicillin (12 g/day divided in six doses) is the recommended regimen.

Bacteremia

Enterococcal bacteremia without endocarditis and with a known extracardiac source generally responds well to 10–14 days of monotherapy. However, Maki and Agger (1988) recommend 4 weeks of bactericidal therapy for patients in whom an extracardiac source cannot be identified, especially if the infection is community acquired and/or if the patient has known valvular heart disease.

HLR Strains

HLR to either streptomycin or gentamicin abolishes the bactericidal synergism usually seen when these drugs are combined with cell-wall-active antibiotics. HLR to gentamicin predicts lack of synergistic killing with all other generally available aminoglycosides, except streptomycin. For this reason, all high-level gentamicin-resistant strains should be screened for high-level streptomycin resistance. Because the normally present chromosomally encoded aminoglycoside-modifying enzyme AAC(6') of *E. faecium*, synergism is not observed with the combination of penicillin and tobramycin for this species. Because both identification to species and screening for HLR to tobramycin [for detecting APH(2'')-AAC(6') or ANT(4'')] would need to be performed, most clinicians avoid using tobramycin for enterococci. Amikacin is also generally avoided because of the need to perform screening for HLR to kanamycin or to perform time-kill synergy studies, which many laboratories are not prepared to do. Some investigators have used 8–10 weeks of continuous intravenous ampicillin or high doses of vancomycin for patients with enterococcal endocarditis caused by isolates with HLR to all aminoglycosides, but the optimal therapy for this condition is uncertain (Eliopoulos, 1993). In some cases, cardiac valve replacement, as an adjunct to medical therapy, may need to be considered if there is an inadequate initial response or relapse.

Multiple Drug-Resistant Isolates

The recognition of isolates resistant to clinically achievable concentrations of penicillin or glycopeptides or both further complicates the

therapy of enterococcal infections. For β -lactamase-producing strains of *E. faecalis*, the combination of penicillin and a β -lactamase inhibitor (ampicillin–sulbactam, amoxicillin–clavulanic acid and piperacillin–tazobactam), vancomycin or imipenem is an alternative option.

Although vancomycin may be used for strains that are highly resistant to penicillins or in penicillin-intolerant patients, the optimal therapy for VRE strains is still unclear. When the infecting VRE strain is *E. faecalis*, ampicillin will almost always be active. Even when a vancomycin-resistant *E. faecium* isolate is reported as ampicillin resistant, based on NCCLS breakpoints, if the MIC is $\leq 64 \mu\text{g/ml}$, high-dose ampicillin (20–24 g/day) might still be effective (Murray, 1997), especially if there is an active aminoglycoside to use in combination. If the VRE isolate is motile, the involved species is either *E. gallinarum* or *E. casseliflavus* with the intrinsic *vanC* gene, and the treatment of choice is ampicillin or penicillin. (Glycopeptides should be avoided even if the MICs are within the susceptible range). VRE strains carrying the *vanB* gene cluster typically display low MIC of teicoplanin; however, emergence of resistance to this agent has been described in animal models (Lefort *et al.*, 1999) and in clinical practice (Hayden *et al.*, 1993). If the VRE infection is limited to the lower urinary tract, nitrofurantoin and fosfomycin tromethamine salt appear to be useful options.

Quinupristin–Dalfopristin

A little more than a decade after the first VRE strain was isolated, two antibiotics were approved for the treatment of VRE (*E. faecium*) infections. The first one was quinupristin–dalfopristin (a 30:70 mixture of two streptogramins). Dalfopristin, a streptogramin A, and quinupristin, a streptogramin B, act synergistically to inhibit bacterial protein synthesis, leading to bacteriostatic to modest bactericidal activity against enterococci (eliminated by the expression of the *ermB* gene found in most VRE isolates), except for *E. faecalis*. This enterococcal species is naturally resistant to quinupristin–dalfopristin because of an efflux mechanism (Singh, Weinstock and Murray, 2002). Clinical trials have demonstrated the usefulness of quinupristin–dalfopristin in the treatment of diverse VR *E. faecium* infections (Moellering *et al.*, 1999; Winston *et al.*, 2000); however, side effects, cost and the need for central venous catheter limit its use.

Linezolid

The second agent with Food and Drug Administration (FDA) approval for the treatment of VRE infections is linezolid, the first antibiotic from the oxazolidinone class. Like quinupristin–dalfopristin, the oxazolidinones also inhibit bacterial protein synthesis, but at an early step, binding to the 23S ribosomal RNA of the 50S subunit to prevent the formation of the initiation complex (Shinabarger *et al.*, 1997). Published studies including patients with various infections caused by VRE strains have reported relatively good clinical and microbiological cure rates (Chien, Kucia and Salata, 2000; Leach *et al.*, 2000).

Other Agents

Occasional reports of successful treatment of VRE using chloramphenicol, tetracyclines or a combination of both exist (Lautenbach *et al.*, 1998; Safdar *et al.*, 2002). Even though quinupristin–dalfopristin and linezolid have brought therapeutic alternatives for infections that were very difficult to eradicate, these agents still have negative aspects, including the lack of bactericidal effect, the high rate of side effects and the already reported development of resistance. These considerations highlight the need to continue the search for new active drugs against VRE. In fact, new agents with promising activity against VRE strains are already in advanced phase of clinical development, including lipopeptide–daptomycin (recently approved by the FDA for

complicated skin and skin structure infections due to staphylococci or streptococci), the semisynthetic glycopeptide oritavancin and the glycylycylcine tigecycline (a derivative of minocycline).

PREVENTION AND CONTROL

After the description of the first VRE strain in the late 1980s, many outbreaks of VRE have been reported. Initial outbreaks of VRE represented clonal dissemination of a single strain, which could often be abolished with infection control measures (Boyce *et al.*, 1994). Later, VRE infection and colonization were often associated with more than one strain and were more difficult to eliminate (Morris *et al.*, 1995). The capability of VRE to cause widespread dissemination has been demonstrated by the finding of the same strain in different hospitals from the same region and even from different states. In this context the role of health care workers (HCWs), the environment and VRE colonized-patients as reservoirs and agents of transmission must be emphasized. The actual proportion of VRE-colonized patients, known as colonization pressure, is another important factor that influences the rate of new VRE-colonized or -infected patient (Bonten *et al.*, 1998). Since the carriage of VRE (and any enterococcal strain) on the hands of HCW has been implicated as the main form of person-to-person transmission, the use of gloves has been recommended when taking care of a VRE-colonized or -infected patient (CDC, 1995), to be followed by handwashing or antisepsis after glove removal. Inanimate objects from the rooms of VRE-colonized patients are frequently contaminated (especially if the patient has diarrhea), explained by the capacity of enterococci to survive on dry surfaces, facilitating the transmission of the resistant strain to other hospitalized patients. It is worth noting that the recovery of the species *E. gallinarum* and *E. casseliflavus* (which carry the nontransferable *vanC* gene) does not necessarily trigger the application of isolation procedures, although highly vancomycin-resistant strains of these species with the transferable *vanA* or *vanB* genes have been reported (Dutka-Malen *et al.*, 1994).

Because control of methicillin-resistant *S. aureus* (MRSA) within the hospital may help in the control of VRE by reducing the selective pressure of vancomycin use (Herwaldt, 1999), the Hospital Infection Control Practices Advisory Committee (HICPAC) recommends restricted use of vancomycin in several situations, the most important being routine surgical prophylaxis, treatment of single positive blood culture for coagulase-negative staphylococci, prophylaxis for intravascular catheter placement, selective decontamination of the digestive tract, attempts to eradicate MRSA colonization and treatment of *Clostridium difficile* colitis (CDC, 1995). The overall decrease of antibiotic selective pressure may also result in better control of VRE in the hospital setting, as suggested by a study showing that antibiotics with antianaerobic activity were associated with higher density of VRE colonization (Donskey *et al.*, 2000). Some of the HICPAC recommendations for controlling nosocomial spread of VRE include the placement of VRE-colonized or -infected patients in private rooms or cohorting with other subjects who are also VRE positive, use of clean nonsterile gloves and gown (the latter if substantial patient contact is anticipated), strict handwashing with antiseptic soap or a waterless antiseptic agent after glove removal and avoiding sharing inanimate objects between patients. Other important measures should include adequate educational programs for personnel and training of the microbiology laboratory staff in the detection and reporting of isolated VRE strains. In settings such as transplant units and ICUs, more aggressive infection control practices may need to be implemented, which will have greater effect when the first VRE strains are isolated. In practical terms, once a patient becomes colonized or infected with VRE it is very difficult to discontinue the isolation precautions described above. Of note, if the patient is readmitted, precautions should resume. Units in an endemic situation might also consider the use of staff cohorting to decrease HCW's exposure to

VRE-positive patients, detect VRE carriers among HCWs and perform environmental cultures to ensure adequate disinfection of the room.

An interesting approach is to attempt to suppress or eradicate VRE from the GI tract to decrease the risk of bacteremia caused by this microorganism in patients who are particularly susceptible to this event (e.g., colonized neutropenic patients with mucositis). Initially, oral bacitracin and doxycycline were tried without much success (Weinstein *et al.*, 1999), but more recently, ramoplanin, a nonabsorbable glycolipopeptide active against VRE, was shown to have efficacy, in a phase II trial, in decreasing counts of VRE, in stool, although only while subjects were taking the drug (Wong *et al.*, 2001).

Staphylococcus aureus

Sharon Peacock

Nuffield Department of Clinical Laboratory Sciences, The John Radcliffe Hospital, Oxford, UK

DESCRIPTION OF THE ORGANISM

Taxonomic History

Rosenbach provided the first taxonomic description of *Staphylococcus* in 1884 when he divided the genus into *Staphylococcus aureus* and *Staphylococcus albus* (Rosenbach 1884), although Pasteur and Ogston had observed spherical bacteria in abscess pus 4 years earlier (Ogston 1880; Pasteur 1880). The staphylococci and a group of saprophytic, tetrad-forming micrococci were placed into the genus *Micrococcus* by Zopf in 1885 (Zopf 1885) and subsequently separated again by Flügge. Evans, Bradford and Niven (1955) divided facultative anaerobic cocci and obligate aerobes into the genus *Staphylococcus* and *Micrococcus*, respectively, based on the oxidation–fermentation (OF) test for glucose fermentation. A major advance occurred when DNA base composition was compared between *Staphylococcus* and *Micrococcus* (Silvestri and Hill 1965). This demonstrated that micrococci have a G+C content of 63–73 mol%, compared with staphylococci which have a G+C content of DNA of 30–39 mol%, indicating that they are not significantly related. More recent systematic studies have distinguished staphylococci from micrococci and other bacteria by using a range of factors including cell-wall composition (Schleifer and Kandler 1972), cytochromes and menaquinones (Faller, Götz and Schleifer 1980; Collins and Jones 1981), cellular fatty acids and polar lipids (Nahaie *et al.* 1984), DNA–rRNA hybridization (Kilpper, Buhl and Schleifer 1980) and comparative oligonucleotide cataloguing of 16S rRNA (Ludwig *et al.* 1981). The genus *Staphylococcus* now belongs to the broad *Bacillus–Lactobacillus–Streptococcus* cluster consisting of Gram-positive bacteria that have a low G+C content of DNA. The closest relatives of staphylococci are the macrococci (Kloos *et al.* 1998a). They are also related to salinicocci, enterococci, planococci, bacilli and listerias on the basis of partial oligonucleotide sequencing of 16S rRNA and rDNA (Ludwig *et al.* 1985; Stackebrandt *et al.* 1987).

Cell Morphology and Cultural Characteristics

Light Microscopy and Staining Reactions

Gram-stained cells of staphylococci are uniformly Gram positive in young (18–24 h) cultures and appear spherical with an average diameter of 0.5–1.5 µm on light microscopy. Cells divide in more than one plane to form irregular clusters. This is the commonest appearance but is not absolute. The possibility of *S. aureus* should not be discounted when organisms are seen as singles, pairs or other configurations, particularly when being observed on direct stain of clinical material. Cell-wall-defective or -deficient (L-form) cells have been described

(Kagan 1972). These fail to take Gram stain, are osmotically sensitive and are not easily cultured on the usual isolation media. As a result, their frequency and clinical relevance are unknown.

Growth Characteristics, Colony Morphology and Metabolism

Staphylococcus aureus is aerobic, facultatively anaerobic and nonmotile. It grows well in a variety of commercial broth media, including trypticase soy broth, brain–heart infusion broth and tryptose phosphate broth, with or without the addition of blood. Commonly used selective media include mannitol salt agar, lipase salt mannitol agar, Columbia colistin–nalidixic acid (CNA) agar and Baird–Parker agar base supplemented with egg yolk tellurite enrichment. These media inhibit the growth of Gram-negative bacteria but allow the growth of staphylococci and certain other Gram-positive bacteria. Staphylococci produce distinctive colonies on a variety of selective and nonselective agar media, but accurate distinction between *S. aureus* and other staphylococci requires further testing. Colonies of the same strain generally exhibit similar features of size, consistency, edge, profile, luster and pigment, but some strains may produce two or more colony morphotypes.

Small-colony variants (SCVs) of *S. aureus* have been described. These are sometimes identified in association with cases of *S. aureus* infection that prove resistant to antibiotic cure as manifest by persistence or relapse (Proctor *et al.* 1995; Kahl *et al.* 1998; Abele-Horn *et al.* 2000). Colony size is around one-tenth or less of that of wild type, indicative of slow growth. These may be mixed with the wild-type morphology, often initially giving the impression of a mixed specimen, or may be the only morphotype observed. SCVs may be stable or may revert to wild type after serial passage (McNamara and Proctor 2000). Reversion within a single colony may also give rise to the appearance of colony sectoring. SCVs lack pigment, are often auxotrophic for menadione or hemin, have a reduced range of carbohydrate utilization, may fail to express several putative virulence factors and are resistant to gentamicin owing to poor drug uptake (Wilson and Sanders 1976; Proctor and Peters 1998). SCVs have been reported to arise following exposure to gentamicin in broth culture, after uptake of bacteria by endothelial cells *in vitro* (Vesga *et al.* 1996), in experimental animal models and during human infection (Proctor *et al.* 1995; von Eiff *et al.* 1997; Kahl *et al.* 1998; Abele-Horn *et al.* 2000; von Eiff *et al.* 2001a). SCVs also persist within endothelial cells *in vitro* (Balwit *et al.* 1994). It has been proposed that SCVs represent a small subpopulation of organisms that become auxotrophs following the acquisition of a mutation in genes involved in the electron transport chain. However, reversible phenotypic switching may occur between *S. aureus* SCV and the parental phenotype (Massey, Buckling and Peacock 2001; Massey and Peacock 2002). It is possible that switching between gentamicin-resistant SCV and

gentamicin-sensitive wild type circumvents the lasting fitness cost of antibiotic resistance associated with permanent genetic mutation.

A rabbit endocarditis model has been used to examine *menD* or *hemB* mutants (resulting in an SCV phenotype and menadione and hemin auxotrophy, respectively). No differences were observed in infectious dose for either mutant compared with wild type. The response to oxacillin therapy was the same for the *hemB* mutant and wild type, but oxacillin therapy failed to reduce bacterial densities of the *menD* mutant in kidney or spleen (Bates *et al.* 2003). A murine model of septic arthritis has also been used to compare a *hemB* mutant with the isogenic wild-type strain. The mutant was more virulent on a per-organism basis compared with wild type (Jonsson *et al.* 2003). This was considered to be due in part to the increase in protease production by the mutant. The similarity between an SCV that arises during human infection and site-directed bacterial mutants with an SCV phenotype is unclear.

Staphylococci are capable of using a variety of carbohydrates as carbon and energy sources. The Embden–Meyerhof–Parnas (EMP) (glycolytic) pathway and the oxidative hexose monophosphate pathway (HMP) are the two central pathways used by staphylococci for glucose metabolism (Strasters and Winkler 1963; Blumenthal 1972). *Staphylococcus aureus* metabolizes glucose mainly by glycolysis and to a limited extent by the HMP (Sivakanesan and Dawes 1980). The major end product of anaerobic glucose metabolism in *S. aureus* is lactate, while only 5–10% of glucose appears as lactate under aerobic conditions. Most staphylococcal species are capable of synthesizing many different amino acids needed for growth. The genetic control of histidine (Kloos and Pattee 1965), isoleucine and valine (Smith and Pattee 1967), lysine (Barnes, Bondi and Fuscaldo 1971), tryptophan (Proctor and Kloos 1970), leucine (Pattee *et al.* 1974) and alanine, threonine, tyrosine and methionine (Schroeder and Pattee 1984; Mahairas *et al.* 1989) biosynthesis has been studied extensively in *S. aureus*. Naturally occurring strains may have mutations in one or more of the amino acid biosynthesis genes, resulting in certain amino acid requirements.

CELLULAR AND SECRETED COMPONENTS

Cellular and Secreted Components

Cell Membrane and Cell Wall

The cell membrane is a typical lipid–protein bilayer composed mainly of phospholipids and proteins. The cytochromes and menaquinones bound to cell membranes are important components of the electron transport system. Proteins isolated from the membranes of *S. aureus* include several penicillin-binding proteins (PBPs), which catalyse terminal reactions of peptidoglycan biosynthesis (Hartman and Tomasz 1984). Iron-regulated cell-membrane proteins are expressed under iron limitation (Domingue, Lambert and Brown 1989). A 42-kDa cell-wall protein that binds human transferrin, the major iron-binding protein in serum, has been detected (Modun, Kendall and Williams 1994). A protein that binds human lactoferrin, an iron-binding protein found in milk, tears, saliva and some other body fluids, has also been identified (Naidu, Andersson and Forsgren 1992).

Peptidoglycan and teichoic acid are the major components of the staphylococcal cell wall. Peptidoglycan makes up 50–60% of the dry weight (Schleifer and Kandler 1972; Schleifer 1983). It is the main structural polymer in the wall and consists of a heteropolymer of glycan chains cross-linked by short peptides. The glycan moiety is made up of alternating β -1,4-linked units of *N*-acetylglucosamine and *N*-acetylmuramic acid. The carboxyl group of muramic acid is substituted by an oligopeptide containing alternating L- and D-amino

acids. These peptide subunits are cross-linked by the insertion of an interpeptide oligoglycine bridge that extends from the COOH-terminal D-alanine in position 4 of one peptide subunit to the ϵ -amino group of L-lysine in position 3 of an adjacent peptide subunit (Schleifer 1973). Biological activities of peptidoglycans include endotoxin-like properties (pyrogenicity, complement activation, generation of chemotactic factors and aggregation and lysis of animal blood platelets), inflammatory skin reactions, inhibition of leucocyte migration and adjuvant activity (Schleifer 1983). Staphylococcal cell-wall teichoic acid is a water-soluble polymer that is covalently linked to peptidoglycan and amounts to about 30–50% dry weight. *Staphylococcus aureus* lipoteichoic acid (LTA) activates immune cells via toll-like receptor 2 (TLR-2), lipopolysaccharide (LPS)-binding protein (LBP) and CD14 (Morath *et al.* 2002; Schroder *et al.* 2003). *Staphylococcus aureus* peptidoglycan is also recognized by TLR-2 (Yoshimura *et al.* 1999; Kyburz *et al.* 2003).

Cell-Surface–Associated and Secreted Adhesins

Adherence to soluble plasma components and/or extracellular matrix proteins is promoted by a range of *S. aureus* cell-wall-associated proteins (Patti *et al.* 1994a) (Table 5.1). These adhesins may play a central role in the colonization of the host and during invasive disease. *In silico* analysis of six *S. aureus* genome sequences has identified 21 genes predicted to encode surface proteins anchored to the peptidoglycan cell wall. The best characterized of these are protein A SpA (Forsgren *et al.* 1983; Uhlén *et al.* 1984; Hartleib *et al.* 2000), two fibronectin-binding proteins FnBPA and FnBPB (Rydén *et al.* 1983; Switalski *et al.* 1983; Signas *et al.* 1989; Jönsson *et al.* 1991; Greene *et al.* 1995), the fibrinogen-binding proteins clumping factors A and B (ClfA and ClfB) (McDevitt *et al.* 1994; Ni Eidhin *et al.* 1998) and a collagen-binding protein Cna (Patti *et al.* 1992). Other proteins include three members of the serine aspartate multigene family (SdrC, SdrD and SdrE) (Josefsson *et al.* 1998), the bone sialoprotein-binding protein Bbp (an allelic variant of SdrE) (Tung *et al.* 2000), the plasmin-sensitive protein Pls (Savolainen *et al.* 2001; Huesca *et al.* 2002) and biofilm-associated protein (Bap) (Cucarella *et al.* 2001, 2002). These proteins have features characteristic of Gram-positive bacterial surface-expressed proteins, including a secretory signal sequence at the N-terminus and a positively charged tail, a hydrophobic transmembrane domain and a wall-spanning region with an LPXTG (Leu-Pro-X-Thr-Gly) motif at the C-terminus. The LPXTG motif represents the target for sortase (SrtA), a membrane-associated enzyme that cleaves the motif between the threonine and glycine residues. The protein is then covalently anchored to the peptidoglycan cell wall (Schneewind, Fowler and Faull 1995; Mazmanian *et al.* 1999; Ton-That *et al.* 1999; Ilangovan *et al.* 2001). A second sortase (SrtB) is required for anchoring a surface protein with an NPQTN motif. The gene encoding SrtB is part of an iron-regulated locus called iron-responsive surface determinants (*isd*), which also contains surface proteins and a ferrichrome transporter with NPQTN and LPXTG motifs (Mazmanian *et al.* 2002). Two further cell-wall proteins (FrpA and FrpB) are expressed under iron-restricted growth conditions. FrpA may be involved in the adhesion of *S. aureus* to plastic *in vitro*, and both are regulated by the ferric uptake regulator Fur (Morrissey *et al.* 2002).

Staphylococcus aureus also expresses bacterial adhesins that lack an LPXTG motif (Table 5.1). These include the major histocompatibility complex class II analogue Map and the highly similar extracellular adhesin protein Eap (McGavin *et al.* 1993; Jönsson *et al.* 1995; Palma, Hagggar and Flock 1999), Efb (formally Fib) (Boden and Flock 1994), the elastin-binding protein EbpS (Park *et al.* 1996; Downer *et al.* 2002) and Ehb, which is a very large fibronectin-binding protein that appears on localization studies to be cell envelope associated (Clarke *et al.* 2002).

Table 5.1 *S. aureus* cell-surface-associated and secreted proteins

Bacterial determinant	Putative function	References
Protein A (SpA)	Binds Fc domain of Ig and von Willebrand factor	Forsgren <i>et al.</i> (1983), Uhlén <i>et al.</i> (1984), Hartleib <i>et al.</i> (2000)
Fibronectin-binding proteins A and B (FnBPA and FnBPB)	Adhesins for fibronectin FnBPA recognizes fibrinogen	Rydén <i>et al.</i> (1983), Switalski <i>et al.</i> (1983), Signas <i>et al.</i> (1989), Jönsson <i>et al.</i> (1991), Greene <i>et al.</i> (1995), Wann, Gurusiddappa and Hook (2000)
Clumping factor A and B (ClfA and ClfB)	Adhesins for fibrinogen ClfA and ClfB mediate platelet activation and aggregation ClfB mediates binding to epidermal cytokeratin	McDevitt <i>et al.</i> (1994), Ni Eidhin <i>et al.</i> (1998), Siboo <i>et al.</i> (2001), O'Brien <i>et al.</i> (2002a, 2002b)
Collagen-binding protein (Cna)	Adhesin for collagen	Patti <i>et al.</i> (1992)
SdrC, SdrD and SdrE – members of serine–aspartate multigene family	Function of SdrC and SdrD unknown; putative adhesins SdrE mediates platelet activation and aggregation	Josefsson <i>et al.</i> (1998)
Bone sialoprotein-binding protein (Bbp)	Adhesin for bone sialoprotein Member of the Sdr family; allelic variant of SdrE	Rydén <i>et al.</i> (1989), Tung <i>et al.</i> (2000)
Plasmin-sensitive protein (Pls)	Associated with <i>mecA</i> in some strains Large surface protein that may interfere with bacterial interactions with host proteins such as fibronectin and immunoglobulins	Savolainen <i>et al.</i> (2001)
Biofilm-associated protein (Bap)	May interfere with bacterial attachment to host tissues and cellular internalization. Present in 5% of bovine strains but absent from 75 human isolates tested	Cucarella <i>et al.</i> (2001, 2002)
Elastin-binding protein (EbpS)	Adhesin for elastin	Park <i>et al.</i> (1996), Downer <i>et al.</i> (2002)
Map/Eap	Map (cell associated) described as MHC class II analogue protein Eap (secreted protein) has a broad binding specificity, involved in adherence to fibroblasts, enhances internalization into eukaryotic cells <i>in vitro</i> and serves as antiinflammatory factor by inhibiting the recruitment of host leucocytes	McGavin <i>et al.</i> (1993), Jönsson <i>et al.</i> (1995), Palma, Hagggar and Flock (1999), Flock and Flock (2001), Hussain <i>et al.</i> (2001, 2002), Chavakis <i>et al.</i> (2002), Hagggar <i>et al.</i> (2003)
Extracellular matrix-binding protein homologue (Ehb)	Very large cell-wall-associated protein; binds human fibronectin	Clarke <i>et al.</i> (2002)

Extracellular Toxins

Staphylococcus aureus produces a group of functionally related pyrogenic toxins that cause fever and shock in its hosts (Table 5.2). These toxins are classified as superantigens (SAGs) and include the staphylococcal enterotoxins (SEs) and toxic shock syndrome toxin-1 (TSST-1), which have, in common, a potent mitogenic activity for T lymphocytes of several host species (Iandolo 1989; Fleischer 1994). Exfoliative toxins are also reported to have superantigenic activity. Positivity of human isolates for the genes encoding enterotoxins varies between toxins. For example, 23%, 8% and 60% of over 300 human isolates tested in one study were positive for *sea*, *seb* and *seg*, respectively (Peacock *et al.* 2002b). TSST-1 causes approximately 75% of all staphylococcal toxic shock syndrome (TSS) cases (Bergdoll *et al.* 1981; Schlievert *et al.* 1981), although about 90% of *S. aureus* strains isolated from the vagina of patients with TSS produce TSST-1. The organisms associated with non-menstrual TSS are positive for TSST-1 in around half of cases, the remainder being positive for staphylococcal enterotoxin B (SEB) and staphylococcal enterotoxin C (SEC) in 47% and 3%, respectively. The incidence of TSST-1 is much lower (in the region of 25%) in *S. aureus* strains isolated from other types of patients or healthy individuals, and it has not been detected in other staphylococcal species. The *S. aureus* epidermolytic toxins (ETs) known as exfoliatin A (ETA) and exfoliatin B (ETB) are recognized as the cause of staphylococcal scalded skin syndrome (SSSS), a disease associated with severe blistering of the skin, especially in

young children (Rogolsky 1979). ETs are produced by a low percentage of *S. aureus* strains (14% and 2% for *eta* and *etb*, respectively, in one study; Peacock *et al.* 2002b). *Staphylococcus aureus* SAGs are encoded by accessory genetic elements (reviewed in McCormick, Yarwood and Schlievert 2001; Novick, Schlievert and Ruzin 2001). The first five to be described (SapI 1–4 and SapI bov) are pathogenicity islands that each encode one or more of the SAGs (Novick, Schlievert and Ruzin 2001). A further six novel pathogenicity islands have been identified in the genome sequences of two *S. aureus* isolates (N315 and Mu50) (Kuroda *et al.* 2001).

Staphylococcus aureus also produces four types of haemolysins known as α -, β -, δ - and γ -toxin (Table 5.2). These attack the membranes of erythrocytes as well as some other cell types from several host species. A high percentage (86–95%) of human *S. aureus* strains produce α -toxin, although many produce only small amounts. α -Toxin-defective mutants have reduced virulence in animal models compared with the wild-type parental strain (Foster *et al.* 1990). β -Toxin has species-dependent activity, with goat, cow and sheep erythrocytes being most sensitive, human erythrocytes having intermediate sensitivity and dog and mouse erythrocytes being resistant (Bohach and Foster 2000). Around 85% of human *S. aureus* strains are positive for β -toxin. δ -Toxin is produced by a high percentage (86–97%) of *S. aureus* strains of human and animal origin. γ -Toxin and Pantón–Valentine leukocidin (PVL) are bicomponent toxins encoded by the *hlg* and *luk-PV* loci, respectively (Bohach and Foster 2000). The toxins contain two synergistically acting

Table 5.2 *S. aureus* toxins

Protein	Biological activities	References
Toxic shock syndrome toxin-1 (TSST-1)	Causes toxic shock syndrome Superantigen with mitogenic activity for T cells	Schlievert <i>et al.</i> (1981), Kreiswirth <i>et al.</i> (1983), Chu <i>et al.</i> (1988)
Exfoliative toxin A (ETA) and Exfoliative toxin B (ETB)	Staphylococcal scalded skin syndrome Causes intraepidermal blisters Has superantigen activity	Melish and Glasgow (1970), Rogolsky (1979), Dancer <i>et al.</i> (1990), Jackson and Iandolo (1986), O'Toole and Foster (1986)
Enterotoxins SEA-SEE and SEG-SEQ	Ingestion of preformed toxin in food results in nausea, vomiting and diarrhoea	Reviewed by Dinges, Orwin and Schlievert (2000)
α -Toxin	Cytolytic pore-forming toxin	Bhakdi and Tranum-Jensen (1991)
β -Toxin	Neutral sphingomyelinase Acts as a type C phosphatase, hydrolyzing sphingomyelin to phosphorylcholine and ceramide	Doery <i>et al.</i> (1965), Smyth, Möllby and Wadström (1975), Coleman <i>et al.</i> (1989)
δ -Toxin	Surfactant on various cells: erythrocytes, leucocytes and bacterial protoplasts	Fitton, Dell and Shaw (1980)
γ -Toxin	Bicomponent toxin Cytolytic for erythrocytes and leucocytes Can form active combinations with Panton-Valentine leukocidin components	Fackrell and Wiseman (1976), Cooney <i>et al.</i> (1988), Prevost <i>et al.</i> (1995)
Panton-Valentine leukocidin	Cytolytic for leucocytes	Noda <i>et al.</i> (1980), Rahman <i>et al.</i> (1991), Prevost <i>et al.</i> (1995)

proteins, one S component (HlgA, HlgC or LukS-PV) and one F component (HlgB or LukF-PV). Any S component may combine with either F component, leading to six combinations in strains that carry both loci (currently reported to be <2% of human isolates) or two combinations in strains positive for *hlg* alone (>95%). γ -Toxin is strongly haemolytic but weakly leukocytic, whereas PVL may lyse neutrophils and macrophages. However, the effect of a given toxin will be modulated depending on the component pairing. For example, Luk-PV paired with HlgA or HlgC results in a toxin that is weakly haemolytic but which has strong leukocytic activity. The recently described community-acquired methicillin-resistant *S. aureus* (CA-MRSA) strains commonly carry the PVL locus (Vandenesch *et al.* 2003). This may result in a rise in the proportion of *S. aureus* positive for PVL.

Other Secreted Extracellular Components

Staphylococcus aureus produces four major extracellular proteases (Karlsson and Arvidson 2002), namely staphylococcal serine protease (V8 protease; SspA), cysteine protease (SspB), metalloprotease (aureolysin; Aur) and staphopain (Scp). These are secreted as proenzymes that are cleaved by proteolysis to become mature enzymes. A survey of 92 clinical isolates demonstrated that protease genes appear to be conserved (Karlsson and Arvidson 2002). Their role in human disease pathogenesis is unknown.

Several other extracellular components are secreted by *S. aureus*, including coagulase, staphylokinase, lipase, urease and hyaluronidase. Coagulase clots plasma in the absence of Ca²⁺ but requires a plasma constituent known as coagulase-reacting factor (CRF). Interaction between the two results in a complex (staphylothrombin) that converts fibrinogen to fibrin (Drummond and Tager 1963). Most *S. aureus* strains (98–99%) exhibit coagulase activity. Staphylokinase binds to plasminogen and activates it to become the fibrinolytic enzyme plasmin. This is produced by a relatively high percentage (60–95%) of human *S. aureus* strains. Hyaluronate lyase (hyaluronidase) is a glycoprotein that hydrolyses the mucopolysaccharide hyaluronate (Rautela and Abramson 1973). Staphylococcal lipases hydrolyse a

wide range of substrates, and a large percentage (95–100%) of strains produce detectable levels of the heat-stable nuclease (or thermonuclease).

Capsule and Biofilm

Staphylococcus aureus strains may be assigned to one of at least 11 capsular serotypes by using polyclonal rabbit antiserum specific for their associated capsular polysaccharides. Human isolates are usually microencapsulated with either serotype 5 or serotype 8 (Arbeit *et al.* 1984; Hochkeppel *et al.* 1987; Albus *et al.* 1988). Capsular polysaccharides have been purified from strains with serotypes 1, 2, 5 and 8, and the biochemical structure has been defined. Readers seeking a review of this area are referred to O'Riordan and Lee (2004).

Staphylococcus aureus produces an extracellular material called slime termed biofilm. The mechanism by which staphylococci attach to prosthetic material and elaborate biofilm is being increasingly understood and is clearly a complex and multistep process (reviewed in Mack 1999; von Eiff, Heilmann and Peters 1999; von Eiff, Peters and Heilmann 2002). One important element in this pathway is the *ica* operon, a gene cluster present in *S. aureus* (and *Staphylococcus epidermidis*) that encodes the production of polysaccharide intercellular adhesin (PIA). This mediates intercellular adherence of bacteria and the accumulation of multilayered biofilm (Heilmann *et al.* 1996). Biofilm production is likely to be relevant to human disease, since it embeds sessile bacteria adherent to prosthetic surfaces, making them more resistant to the effect of antibiotics and inaccessible to the immune response.

Regulation of Gene Expression

Staphylococcus aureus gene expression is under the control of regulatory systems that respond to changes in environmental conditions. As a broad generalization and largely based on experimental data from *in vitro* systems, syntheses of surface proteins occur very early

in exponential phase and are downregulated at the transcriptional level later in the exponential phase. This is followed in the post-exponential phase by the transcription of many genes encoding extracellular proteins. These observations may be explained by the coordinated action of several regulatory systems. The best characterized of these is Agr (accessory global regulator) and Sar (staphylococcal accessory regulator), with a third regulator termed Sae (*S. aureus* exoprotein expression). Readers are referred to the large bodies of published work by Richard Novick and colleagues and Ambrose Cheung and colleagues for more in-depth details on Agr and Sar, respectively. Relevant literature on Sae includes Giraudo *et al.* (1994, 1996, 1999, 2003), Giraudo, Cheung and Nagel (1997), Goerke *et al.* (2001), Novick and Jiang (2003) and Steinhuber *et al.* (2003). Regulation *in vivo* is poorly defined overall, but studies addressing this area indicate that regulation does not always mirror that seen under laboratory conditions (Goerke *et al.* 2000).

Other factors may also affect gene expression. For example, FnBP expression is altered *in vitro* on exposure to subinhibitory ciprofloxacin (Bisognano *et al.* 2000). Clinical isolates with *grlA* and *gyrA* mutations (encoding altered topoisomerase IV and DNA gyrase, respectively) exhibited significant increases in attachment to fibronectin-coated surfaces after growth in the presence of one-quarter the minimal inhibitory concentration (MIC) of ciprofloxacin. This phenomenon may be explained by the observation that ciprofloxacin activates the *fnbB* promoter (Bisognano *et al.* 2000). It is also associated with the activation of *recA* and derepression of *lexA* (an SOS repressor)-regulated genes (Bisognano *et al.* 2004). A *hemB* mutant defective in hemin biosynthesis and exhibiting an SCV phenotype has also been reported to have increased expression of genes encoding ClfA and fibronectin-binding proteins (Vaudaux *et al.* 2002).

GENETIC EXCHANGE

Antimicrobial Resistance of *S. aureus*

The most significant events in the history of *S. aureus* antibiotic resistance are the emergence of resistance to penicillin (which is now almost ubiquitous), the emergence of and epidemic rise in methicillin resistance, the recognition of strains with intermediate resistance to vancomycin and the recent emergence of *S. aureus* that is fully resistant to vancomycin. The mechanisms of resistance to other antimicrobial agents are summarized in Table 5.3.

Resistance to β -Lactam Antibiotics

Penicillin-resistant *S. aureus* strains emerged in the early 1940s, shortly after the introduction of penicillin into clinical practice. Resistance to methicillin and other β -lactamase-resistant penicillins was likewise observed soon after methicillin was introduced into clinical use in Britain (Jevons 1961). At this time the methicillin-resistant strains isolated in Britain demonstrated heterogeneous resistance to methicillin (i.e. affecting only a minority of the cell population), were multiply antibiotic resistant and were isolated from hospitalized patients (Barber 1961). After the mid-1970s, large outbreaks of infection caused by MRSA were reported in many hospitals in Britain (Shanson, Kensit and Duke 1976; Cookson and Phillips 1988), Ireland (Cafferkey *et al.* 1985), the United States (Schaeffler *et al.* 1981) and Australia (Pavillard *et al.* 1982). Many of these early MRSA epidemics were caused by a single epidemic strain that was transferred between hospitals (Duckworth, Lothian and Williams 1988). Since then, many clones of MRSA associated with epidemic spread or sporadic infections have been described throughout the world.

Approximately one-third of serious *S. aureus* infections in the United Kingdom are now caused by MRSA, although the figure varies considerably worldwide. Until recently, MRSA was mostly confined to the hospital setting and MRSA colonization of those discharged from the community rarely persisted long term except when associated with

defects in the skin integrity or the presence of prosthetic material. However, community-acquired MRSA associated with both colonization and infection is being increasingly recognized (Daum *et al.* 2002; Okuma *et al.* 2002). These strains are resistant to fewer non- β -lactam antibiotics than most of the previously defined MRSA strains.

The gene encoding methicillin resistance (*mecA*) is carried by the chromosome of MRSA and methicillin-resistant *S. epidermidis* (MRSE), the mechanism for which is the synthesis of an altered low-affinity PBP termed PBP2a. *mecA* is part of a mobile genetic element termed staphylococcal cassette chromosome *mec* (SCC*mec*) (Katayama, Ito and Hiramatsu 2000). Four types of SCC*mec* have been defined based on sequence analysis. Comparison of SCC*mec* types I–III has demonstrated substantial differences in both size and nucleotide sequence but shared conserved terminal inverted repeats and direct repeats at the integration junction points, conserved genetic organization around the *mecA* gene and the presence of *ccr* genes, which are responsible for the movement of the island (Ito *et al.* 2001). Evaluation of 38 epidemic MRSA strains isolated in 20 countries showed that the majority possessed one of the three typical SCC*mec* elements on the chromosome (Ito *et al.* 2001). SCC*mec* type IV was subsequently defined in community-acquired MRSA (Daum *et al.* 2002). This element is smaller and lacks non- β -lactam genetic-resistance determinants. Multiple MRSA clones carrying type IV SCC*mec* have been identified in community-acquired MRSA strains in the United States and Australia (Okuma *et al.* 2002). An evaluation of SCC*mec* types (as defined by the PCR) present in 202 MRSA isolates from two hospitals in Florida reported that four isolates failed to give an amplification product, indicating the possible existence of additional types (Chung *et al.* 2004).

Genetic relationships of 254 MRSA isolates recovered between 1961 and 1992 from nine countries on four continents have been analysed using electrophoretic mobility of enzymes (multilocus enzyme electrophoresis) (Musser and Kapur 1992). Fifteen distinctive electrophoretic types (clones) were identified, and the *mec* gene was found in divergent phylogenetic lineages. This was interpreted as evidence that multiple episodes of horizontal transfer and recombination have contributed to the spread of methicillin resistance. MLST has subsequently been used to define the population genetic structure of MRSA and methicillin-susceptible strains (Enright *et al.* 2002). Eleven major MRSA clones were identified within five groups of related genotypes. The major MRSA clones appeared to have arisen repeatedly from successful epidemic MSSA strains, and isolates with decreased susceptibility to vancomycin have arisen from some of these major MRSA clones (Enright *et al.* 2002).

Possible precursors and reservoirs of the genetic determinants of methicillin resistance include *Staphylococcus sciuri* (Wu, de Lencastre and Tomasz 1998) and *Staphylococcus hominis* subsp. *novobiosepticus* (Kloos *et al.* 1998b). A genetic element that is structurally very similar to SCC*mec* except for the absence of *mecA* has been defined in a methicillin-susceptible strain of *S. hominis* (Katayama *et al.* 2003). An SCC element that lacks *mecA* has also been defined during sequencing of *S. aureus* MSSA252 (Holden *et al.* 2004). The role of this element in horizontal transfer of genes encoding antibiotic resistance and other determinants that may endow a biological fitness requires further investigation.

Some *mecA* *S. aureus* strains exhibit borderline susceptibility to methicillin (oxacillin MIC, 1–2 μ g/ml) and other β -lactamase-resistant penicillins (McMurray, Kernodle and Barg 1990; Barg, Chambers and Kernodle 1991). This is partly due to the hyperproduction of β -lactamase type A (McDougal and Thornsberry 1986; Chambers, Archer and Matsuhashi 1989).

Resistance to Vancomycin

The glycopeptide antibiotics vancomycin and teicoplanin prevent the transglycosylation and transpeptidation steps of cell-wall peptidoglycan synthesis by binding to the peptidyl-D-alanyl-D-alanine termini

Table 5.3 Antibiotic resistance mechanisms for *S. aureus* (see text for β -lactams and glycopeptides)

Responsible protein	Major activity or mechanism	Gene	Gene location	References
<i>Macrolide, lincosamide and streptogramin B (MLS)</i> 23S rRNA methylases A-C	Methylases cause a conformational change in the ribosome, resulting in a reduced binding of MLS antibiotics to target site in 50s subunit Require induction by erythromycin or are made constitutively	<i>ermA</i> <i>ermB</i> <i>ermC</i>	Chromosome: on transposon Tn554 which prefers a single <i>att</i> site Plasmids and chromosome: on transposon Tn551 which can transpose to many sites Plasmids (mainly class I) > chromosome	Murphy (1985a), Murphy, Huwyler and de Freire Bastos Mdo (1985), Thakker-Varia <i>et al.</i> (1987), Lim <i>et al.</i> (2002), Strommenger <i>et al.</i> (2003) Khan and Novick (1980), Luchansky and Pattee (1984) Horinouchi and Weisblum (1982), Weisblum (1985)
<i>Macrolide and streptogramin B (MS)</i> ATP-dependent efflux protein MsrA	ATP-dependent efflux pump to remove MS antibiotics	<i>msrA</i>	Plasmid	Ross <i>et al.</i> (1989, 1990), Lina <i>et al.</i> (1999)
<i>Streptogramin A</i> Acetyltransferase	Inactivation of drug by enzymatic modification	<i>vaiA</i> <i>vaiB</i>	Plasmid	Allignet <i>et al.</i> (1993, 1996), Allignet, Loncle and el Solh (1992), Allignet and el Solh (1995), Allignet and El Solh (1997), Haroche <i>et al.</i> (2000, 2003), Haroche, Allignet and El Solh (2002), Strommenger <i>et al.</i> (2003)
ATP-binding proteins	Mechanism not fully elucidated	<i>vgaA</i> <i>vgaB</i> <i>vgaAv</i> (variant of A)	Plasmid vgaAv is carried by Tn5406 located on plasmid and/or chromosome	
<i>Streptogramin B</i> Hydrolase	Hydrolysis of drug	<i>vgbA</i> <i>vgbB</i>	Plasmid Located on plasmids conferring resistance to A compounds	Allignet <i>et al.</i> (1988), Allignet, Liassine and el Solh (1998), Haroche <i>et al.</i> (2003)
<i>Lincosamide</i> 3-Lincosmycin, 4-clindamycin O-nucleotidyltransferase	Inactivates lincosamides	<i>linA'</i>	Plasmid	Brisson-Noël <i>et al.</i> (1988), Lina <i>et al.</i> (1999)
<i>Tetracycline</i> Tetracycline export proteins	Energy-dependent efflux pump removes tetracycline	<i>tetK</i> <i>tetL</i>	Plasmid	Khan and Novick (1983), Mojumdar and Khan (1988), Guay, Khan and Rothstein (1993), Strommenger <i>et al.</i> (2003)
<i>Tetracycline and minocycline</i> Ribosomal protection protein		<i>tetM</i>	Chromosome: Tn916- and Tn916-like transposons	Nesin <i>et al.</i> (1990), Burdett (1993), Strommenger <i>et al.</i> (2003)
<i>Aminoglycosides</i> Aminoglycoside-modifying enzymes				
Aminoglycoside acetyltransferase (AAC)	Acetylation of an amino group: tobramycin, netilmicin, amikacin and gentamicin	<i>aac(6')-aph(2'')</i>	Plasmids (mainly class III) and chromosome on transposons (Tn4001 and Tn4001-like, Tn4031, Tn3851)	Townsend, Grubb and Ashdown (1983), Townsend <i>et al.</i> (1984), Rouch <i>et al.</i> (1987)

Aminoglycoside phosphotransferase (APH)	Phosphorylation of a hydroxyl group: kanamycin, neomycin, paromomycin, amikacin and gentamicin	<i>aphI(3')-IIIa (aphA)</i>	Plasmids and chromosome	Gray and Fitch (1983), Coleman <i>et al.</i> (1985), el Solh, Moreau and Ehrlich (1986)
Aminoglycoside adenylyltransferase (ANT)	Adenylation of a hydroxyl group: tobramycin, amikacin, paromomycin, kanamycin, neomycin, gentamicin and dibekacin	<i>ant(4')-Ia (aadD)</i>	Plasmids	Schwotzer, Kayser and Schwotzer (1978), Thomas and Archer (1989)
Aminoglycoside adenylyltransferase	Adenylylates spectinomycin	<i>ant(9)-Ia (spc)</i>	Chromosome: on transposon Tn554	Murphy (1985b)
<i>Trimethoprim</i> Dihydrofolate reductase (DHFR)	Single amino acid substitution of <i>dhfr</i> gene leads to marked reduced affinity for trimethoprim	<i>dhfrB</i>	Plasmid > chromosome	Coughter, Johnston and Archer (1987), Tennent <i>et al.</i> (1988), Rouch <i>et al.</i> (1989), Dale, Then and Stuber (1993)
<i>Chloramphenicol</i> Chloramphenicol acetyltransferase (CAT)	Acquisition of second gene via plasmid that encodes trimethoprim-resistant DHFR	<i>dhfrA</i>		
	Acetylates chloramphenicol via acetyl coenzyme A to yield derivatives that are unable to bind to the ribosome	<i>cat</i>	Plasmids (class I)	Shaw (1983), Projian and Novick (1988), Cardoso and Schwarz (1992)
<i>Fluoroquinolones</i> DNA gyrase subunits GyrA and GyrB	Mutation in genes encoding two subunits of DNA gyrase	<i>gyrA</i> <i>gyrB</i>	Chromosome	Sreedharan, Peterson and Fisher (1991), Goswitz <i>et al.</i> (1992), Margerrison, Hopewell and Fisher (1992), Brockbank and Barth (1993), Ito <i>et al.</i> (1994)
DNA topoisomerase IV	Mutation in genes encoding two subunits of DNA gyrase Reduced target enzyme expression (ParE)	<i>grlA</i> <i>grlB</i> (also termed <i>parC</i> and <i>parE</i>)	Chromosome	Trucksis, Wolfson and Hooper (1991), Ferrero <i>et al.</i> (1994), Ferrero, Cameron and Crouzet (1995), Hooper (2001), Ince and Hooper (2003)
Multidrug efflux protein NorA	Energy-dependent efflux pump removes hydrophilic fluoroquinolones; associated with alterations in gene or increased transcription of <i>norA</i>	<i>norA</i> Regulation of <i>norA</i> affected by <i>flqB</i>	Chromosome	Ohshita, Hiramatsu and Yokota (1990), Yoshida <i>et al.</i> (1990), Kaatz, Seo and Ruble (1993), Ng, Trucksis and Hooper (1994)
<i>Rifampin</i> DNA-dependent RNA polymerase β -subunit	Single base pair change in <i>rpoB</i> resulting in an amino acid substitution in the β subunit of RNA polymerase	<i>rpoB</i>	Chromosome	Aubry-Damon, Soussy and Courvalin (1998)
<i>Mupirocin</i> Isoleucyl-tRNA synthetase	Low-level mupirocin resistance (MIC 8–256 mg/l) because of mutation in gene for target enzyme High-level resistant (MIC > 512 mg/l) mediated by <i>ileS-2</i> gene, which encodes an additional isoleucyl-tRNA synthetase	<i>ileS</i> <i>MupA</i>	Chromosome Val-to-Phe changes at either residue 588 (V5 88F) or residue 631 (V63IF) Plasmid	Gilbart, Perry and Slocombe (1993), Hodgson <i>et al.</i> (1994), Cookson (1998), Antonio, McFerran and Pallen (2002)

of peptidoglycan precursors. Glycopeptides are important in clinical practice because they are used to treat severe infections caused by MRSA. Three categories of *S. aureus* resistances to vancomycin have been described since 1997:

1. *S. aureus* with intermediate-level resistance to vancomycin (VISA);
2. *S. aureus* with heteroresistance to vancomycin (hVISA);
3. vancomycin-resistant *S. aureus* (VRSA).

Criteria have been developed by the CDC for the identification of VISA. These are the following:

1. growth within 24 h on commercial brain–heart infusion agar screen plates containing 6 µg/ml of vancomycin;
2. E-test vancomycin MIC >6 µg/ml;
3. broth microdilution MIC of 8–16 µg/ml (Tenover *et al.* 1998).

A variety of screening methods has been described to detect hVISA, but the optimal method is still under debate (Liu and Chambers 2003). VRSA is defined by an MIC >32 µg/ml (National Committee for Clinical Laboratory Standards 2002a).

Staphylococcus aureus with intermediate-level resistance to vancomycin (VISA) was first detected in Japan in 1996 (Hiramatsu *et al.* 1997b). The strain (Mu50) was isolated from an infant who developed a sternal wound infection that was refractory to treatment following surgery to correct a congenital cardiac defect. This strain was reported to have an MIC of 8 mg/l (Hiramatsu *et al.* 1997b). VISA strains have since been identified worldwide, although they are currently rare in clinical practice, and most appear to evolve from MRSA strains in patients who have received prolonged vancomycin treatment. The first hVISA (Mu3) was identified in Japan from the sputum of a patient with MRSA pneumonia following surgery (Hiramatsu *et al.* 1997a). This strain was reported to have an MIC of 3 µg/ml (Hiramatsu *et al.* 1997a). Serial passage of Mu5 in increasing concentrations of vancomycin gave rise to subpopulations with levels of resistance comparable to those of Mu50, and typing showed that Mu3 and Mu50 had the same PFGE pattern (Hiramatsu *et al.* 1997a). hVISA has since been reported from around the world and appears to be more common than VISA (Hiramatsu *et al.* 1997a; Hiramatsu 2001; Liu and Chambers 2003). The first VRSA was reported in Michigan in July 2002, with a second apparently unrelated case in Pennsylvania 2 months later (Centers for Disease Control and Prevention 2002a, 2002b).

The mechanisms of vancomycin resistance for VISA and hVISA are not fully elucidated. These strains do not carry the enterococcal vancomycin-resistance gene *vanA*, *vanB* or *vanC* 1–3 (Hanaki *et al.* 1998a). Findings at the time of writing indicate that changes in the cell wall are important in this process. Strain Mu50 has increased amounts of glutamine-non-amidated muropeptides and decreased cross-linking of peptidoglycan compared with Mu3, together with a decreased dimer-to-monomer ratio of muropeptides (Hanaki *et al.* 1998b). The peptidoglycan of Mu50 binds 1.4 times more vancomycin than that of Mu3 (Hanaki *et al.* 1998b). Both strains produce three to five times the amount of PBPs when compared with vancomycin-susceptible *S. aureus* control strains with or without methicillin resistance, and transmission electron microscopy has shown a doubling in the cell-wall thickness in Mu50 compared with control strains (Hanaki *et al.* 1998a). An increase in the consumption of vancomycin by the cell wall and reduction in the amount of vancomycin reaching the cytoplasmic membrane may both contribute to vancomycin resistance. Microarray transcription analysis of two clinical VISA isolates was compared with two derivatives with MIC of 32 µg/ml after passage in the presence of vancomycin (Mongodin *et al.* 2003). Of 35 genes with increased transcription, 15 involved purine biosynthesis or transport, and the regulator of the major purine biosynthetic operon was mutant (Mongodin *et al.* 2003). These genes may be involved in the metabolic

processes required for the production of the thicker cell wall. The genome sequences of Mu50 and vancomycin-susceptible MRSA strains N315, EMRSA-16 and COL have been compared (Avison *et al.* 2002). Several mutations affecting important cell-wall biosynthesis and intermediary metabolism genes were identified in Mu50.

Vancomycin-resistant enterococci were reported in 1988. Transfer from *Enterococcus faecalis* to *S. aureus* of high-level resistance to both vancomycin and teicoplanin was performed in the laboratory in the early 1990s through the interstrain transfer of *vanA* (Noble, Virani and Cree 1992). This gene encodes a ligase that causes an alteration in the composition of the terminal dipeptide in muramyl pentapeptide cell-wall precursors, leading to decreased binding affinity to glycopeptides (Framow and Courvalin 2000). This represents the mechanism of resistance in the two VRSA isolated in the United States that contain the *vanA* gene (Weigel *et al.* 2003; Tenover *et al.* 2004).

Resistance to Other Antibiotics

Table 5.3 summarizes the antibiotic-resistant mechanisms for *S. aureus* to the other major antibiotic groups.

Plasmids and Bacteriophages

Staphylococcus aureus plasmids have been classified into three general classes. Class I plasmids are small (1–5 kbp), have a high copy number (10–55 copies per cell) and are either cryptic or encode a single antibiotic resistance. These plasmids are the most widespread throughout the genus *Staphylococcus*. For example, the pT181 family comprises a group of small (4–4.6 kbp) plasmids that usually encode tetracycline or chloramphenicol resistance, and the pSN2 family plasmids often encode erythromycin resistance. Class II plasmids, commonly called penicillinase or β-lactamase plasmids, are relatively large (15–33 kbp), have a low copy number (4–6 per cell) and carry several combinations of antibiotic and heavy-metal resistance genes, many of which are located on transposons (Shalita, Murphy and Novick 1980; Lyon and Skurray 1987). Class III plasmids appear to be assemblages of transposons and transposon remnants (Gillespie *et al.* 1987).

Most strains of *S. aureus* are multiply lysogenic (Verhoef, Winkler and van Boven 1971; Pulverer, Pillich and Haklová 1976). The temperate phages of *S. aureus* may be subdivided into three main serological groups termed A, B and C. The relevance of bacteriophage is threefold:

1. these are commonly used in experimental transduction;
2. bacterial susceptibility to phage has been used for many years as the basis for a typing scheme;
3. phage may influence the gene complement or gene expression of an organism.

Alterations in gene complement or expression may occur either via carriage of genes into the organism [lysogenic conversion by prophage that carries genes encoding staphylokinase and staphylococcal enterotoxin A (SEA)] or via negative lysogenic conversion in which genes that contain phage-attachment sites within their sequence are disrupted (e.g. *hlyB* encoding β-toxin; Coleman *et al.* 1986).

Genetic Elements and the *S. aureus* Genome Sequence

The genome of *S. aureus* is composed of a single chromosome of around 2.8 Mb, which is predicted to encode approximately 2500 genes. The genome sequence of two related *S. aureus* strains (N315 and Mu50) was published in 2001 (Kuroda *et al.* 2001). N315 is an MRSA strain isolated in Japan in 1982, and Mu50 is an MRSA strain with intermediate-level resistance to vancomycin, isolated in Japan in 1997. It was observed that most of the antibiotic resistance genes were carried either by plasmids or by mobile genetic elements including

a unique resistance island and that many putative virulence genes seem to have been acquired by lateral gene transfer. Three classes of new pathogenicity islands were identified: a TSST island family, an exotoxin island and an enterotoxin island. Sequencing of strain MW2 was subsequently undertaken (Baba *et al.* 2002). This strain is a community-acquired MRSA isolated from a 16-month-old girl in the United States with fatal septicaemia and septic arthritis. The genome of this strain was compared with that of N315 and Mu50, including a comparison between the staphylococcal cassette chromosome *mec* (SCC*mec*) that carries the *mec* gene encoding methicillin resistance. Nineteen additional virulence genes were found in the MW2 genome, all but two of which were carried by one of the seven genomic islands of MW2. Sequencing of two further isolates by The Wellcome Trust Sanger Institute, UK, has provided an opportunity to undertake comparative genomics for five genomes (Holden *et al.* 2004). The strains sequenced were a methicillin-susceptible *S. aureus* (MSSA) strain (MSSA476) that is phylogenetically close to MW2 and a hospital-acquired representative of the epidemic methicillin-resistant EMRSA-16 clone (MRSA252) that is phylogenetically divergent from any other sequenced strain. Schematic circular diagrams of the *S. aureus* MRSA252 and MSSA476 genomes are shown in Plate 2. Comparison of the five *S. aureus* whole-genome sequences showed that 166 genes (6%) in the phylogenetically divergent MRSA252 genome were not found in the other published genomes. Around 80% of the genome was highly conserved between strains, the remaining 20% of each consisting of highly variable genetic elements that spread horizontally between strains at high frequency. This is consistent with the findings of a study that used a DNA microarray representing more than 90% coverage of the *S. aureus* genome (Fitzgerald *et al.* 2001). Comparison of the genomes of 36 strains from divergent clonal lineages showed that genetic variation was very extensive, with approximately 22% of the genome being comprised of dispensable genetic material.

Publication of the genome sequence of two further strains (COL and 8325) is imminent, with genome sequence of additional strains reportedly in progress. Comparison of the *S. aureus* genome with the genome sequence of *S. epidermidis* (ATCC 12228) has demonstrated that *S. epidermidis* contains a lower number of putative virulence determinants (Zhang *et al.* 2003).

Sequencing of smaller fragments of the genome in populations of isolates has provided interesting insights into rates of genetic mutation. Examination of the sequence changes at multilocus sequence typing (MLST) loci during clonal diversification has shown that point mutations give rise to new alleles at least 15-fold more frequently than by recombination (Feil *et al.* 2003). This contrasts with the naturally transformable species *Neisseria meningitidis* and *Streptococcus pneumoniae*, in which alleles change between five- and tenfold more frequently by recombination than by mutation.

STAPHYLOCOCCUS AUREUS AND THE HUMAN HOST

Staphylococcus aureus Carriage

Three *S. aureus* carriage patterns have been described in the healthy adult population, with approximately 20% of individuals being persistent *S. aureus* carriers, about 60% intermittent carriers and 20% persistent non-carriers (Kluytmans, van Belkum and Verbrugh 1997). This represents a useful framework during the study of *S. aureus* carriage (Peacock, de Silva and Lowy 2001) and has become accepted and widely quoted for many years. A review of the few longitudinal studies that are to be found in the older published literature suggests that this may be an oversimplification. However, there is sufficient data to support the idea that there is considerable heterogeneity within the population in which some individuals never or hardly ever carry *S. aureus*, others are usually carriers and the remainder carry the organism for variable periods of time. Rates of *S. aureus* carriage are

higher in those infected with human immunodeficiency virus compared with both healthcare workers and patients with a range of chronic diseases (Weinke *et al.* 1992). Carriage rates are also higher in individuals with insulin-dependent diabetes, in patients on continuous ambulatory peritoneal dialysis (CAPD) and haemodialysis and in intravenous drug abusers when compared with the healthy population (Kluytmans, van Belkum and Verbrugh 1997). Carriage rates vary between different ethnic groups (Noble 1974), and a community-based carriage study has reported a family predisposition to nasal carriage of *S. aureus* (Noble, Valkenburg and Wolters 1967). Several small genetic studies have been performed, but their findings are inconclusive (Hoeksma and Winkler 1963; Aly *et al.* 1974; Kinsman, McKenna and Noble 1983).

The nose is the dominant ecological niche for *S. aureus*, as demonstrated by loss of carriage from other sites following nasal decolonization using a topical antibiotic (assuming the absence of prosthetic material, wounds or skin defects). *Staphylococcus aureus* resides in the anterior nares, an area covered by stratified, keratinized, non-ciliated epithelium. Other sites of colonization include the axilla, perineum and hairline. Throat carriage also occurs in some individuals, sometimes in the context of a negative nasal swab.

The cellular and molecular basis of the interaction between bacterium and host that facilitates carriage and host tolerance is poorly understood. It seems likely that bacteria recognize one or more host receptors during attachment and colonization. Epithelial cells express glycoproteins, glycolipids and proteoglycans, and the presence/absence of heterogeneity in one or more of these molecules could be involved. Mucin may enhance adherence since *S. aureus* has been shown to adhere to ferret airway mucus, bovine submaxillary gland mucin and purified human mucin *in vitro* (Sanford, Thomas and Ramsay 1989; Shuter, Hatcher and Lowy 1996). An association has been described between adhesion of *S. aureus* to buccal epithelial cells and expression of the Lewis^a blood group antigen (Saadi *et al.* 1993). Asialoganglioside 1 has been identified as a receptor for *S. aureus* in a cystic fibrosis bronchial epithelial cell line (Imundo *et al.* 1995). *Staphylococcus aureus* also adheres to glycolipids (fucosylasialo-GM1, asialo-GM1 and asialo-GM2) extracted from lung tissue (Krivan, Roberts and Ginsburg 1988). Adherence of *S. aureus* to gangliosides and asialo-GM1 extracted from corneal epithelial cells has also been described (Schwab *et al.* 1996). Studies are required to examine the role of these and other host receptors in the process of *S. aureus* carriage in the nose. The number or nature of host receptors in the nares may vary, since one study demonstrated significantly greater adherence of *S. aureus* to desquamated epithelial cells from carriers compared with non-carriers (Aly *et al.* 1977). The surface-expressed *S. aureus* protein clumping factor B (ClfB) is a multifunctional adhesin that interacts with epidermal cytokeratins and desquamated nasal epithelial cells *in vitro* (O'Brien *et al.* 2002b). The *S. aureus* surface protein SasG, identified previously by *in silico* analysis of genome sequences, and two homologous proteins, Pls of *S. aureus* and AAP of *S. epidermidis*, also promote bacterial adherence to desquamated nasal epithelial cells *in vitro* (Roche, Meehan and Foster 2003). Variation in host phenotype in the nares has been demonstrated by a study in which nasal secretions from three subjects colonized with *S. aureus* lacked antimicrobial activity against *S. aureus in vitro*, whereas fluid from non-carriers was bactericidal (Cole, Dewan and Ganz 1999). The host may modulate carriage through immune regulation. In a human experimental inoculation study, those susceptible to the smallest initial inoculum were colonized for the greatest period of time (Ehrenkranz 1966). After spontaneous nasal elimination, survival of the same strain on repeated reinoculation was uniformly brief, but duration of colonization of a second strain of *S. aureus* mirrored that of the primary inoculation. These data suggest an acquired immune response.

Colonization resistance caused by bacterial interference between different strains or species is likely to influence the strain of *S. aureus* carried. During the late 1950s it was recognized that colonization of

newborn infants with *S. aureus* of the 52/52A/80/81 phage group complex was often followed by disease in infants and their contacts (Shaffer *et al.* 1957) and that the presence of *S. aureus* in the nose before contact with phage type 80/81 strains prevented colonization with this strain. Newborn infants inoculated with the nonpathogenic *S. aureus* strain 502A demonstrated reduction in colonization with a second strain (Shinefield *et al.* 1963), but recognition that 502A could cause both minor and major *S. aureus* disease led to a rapid halt to this practice. The interaction between *S. aureus* and other microbial species has been examined by a small number of studies. The presence of viridans streptococci has been reported to prevent colonization with MRSA in newborns, perhaps because of streptococcal production of H₂O₂ (Uehara *et al.* 2001a, 2001b). A low incidence of *S. aureus* carriage was found in individuals positive on nasal culture for *Corynebacterium* sp., and *S. aureus* carriage was interrupted in 12 of 17 persistent carriers after an average of 12 inoculations of *Corynebacterium* sp. (Uehara *et al.* 2000). The bacterial nasal flora of 216 healthy volunteers was defined to identify possible interactions between different species (Lina *et al.* 2003). The *S. aureus* colonization rate correlated negatively with the rate of colonization by *Corynebacterium* spp. and non-aureus staphylococci, especially *S. epidermidis*, suggesting that both *Corynebacterium* spp. and *S. epidermidis* antagonize *S. aureus* colonization. The effect of other components of the normal nasal flora on the development of *S. aureus* carriage has also been examined in 157 consecutive infants over the first 6 months of life (Peacock *et al.* 2003). Putative bacterial interference between *S. aureus* and other species occurred early in infancy but was not sustained. An increasing anti-staphylococcal effect was observed over time, but this was not attributable to bacterial interference.

Determinants of *S. aureus* Infection

Determinants of infection may be divided into host and bacterial factors. Whether a given individual develops *S. aureus* infection is likely to depend on a complex interplay between the two. Little is currently understood regarding the dominant players.

Host Factors

There is a paucity of studies examining host genetic susceptibility to *S. aureus* carriage or disease. The increased susceptibility for *S. aureus* infection seen in individuals with disorders of the immune system such as leucocyte adhesion deficiency syndromes, Job's syndrome (hyperimmunoglobulin E syndrome) and chronic granulomatous disease (Nauseff and Clark 2000) indicates the importance of host factors. The role of the innate immune system in *S. aureus* disease is undergoing investigation. *Staphylococcus aureus* is recognized by TLR-2. The role of TLR-2 and MyD88 (an adaptor molecule that is essential for TLR family signalling) in *S. aureus* disease has been examined using TLR-2- or MyD88-deficient mice. Both mutations led to an increased susceptibility to *S. aureus* infection (Takeuchi, Hoshino and Akira 2000).

The involvement of host factors may also be inferred from known risk factors for *S. aureus* disease. For example, the onset of septic arthritis after closed joint trauma is well recognized, and there is an increased risk of *S. aureus* septic arthritis in those with inflammatory arthritides such as rheumatoid arthritis. Diabetes mellitus is associated with a higher risk of *S. aureus* infection, but the relative importance of factors such as higher *S. aureus* carriage rate, relative immunodeficiency and repeated needle puncture is uncertain. Immune dysfunction may also be an important contributor to the higher rate of *S. aureus* sepsis in patients undergoing chemotherapy for malignant disease or haemodialysis. The presence of surgical incisions and prosthetic devices that breach the normal host defences is an important risk factor for nosocomial disease. Prosthetic material also

provides a site of colonization. The importance of foreign material as a determinant of infection is demonstrated by the variable rates of sepsis associated with different types of haemodialysis vascular accesses. Endogenous arteriovenous fistulae are less prone to infection than prosthetic shunts (Bonomo *et al.* 1997), and intravenous haemodialysis catheters have the greatest associated risk and are a leading cause of *S. aureus* bacteraemia in patients requiring renal replacement therapy (Hoen *et al.* 1998).

Bacterial Factors

Bacterial determinants of infection have undergone extensive study using *in vitro*, *ex vivo* and animal models. Fibrinogen and fibronectin-binding proteins facilitate adherence of *S. aureus* to host proteins deposited on artificial surfaces (Vaudaux *et al.* 1984, 1989, 1993, 1995; Herrmann *et al.* 1988) and are likely to be important in *S. aureus* device-related infection in humans. Experimental *S. aureus* endocarditis has been used to examine the role of several bacterial adhesins. ClfA appears to be involved in the disease process (Moreillon *et al.* 1995; Que *et al.* 2001), whereas ClfB has a limited effect in this model (Entenza *et al.* 2000). Rats inoculated with a transposon mutant defective in fibronectin binding had fewer bacteria on the heart valve (Kuypers and Proctor 1989). A second study that compared wild-type *S. aureus* strain 8325-4 and an isogenic mutant defective in fibronectin binding did not find a difference between the two (Flock *et al.* 1996). However, the nonpathogenic *Lactococcus lactis* engineered to express FnBPA required a lower infective dose to induce endocarditis (Que *et al.* 2001). Experimental septic arthritis has also been used widely to study disease pathogenesis. ClfA and Cna are determinants of experimental septic arthritis (Patti *et al.* 1994b; Josefsson *et al.* 2001), and Cna has been implicated in osteomyelitis (Elasri *et al.* 2002). FnBP has been shown to be involved in adherence to human airway epithelium (Mongodin *et al.* 2002), although FnBP expression was associated with decreased virulence in a rat model of pneumonia (McElroy *et al.* 2002). A study comparing the presence of 33 putative virulence determinants in a large number of *S. aureus* isolates associated with carriage and disease showed that the genes for three surface proteins (*fnbA*, *can* and *sdrE*) were more commonly detected in invasive isolates (Peacock *et al.* 2002b).

The fibronectin-binding proteins confer bacterial attachment to and invasion of a range of host cells *in vitro* (Vercellotti *et al.* 1984; Ogawa *et al.* 1985; Dziwanowska *et al.* 1999; Lammers, Nuijten and Smith 1999; Peacock *et al.* 1999; Sinha *et al.* 1999, 2000; Fowler *et al.* 2000; Massey *et al.* 2001). Plate 3 shows *S. aureus* adhering to and being taken up by endothelial cells *in vitro*. Cell invasion is an active process and appears to involve host cell integrins (Sinha *et al.* 1999; Dziwanowska *et al.* 1999; Fowler *et al.* 2000; Massey *et al.* 2001). The relevance of these observations to human disease is currently unknown.

Signature-tagged mutagenesis has been used to identify *S. aureus* genes required for virulence in a murine model of bacteraemia. Gene mutations associated with reduced virulence were of unknown function in half of mutants identified, the remaining genes being mainly involved in nutrient biosynthesis and cell-surface metabolism (Mei *et al.* 1997). Signature-tag transposon mutants have also been screened in four animal infection models (mouse abscess, wound, bacteraemia and rabbit endocarditis) (Coulter *et al.* 1998). The largest gene class identified encoded peptide and amino acid transporters, some of which were important for *S. aureus* survival in all four animal infection models.

CLINICAL SYNDROMES OF *S. AUREUS* DISEASE

Staphylococcus aureus causes a wide range of infections that may be broadly divided into community and hospital acquired.

Community-acquired infections include toxin-mediated diseases such as TSS and food poisoning, infections affecting the skin and soft tissues, infection of bones and joints, infection relating to other deep sites (e.g. endocarditis, abscess formation in liver and spleen) and infection of lung and urinary tract. This wide range of manifestations occurs both in predisposed and in previously healthy individuals. The commonest deep-site infections are endocarditis and bone and joint infection (Fowler *et al.* 2003).

Toxin-Mediated Staphylococcal Diseases

An epidemic of TSS in young women in the early 1980s associated with menstruation and the use of high-absorbency tampons was caused by TSST-1-producing organisms (Dinges, Orwin and Schlievert 2000). Modification in tampon manufacture resulted in a fall in the number of cases in this group. Non-menstrual TSS is associated with a range of *S. aureus* disease types including invasive *S. aureus* infection. TSS may also occur in association with influenza and in patients with a wound that is colonized by TSST-1-producing organisms, but where clinical features of wound sepsis are absent.

TSS is a severe disease characterized by high fever, hypotension, diffuse erythematous rash with subsequent desquamation 1–2 weeks later and involvement of three or more organ systems (Dinges, Orwin and Schlievert 2000). Clinical features may include mucous membrane hyperaemia, myalgia, vomiting and diarrhoea, renal and hepatic impairment, altered level of consciousness, coagulopathy and low platelet count. The diagnosis is made on clinical grounds, and the Centers for Disease Control and Prevention (CDC) have devised a clinical case definition (Centers for Disease Control and Prevention 1997). Not all patients with clinical features consistent with TSS meet the CDC diagnostic criteria (Dinges, Orwin and Schlievert 2000). The results of the following laboratory tests may be helpful in reaching a diagnosis in such cases (Parsonnet 1998):

1. isolation of *S. aureus* from a mucosal or normally sterile body site;
2. production by this organism of TSST-1 or other SAg known to be associated with TSS;
3. absence of antibodies to the relevant toxin at the time of illness;
4. seroconversion to this toxin with detection of antibodies during convalescence.

SSSS primarily affects neonates and young children. This disease results from the action of *S. aureus* exfoliative toxins on skin epidermidis. Mid-epidermal splitting leads to the development of fragile, thin roofed blisters that rapidly rupture to leave denuded areas (Ladhani *et al.* 1999). SSSS often follows a localized infection in sites such as the umbilical stump, ear or conjunctiva. Presenting clinical features include fever, lethargy, poor feeding and irritability, followed by a tender red rash that spreads to involve the entire body within a few days. Patients have poor temperature control, suffer large fluid losses and may develop secondary infection. Diagnosis is made on the basis of clinical features, including Nikolsky's sign in which the skin wrinkles on gentle pressure. Culture of blister fluid in SSSS is usually negative since the blisters have developed because of toxin formed by *S. aureus* at a distant site. Bullous impetigo has been described as a less severe form of disease with localized skin blistering. Culture of blister fluid is often positive for *S. aureus*. This might indicate that features are caused by local production of bacterial factors.

Staphylococcal food poisoning results from ingestion of preformed SEs (Dinges, Orwin and Schlievert 2000). This occurs when *S. aureus* is inoculated into food which is then left in conditions that are permissive for bacterial multiplication and toxin secretion before consumption. The mechanism of action of the toxin is still under study, but the initiation of the emetic response is thought to be due to interactions with the emetic reflex located in the abdominal viscera,

with subsequent activation of the medullary emetic centre in the brain stem that is stimulated via the vagus and sympathetic nerves (Dinges, Orwin and Schlievert 2000). Nausea and vomiting occur after an incubation period of 2 and 6 h. Abdominal pain and diarrhoea are also common features. Diagnosis is made on clinical grounds. Suspected food may be cultured for the presence of *S. aureus*.

Bacteraemia and Endocarditis

Around two-thirds of *S. aureus* bacteraemia cases are attributable to nosocomial sepsis, most of which relate to an intravenous device. The remainder represent community-acquired bacteraemia. Data from the National Nosocomial Infections Surveillance System indicate that rates of *S. aureus* bacteraemia are increasing (Banerjee *et al.* 1991). Rates of *S. aureus* endocarditis have also increased (Sanabria *et al.* 1990; Watanakunakorn and Burkert, 1993). The use of intravenous catheters may have contributed to this rise. These figures pertain to settings with systems of advanced medical care. Rates of nosocomial *S. aureus* sepsis are likely to vary considerably depending on the global setting, although there is a paucity of data from many parts of the world.

Readers are referred to an excellent review on *S. aureus* bacteraemia and endocarditis written by Cathy Petti and Vance Fowler (Petti and Fowler 2003). The general medical condition of cases presenting with *S. aureus* bacteraemia ranges from the febrile but haemodynamically stable patient, to one who is profoundly shocked and has multiorgan failure with respiratory distress and coagulopathy. All patients with *S. aureus* bacteraemia require assessment to distinguish between those with uncomplicated versus complicated bacteraemia. Uncomplicated bacteraemia may be defined as *S. aureus* bacteraemia but no evidence of seeding of bacteria from the bloodstream to other sites (such as heart valves, bone and joint), and complicated bacteraemia is defined as the presence of one or more foci. A study of 724 adult patients presenting to a hospital with *S. aureus* bacteraemia identified complications in 43% (Fowler *et al.* 2003). This distinction is important since the presence of complications will determine the length of treatment and the need for investigations and additional intervention. Clinical assessment should be repeated during admission since metastatic complications of bacteraemia may only become evident some time after the initial bacteraemia. However, clinical examination may be inadequate in identifying the complicated case. For example, the absence of signs of endocarditis does not exclude the diagnosis. A study of *S. aureus* endocarditis over a 10-year period in Denmark reported that the diagnosis was not suspected and was first detected at autopsy in 32% of patients (Roder *et al.* 1999). Underlying cardiac valvular disease or prosthetic heart valves are risk factors for endocarditis in patients with bacteraemia and should increase clinical suspicion. The Duke criteria should be used in the clinical evaluation of patients suspected of having endocarditis (Durack, Lukes and Bright 1994; Bayer *et al.* 1998). Cardiac echocardiography has been used widely in many centres because of the clinical difficulty in identifying patients with endocarditis. The sensitivity of transthoracic and transoesophageal echocardiography is around 60% and 90%, respectively (Chamis *et al.* 1999).

A study of clinical identifiers of complicated *S. aureus* bacteraemia represents significant progress (Fowler *et al.* 2003). A scoring system based on the presence or absence of four risk factors (community acquisition, skin examination findings suggesting acute systemic infection, persistent fever at 72 h and positive follow-up blood culture results at 48–96 h) was able to identify accurately complicated *S. aureus* bacteraemia. The findings of this study allow readily available clinical variables to be used in the identification of patients requiring further investigation and prolonged therapy. Serological testing in its present form is not useful for confirming the diagnosis of *S. aureus* sepsis or for defining complicated bacteraemia or the extent of disease.

Bone and Joint Sepsis

Staphylococcus aureus is the leading cause of primary septic arthritis and osteomyelitis in all ages except neonates (Baker and Schumacher 1993; Lew and Waldvogel 1997). The route of infection is obvious for individuals with conditions that allow direct bacterial access, including open fractures (where the bone is exposed), surgery involving the bone (including joint replacement or internal fracture fixation) and chronic ulceration down to bone or joint (e.g. in the diabetic foot or in a bed-bound patient with a pressure sore). However, many patients have no obvious predisposing factor and do not have identifiable skin lesions or any other primary focus. In such cases, bacteria presumably gain access to bone and joint because of seeding from the bloodstream. Once present in the bone or joint, they multiply, which triggers a host inflammatory response, the features of which are increased blood flow, increased capillary permeability to fluids and cells and the recruitment of inflammatory cells, initially neutrophil polymorphs. If this immune response is unsuccessful in controlling infection, the result is intense inflammation surrounding an area with high densities of bacteria and the development of an abscess. Figure 5.1 shows the appearance, on magnetic resonance imaging, of osteomyelitis of the femur, with oedema in the bone marrow and a large subperiosteal abscess. Secondary bacteraemia is common at this point in the absence of antibiotic therapy. On presentation, fever is common, but once again the overall condition of the patient may be highly variable, and signs and symptoms will depend on the site affected.

Pulmonary Infections

Infection arises because of inhalation of the organism from a site of colonization (community acquired), via an endotracheal tube in ventilated patients or, more rarely, because of haematogenous spread in a bacteraemic patient. *Staphylococcus aureus* infection may involve the lung parenchyma (localized abscess or more diffuse pattern), pleural cavity (empyema) or both. No clinical or radiological features are typical of *S. aureus* pneumonia. Microbiological diagnosis is complicated in that *S. aureus* is a normal commensal of the upper respiratory tract (predominantly the nose) in a proportion of individuals. As a result, interpretation of *S. aureus* in sputum culture is difficult, and more invasive procedures such as bronchoscopy and lavage may be necessary. A syndrome of rapidly progressive *S. aureus* necrotizing pneumonia affecting previously healthy children and young adults has been described (Gillet *et al.* 2002). The strains responsible were positive for PVL, and pneumonia was often preceded by influenza-like symptoms.

Figure 5.1 Osteomyelitis of the femur. Magnetic resonance imaging demonstrating features indicative of oedema in the bone marrow and a large subperiosteal abscess.

Other Clinical Manifestations

As a generalization, *S. aureus* may infect any organ or region of the body. Additional deep-site infections such as abscess formation in liver, spleen and kidney usually occur in the setting of a bacteraemic patient who develops seeding to multiple sites. Meningitis is an uncommon primary manifestation and usually occurs because of septic embolization associated with endocarditis.

Staphylococcus aureus is a common cause of skin and soft-tissue infections such as boils, impetigo and cellulitis. Primary infection of muscle is unusual in temperate climatic regions but is reported to be common in the tropical setting where paediatric centres may see several cases requiring surgical drainage each week. The reason for this difference is poorly understood. One possible explanation is that parasitic infection with muscle involvement provides a foreign body nidus that predisposes to infection. *Staphylococcus aureus* may cause acute otitis media, although is much less commonly found than other pathogens such as *S. pneumoniae* and *Haemophilus influenzae*. *Staphylococcus aureus* may cause urinary tract infection. Patients with *S. aureus* bacteraemia may also have viable organisms in the urine (Lee, Crossley and Gerding 1978). Whilst the overwhelming majority of patients with *S. aureus* cultured from the urine will not have bacteraemia, it is useful to bear this in mind as a possibility in those patients presenting unwell to hospital.

Nosocomial Infection

The range of nosocomial or hospital-acquired infections includes surgical wound infection, ventilator-associated pneumonia, bacteraemia associated with intravenous devices and infection associated with other types of prosthetic materials such as cerebrospinal fluid (CSF) shunts, prosthetic joints and vascular grafts. However, any disease manifestation may occur in the hospital setting. Investigation will depend on the nature and severity of infection and requires individual assessment for a given patient. The distinction between community and hospital infection is becoming less clear with the rise in home intravenous therapy and the intravenous device-related bacteraemia that occurs in a proportion of cases.

LABORATORY ISOLATION AND IDENTIFICATION OF *S. AUREUS*

This section provides an overview of the laboratory techniques used to isolate and identify *S. aureus*. Readers wishing to undertake this in practice are referred to dedicated texts detailing Standard Operating Procedures.

Direct microscopic examination of normally sterile fluids may provide a rapid, presumptive report of Gram-positive cocci resembling staphylococci. Isolation of *S. aureus* from primary clinical specimens is performed using 5% blood agar following an incubation period of 18–24 h in air at 35–37 °C. Screening for the presence of *S. aureus* in mixed cultures requires the use of selective agar. One example of a medium in common use is mannitol salt agar that is often used for nose swabs. *Staphylococcus aureus* ferments mannitol, resulting in a change in the colour of the medium from pink to yellow. Blood agar containing antibiotics that inhibit Gram-negative organisms should be used for specimens containing mixed flora from sites such as wounds.

Colony morphology may be used by the experienced observer to define presumptive staphylococci. Each discernible staphylococcal morphotype in a given specimen should be analysed. A Gram stain appearance of cocci in clusters and a positive catalase test provide rapid indicators of staphylococci. Distinguishing between *S. aureus* and the remaining staphylococcal species requires further testing. This is commonly performed using two or three simple tests. The coagulase test detects the production of coagulase by *S. aureus*. One colony is mixed with plasma, incubated at 37 °C for 4 h and observed for clot

formation. Samples that are negative at 4 h are incubated and observed again for clotting at 24 h. The slide agglutination test detects clumping factor (ClfA). This is performed by making a heavy homogeneous suspension of cells in distilled water on a glass slide to which a drop of plasma is added. The mixture should be examined for clumping within about 10 s. The DNase test detects the production of deoxyribonuclease. The test isolate is streaked onto solid agar containing DNA and incubated for 24 h. Hydrochloric acid is added to the surface of the plate that precipitates unhydrolysed DNA to produce a white opacity. A zone of clearing around the bacterial growth indicates the production of deoxyribonuclease that results in the hydrolysis of DNA. Most *S. aureus* isolates are positive for all three tests, but rare strains may be negative for one or more. Furthermore, some strains of coagulase-negative staphylococci are positive for one or more of these tests. For example, about 10–15% of *Staphylococcus intermedius* strains are clumping factor positive, and *Staphylococcus lugdunensis* and *Staphylococcus schleiferi* subsp. *schleiferi* are also positive if human plasma is used in the slide test (Freney *et al.* 1988). Many commercial tests are available that detect one or more of clumping factor, protein A, capsular polysaccharide and group-specific antigen by using latex agglutination (van Griethuysen *et al.* 2001). These are easy to use, reliable and popular in diagnostic laboratories. Other commercial rapid identification tests are available, such as the AccuProbe identification test for *S. aureus* (General-Probe, San Diego, CA, USA) and an immunoenzymatic assay based on a monoclonal antibody prepared against the *S. aureus* endo- β -N-acetylglucosaminidase (Guardati *et al.* 1993). These do not replace the inexpensive and reliable tests described above but may find a role in identifying coagulase-negative, protein A-negative, and/or clumping factor-negative mutants of *S. aureus* that would otherwise be misidentified by coagulase and latex agglutination tests. Any persisting uncertainty may usually be resolved using a commercially available rapid identification kit such as API STAPH. There are also a range of fully automated identification systems currently available.

Antibiotic susceptibility testing should be performed using guidelines and Standard Operating Procedures prepared by the National Committee for Clinical Laboratory Standards (NCCLS) or British Society for Antimicrobial Chemotherapy (BSAC). The method used will be strongly influenced by the global setting of the laboratory. Well-funded laboratories often use fully automated systems for identification and/or susceptibility testing. Many laboratories in the United Kingdom continue to use disc susceptibility testing for most antimicrobial agents. Accurate detection of MRSA is an essential service provided by diagnostic laboratories. The oxacillin agar screen test has been a mainstay for the detection of MRSA in diagnostic laboratories for many years. Readers are referred to NCCLS (National Committee for Clinical Laboratory Standards 2002a, 2002b) or BSAC recommendations for a detailed description of methodology for the reference methods (broth microdilution, disk diffusion and oxacillin agar screen).

A wide range of other tests are available for identifying methicillin resistance. Genotypic testing for detecting the presence of *mecA* is performed using the polymerase chain reaction (PCR) (Swenson *et al.* 2001; Grisold *et al.* 2002; Jonas *et al.* 2002; Fang and Hedin 2003). This is not in routine use in most clinical diagnostic laboratories but has become a gold standard for comparing sensitivity and specificity of other tests. Some investigators include PCR detection of a second gene such as *femA*, *femB* or the *S. aureus*-specific marker gene *nuc*, and multiplex PCR may be performed to detect several genes associated with resistance to different antibiotic groups (Perez-Roth *et al.* 2001). PCR methodology may also be used to detect MRSA directly from swabs (Jonas *et al.* 2002), although this involves an enrichment step for *S. aureus* by using immunomagnetic separation (Francois *et al.* 2003). Real-time PCR has also been developed for detecting MRSA (Grisold *et al.* 2002; Fang and Hedin 2003). Gene probe hybridization assays are commercially available, such as the EVIGENE MRSA detection kit that is accurate when valid tests are

produced (Levi and Towner 2003; Poulsen, Skov and Pallesen 2003). Many commercial automated systems are also available. Detection of PBP2a may be performed using a latex agglutination test (e.g. MRSA-Screen test; Horstkotte *et al.* 2001), although this has a lower sensitivity and specificity compared with PCR (Jureen *et al.* 2001; Yamazumi *et al.* 2001). A study using a set of 55 *S. aureus* challenge organisms including several borderline oxacillin-resistant strains that were *mecA* positive compared six routine methods [three reference methods (broth microdilution, disk diffusion and oxacillin agar screen), two commercial automated systems (MicroScan conventional panels and Vitek cards) and the MicroScan rapid panel] and two new rapid methods, Velogene (cycling probe assay) and the MRSA-Screen (latex agglutination). PCR for *mecA* was used as the gold standard (Swenson *et al.* 2001). Results (% sensitivity/% specificity) were reported as follows: broth microdilution, 100/100; Velogene, 100/100; Vitek, 95/97; oxacillin agar screen, 90/92; disk diffusion, 100/89; MicroScan rapid panels, 90/86; MRSA-Screen, 90/100; and MicroScan conventional, 74/97. The MRSA-Screen sensitivity improved to 100% if agglutination reactions were read at 15 min.

Clinical Interpretation of Cultures Positive for *S. aureus*

Isolation of *S. aureus* from a normally sterile site (such as CSF, pus from joints or deep sites obtained by aspiration or during theatre procedures and blood cultures) should be considered clinically significant until clearly proven otherwise. Unlike the case for coagulase-negative staphylococci, *S. aureus* are rare contaminants in good-quality specimens. Patients with invasive community-acquired *S. aureus* disease frequently have a relevant history and clinical signs and symptoms of disease, making the interpretation of a positive culture straightforward. Review of individuals with nosocomial infection should take account of the clinical setting, including recent medical procedures and the presence of intravenous devices and other prosthetic materials. Interpretation of *S. aureus* isolated from samples such as urine and bronchial lavage that have been taken from sites colonized with normal flora may be more difficult and will only approach accuracy if interpreted at the bedside with the full knowledge of the patient's clinical features. Isolation of *S. aureus* in swabs from wounds, ulcers and other skin defects may reflect colonization or infection, and the diagnosis of superficial tissue infection is best judged using clinical criteria. All clinically important positive cultures are best interpreted by a team including primary clinician and microbiologist.

Staphylococcus aureus Typing in the Clinical and Research Setting

Typing techniques performed in diagnostic or reference laboratories for clinical purposes usually aim to examine one of a limited number of situations. A cluster of *S. aureus* cases in a single ward or unit may be investigated to define whether strains are the same (indicating an outbreak) or different. This may be extended to tracking of the spread of strains between units or hospitals and to defining the relatedness of strains giving rise to outbreaks in more than one location. This type of information is important to infection control that aims to prevent further spread of disease. Typing may also be used for isolates cultured from the same patient over time to help define whether a second episode of *S. aureus* infection is due to relapse or reinfection. If isolates from a first and second episode have different genotypes, this is indicative of reinfection. If organisms have the same genotype, this is suggestive of relapse, although it could also represent a second episode of infection with a stable carriage strain. Typing in the research setting is most often applied to address questions of microepidemiology. Other applications include the evaluation of global population genetic structure, genetic evolution, genetic diversity and pathogenicity.

A wide range of typing techniques has been described. These differ in their reproducibility, portability and discriminatory ability, factors that will influence the choice of method for a given situation. The commonest method currently used worldwide is pulsed-field gel electrophoresis (PFGE). This technique is particularly suitable for use in outbreak situations. Problems of reproducibility exist both within and between laboratories, and large collaborative studies have been undertaken in Europe and Canada in an attempt to standardize methodology for the typing of MRSA (Mulvey *et al.* 2001; Murchan *et al.* 2003). MLST is a sequence-based technique that is both reproducible and portable. It promises to be useful for the study of *S. aureus* in a wide range of settings, particularly as sequencing technology becomes more widespread and easily accessible. This technique is based on the principles of multilocus enzyme electrophoresis. Fragments (around 500 bp) of seven unlinked housekeeping genes are amplified by PCR and sequenced. The sequences obtained are assigned allele numbers following comparison of the DNA sequence with results from previously typed strains using the MLST website (<http://www.mlst.net>). For each isolate, the allele numbers at each of the seven loci defines the allelic profile or sequence type (ST) (Enright *et al.* 2000). This technique may be used for studies of both micro- and macroepidemiology. Comparison of PFGE and MLST in a microepidemiological setting found them to have very similar discriminatory abilities (Peacock *et al.* 2002a). MLST is also well suited for the study of *S. aureus* population genetic structure and has been used to examine and compare isolates from around the world.

Other typing techniques that have been used include ribotyping, plasmid profiling (reviewed by Kloos and Bannerman 1994; Arbeit 1995), random amplified polymorphic DNA (RAPD) (Welsh and McClelland 1991; Marquet-Van Der Mee *et al.* 1995), PCR amplification and restriction digest of *coa* (Goh *et al.* 1992) and sequence analysis of *coa* (encoding coagulase) (Shopsin *et al.* 2000) and *spa* (encoding protein A) (Koreen *et al.* 2004). The PCR-based methodology applied to multiple-locus variable-number tandem repeat (VNTR) analysis has been applied to MRSA. A scheme using five VNTR loci (*sdr*, *clfA*, *clfB*, *ssp* and *spa*) was reported to be equivalent to PFGE in terms of discriminatory power and reproducibility (Sabat *et al.* 2003). Its utility in clinical practice and in the research setting awaits further validation. Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS) has been used to examine the bacterial fingerprints of two *S. aureus* strains over time and to determine whether a profile for MRSA could be defined (Bernardo *et al.* 2002). Bacterial fingerprints obtained were specific for any given strain, but a uniform signature profile for MRSA could not be identified. Studies that define the utility of this technique in epidemiological studies are ongoing. Although phage typing was the mainstay of typing methodology for many years following its inception in 1952–1953 (Williams and Rippon 1952), this has largely been replaced by newer methods that are more discriminatory and/or reproducible.

TREATMENT OF *S. AUREUS* DISEASE

Toxin-Mediated Disease

Management of TSS often includes the need for a high-dependency setting. The presence of tampons should be determined and removed where appropriate, and possible sources of infection should be carefully considered in non-menstrual cases. Cultures should be taken for the isolation of *S. aureus* and the organism sent to a reference laboratory to determine TSST-1 production if the diagnosis is in doubt. Acute and convalescent sera should be taken and stored and tested for evidence of seroconversion to TSST-1 in doubtful cases. The need for other investigations should be guided by clinical need. A β -lactamase-resistant anti-staphylococcal antibiotic should be given to eradicate the toxin-producing strain of *S. aureus*. Clindamycin has been

advocated for use as an adjunct to penicillin for the treatment of streptococcal TSS because of its ability to reduce toxin production *in vitro* (Sriskandan *et al.* 1997; Mascini *et al.* 2001). Evidence for the value of clindamycin in TSS caused by *S. aureus* is laboratory based. The effect of clindamycin, flucloxacillin or flucloxacillin plus gentamicin has been defined in terms of *S. aureus* growth and toxin production *in vitro*. Flucloxacillin alone or in combination with gentamicin was rapidly cidal, but clindamycin was bacteriostatic for logarithmic phase cultures. All three inhibited toxin production during logarithmic growth, with inhibition of 75%, 30% and 75% of the control, respectively, during stationary phase growth (van Langevelde *et al.* 1997). The relevance of these data to clinical practice is unclear, but many centres commonly give combination therapy using a β -lactamase-resistant anti-staphylococcal antibiotic plus clindamycin. The case fatality rate is reported to be 3%, although this reflects the outcome of individuals treated in affluent nations.

Fluid and electrolyte replacement are the mainstay of the treatment for scalded skin syndrome. Antibiotics are given to eradicate the toxin-producing *S. aureus* isolate. Fever usually settles after 2 or 3 days, and no new bullae form, although it takes 2–3 weeks for the skin lesions to resolve completely. Affected neonates should be isolated and strict barrier precautions applied to prevent cross-infection. Management of food poisoning requires fluid and electrolyte replacement, but antibiotic treatment is not necessary. The disease is self-limiting and usually resolves within 24 h.

Invasive Disease

Invasive disease includes bacteraemia, endocarditis, bone and joint infection and deep-site abscesses. One or more investigations may be required to delineate the extent of disease. Collections of pus should be drained where technically possible. Infected joints should be washed out by an orthopaedic surgeon in theatre to reduce joint damage and concomitant poor function. Temporary prosthetic material such as intravenous devices should be removed without delay.

Infection caused by methicillin-susceptible strains should be treated with a β -lactamase-resistant penicillin such as flucloxacillin. The current parenteral treatment of choice for methicillin-resistant strains is vancomycin. The choice of antibiotic for empiric treatment of suspected *S. aureus*, or for culture-proven disease before susceptibility test results becoming available, will depend on the rate of MRSA endemicity within a given unit and/or recent significant exposure to another patient either carrying or infected with MRSA. Strains with reduced susceptibility to vancomycin are currently rare in clinical practice, and treatment of such patients should be guided by a team including clinicians, microbiologists and the hospital infection control officer.

The broad range of clinical manifestations of *S. aureus* disease makes it impossible to present a suitable treatment regimen and duration in all cases. The optimal duration of treatment for patients with bacteraemia but no evidence of seeding to distant sites or heart valves is unclear. A meta-analysis of 11 studies in which patients were treated with 2 weeks of therapy reported an average late complication rate of 6.1% (Jernigan and Farr 1993). This study has been used to support the use of 2 weeks of intravenous antibiotics for uncomplicated *S. aureus* bacteraemia. Many centres are keen to treat for shorter periods or to change from intravenous to oral treatment after signs and symptoms have resolved. A switch to oral therapy for patients considered to be at low risk of complicated bacteraemia would reduce the potential problems associated with an extended hospital stay and the risk of (further) intravenous device-related infection. However, efficacy of shorter treatment has not been validated by clinical trial. It is recommended that management follow published guidelines and existing recommendations (Mermel *et al.* 2001).

Guidelines have been published for the treatment of native or prosthetic valve *S. aureus* endocarditis (Wilson *et al.* 1995; Working Party of the British Society for Antimicrobial Chemotherapy 1998; Horstkotte *et al.* 2004). An overview is given below.

Native Valve Endocarditis

Left-sided native valve *S. aureus* endocarditis requires 4 weeks of parenteral antibiotic therapy. MSSA infection is treated with a β -lactamase-resistant penicillin such as flucloxacillin. Vancomycin is the treatment of choice for patients with MRSA native valve endocarditis or for those with an anaphylactic penicillin allergy, although this is associated with a higher rate of treatment failure (Small and Chambers 1990; Levine, Fromm and Reddy 1991). Evidence for the benefit of combination therapy with gentamicin is limited. One study demonstrated that patients receiving nafcillin plus gentamicin had a more rapid rate of bacteraemia clearance, a higher rate of nephrotoxicity but no difference in mortality compared with those treated with nafcillin alone (Korzeniowski and Sande 1982). Gentamicin is currently added for the first 3–5 or 7 days (the duration of gentamicin differing between US and UK guidelines, respectively). The benefit of adding rifampicin to a penicillinase-resistant penicillin or vancomycin is also uncertain. Individuals with right-sided native valve endocarditis caused by MSSA (usually intravenous drug users) may be suitable for a shorter course of therapy (as little as 2 weeks) (Korzeniowski and Sande 1982; Chambers, Miller and Newman 1988; DiNubile 1994; Ribera *et al.* 1996).

Prosthetic Valve Endocarditis

Treatment requires a combined medical and surgical approach. Recommended antimicrobial therapy is 6 weeks of a penicillinase-resistant penicillin (or vancomycin if methicillin resistant) plus rifampicin and gentamicin for the first 2 weeks. Surgery is often required, and timely valve replacement surgery may be life saving. Mortality is high at 40% (Petti and Fowler 2003).

The decision to undertake valve replacement during the management of patients with both native and prosthetic valve *S. aureus* endocarditis should be taken on an individual patient basis. Clinical indications for surgery include uncontrolled infection, congestive cardiac failure, paravalvular abscess or haemodynamically significant valvular dysfunction (Petti and Fowler 2003). The American Heart Association Committee on infective endocarditis has identified echocardiographic features associated with a potential need for surgery (Bayer *et al.* 1998).

Other Invasive Disease

Infection of other deep sites often requires 4–6 weeks or more of treatment, depending on the nature and extent of infection, and treatment should be guided by experienced medical staff. Microbiologists in many hospitals in the United Kingdom provide bedside consultations and advice, while some hospitals have a more extensive consult service of microbiologists and virologists and general and infectious disease physicians.

There is a lack of consensus about the management of *S. aureus* meningitis (Norgaard *et al.* 2003). The rare community-acquired cases may be treated with high-dose β -lactamase-resistant penicillin assuming that the isolate is methicillin susceptible (Roos and Scheld 1997). Empiric treatment for community-acquired meningitis before culture results often includes the use of ceftriazone, which is a suitable alternative for MSSA. Community-acquired meningitis caused by MRSA is most unusual given the current low rate of MRSA carriage in the community and usually occurs as a complication of neurosurgery, often in the presence of a ventricular shunt. Entry of vancomycin

into the CSF is poor in the absence of meningeal inflammation, and penetration in the presence of inflammation is not well documented in human infection. Vancomycin is used for this infection, but intrathecal instillation may be used in the presence of a shunt or drain, and a second antibiotic is usually added (Pintado *et al.* 2002). This highly specialized area is best managed by experienced medical staff.

Management of Other *S. aureus* Infections

Individuals with mild skin and soft-tissue sepsis are often treated in the community with oral antibiotics. Duration of treatment will depend on the extent of infection but is generally around 1 week. Soft-tissue sepsis such as cellulitis that is severe enough to warrant hospital admission should be treated with a period of parenteral therapy. As a broad generalization, patients in this category who do not have documented bacteraemia may be treated by parenteral therapy until the fever has come under control. Oral antibiotics are then continued until the infection has clinically resolved. There is currently no good test to determine the causative pathogen associated with cellulitis, but most are caused by either *S. aureus* or group A streptococci. Community-acquired *S. aureus* pneumonia is uncommon. Patients presenting to hospital may be extremely unwell and require treatment as for invasive disease. The approach to the treatment of community-acquired urinary tract infection is no different from that associated with other pathogens.

Treatment of patients with nosocomial infection will depend on the nature of the infection. Superficial wound infection is usually treated for about 1 week or until clinical features of infection resolve. Intravenous catheter-related bacteraemia is treated as for other bacteraemias, current recommendations being 2 weeks of therapy. Infected permanent prosthetic material such as vascular grafts may be salvaged by long courses of antibiotics, but this should ideally be undertaken by a unit with specialist experience. Infected joint prostheses may be left *in situ* or removed in a one- or two-stage procedure. Again, such complicated disease should be treated in a unit with an interest in bone and joint infection.

PREVENTION AND CONTROL

Prevention of *S. aureus* disease falls into three main categories:

1. hospital infection control measures to prevent nosocomial infection, including perioperative antibiotic prophylaxis;
2. eradication of *S. aureus* carriage;
3. vaccination strategies.

Hospital Infection Control and Antibiotic Prophylaxis

Hospital infection control measures may prevent a proportion of nosocomial infections. Handwashing plays a central role, reducing transmission of pathogens between individuals and from the hands of a given individual to vulnerable sites such as wounds and dialysis catheters. Perioperative antibiotic prophylaxis is also important in preventing surgical sepsis, together with good skin preparation before surgery and aseptic and surgical techniques. There is a wide range of other possible measures, implementation of which will be dictated by the global setting and healthcare infrastructure. Affluent nations can implement hospital infection control through an infection control team who devise policies, monitor hospital infections from a diagnostic microbiology laboratory or by active ward-based surveillance and implement outbreak procedures where necessary. An infection control manual containing policies detailing the approach to a wide range of issues from antibiotic use, to dealing with patients colonized or infected with MRSA, waste disposal and disinfection is usually produced. Medical staff are educated and actively encouraged to follow

guidelines that reduce infection rates in given settings. For example, high-quality care of intravenous devices includes training of staff on line insertion and after care, the use of protocols and good mechanisms for recording line insertion and removal and infective complications. Hospital infection control in resource-poor areas of the world, where even the cheapest of antibiotics are barely affordable, is low on the priority list. The extent to which nosocomial infection occurs in such settings is little studied.

Eradication of *S. aureus* Carriage

Rates of *S. aureus* infection are higher in carriers than in non-carriers in a range of clinical settings (Weinstein 1959; Yu *et al.* 1986; Luzar *et al.* 1990; Weinke *et al.* 1992). This is consistent with the finding that individuals are usually infected with their own carriage isolate (Yu *et al.* 1986; Luzar *et al.* 1990; Nguyen *et al.* 1999; von Eiff *et al.* 2001b). Temporary eradication of carriage has been reported to result in a reduction in nosocomial infection in several patient groups and has been the focus of much recent interest and research. Eradication of *S. aureus* carriage is usually achieved by the topical application of antibiotic to the anterior nose. The most common agent in use is mupirocin, which has also been applied to exit sites of prosthetic devices such as intravenous and peritoneal dialysis catheters. A potentially promising agent currently under trial is lysostaphin, a peptidoglycan hydrolase secreted by *Staphylococcus simulans* that cleaves the polyglycine interpeptide bridges of the *S. aureus* cell wall. This agent is undergoing evaluation in both treatment and carriage eradication trials. Lysostaphin has been shown to have efficacy in the treatment of experimental *S. aureus* keratitis (Dajcs *et al.* 2000) and endocarditis (Climo *et al.* 1998; Patron *et al.* 1999). A single application of 0.5% lysostaphin formulated in a petrolatum-based cream eradicates *S. aureus* nasal colonization in 93% of animals in a cotton rat model. A single dose of lysostaphin cream was more effective than a single dose of mupirocin ointment at eradicating *S. aureus* nasal colonization in this animal model (Kokai-Kun *et al.* 2003). Exposure of *S. aureus* to lysostaphin alone results in the emergence of lysostaphin-resistant mutants *in vitro* and *in vivo* (Climo, Ehlert and Archer 2001), but it is unclear whether this will prove to be a limiting factor in clinical practice. Publication of study data pertaining to human use is awaited.

Many studies have been conducted to examine the effect of temporary carriage eradication, most of which have been in the dialysis population. Eradication of carriage by topical application of mupirocin to the nose in a cohort of haemodialysis patients led to a reduction in the number of episodes of *S. aureus* infection per patient year (Boelaert *et al.* 1989, 1993; Holton *et al.* 1991; Kluytmans *et al.* 1996). Efficacy of nasal *S. aureus* carriage eradication has also been evaluated for patients received peritoneal dialysis, but the evidence for efficacy of nasal mupirocin in preventing morbidity in CAPD patients is not convincing. Topical application of mupirocin to the peritoneal dialysis catheter exit site has been shown to reduce exit-site infection and peritonitis (Bernardini *et al.* 1996; Thodis *et al.* 1998). However, routine application of mupirocin to the exit site of all patients is likely to result in the rapid emergence of drug resistance. A double-blind, placebo-controlled trial of patients undergoing surgery was conducted to assess the effect of mupirocin on rates of postoperative *S. aureus* infection. Mupirocin did not significantly reduce the rate of *S. aureus* surgical-site infections overall, but it did significantly decrease the rate of all nosocomial *S. aureus* infections among patients who were *S. aureus* carriers (Perl *et al.* 2002). An evidence-based review has been performed to examine the efficacy of intranasal mupirocin in the eradication of *S. aureus* nasal carriage and in the prophylaxis of infection. Sixteen randomized, controlled trials were appraised, of which seven assessed the reduction in the rate of infection and nine trials assessed eradication of colonization as a primary outcome measure. Mupirocin was highly effective at eradication of nasal carriage in the short term, although 2–14-day courses did not result in long-term

eradication. This did not convert into clinical benefit overall, although subgroup analyses and several small studies revealed lower rates of *S. aureus* infection among selected populations of patients with nasal carriage treated with mupirocin (Laupland and Conly 2003). The authors concluded that the available literature does not support routine use of topical intranasal mupirocin to prevent subsequent infections, but suggested that there are some patient groups who would benefit, particularly those with acute disease (cardiac surgery and head injury). Further studies are required to clarify this area. A Cochrane review has also been performed to examine the effects of topical and systemic antimicrobial agents on nasal and extranasal MRSA carriage, adverse events and incidence of subsequent MRSA infections. This study concluded that there is insufficient evidence to support the use of topical or systemic antimicrobial therapy for eradicating nasal or extranasal MRSA (Loeb *et al.* 2003).

Vaccination

A considerable body of experimental vaccine-related work has been published, although this has not yet translated into a licensed vaccine preparation. The most significant human anti-staphylococcal vaccine study published to date evaluated a single dose of a conjugate vaccine comprising *S. aureus* types 5 and 8 capsular polysaccharides conjugated to nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A. Evaluation by randomized trial of 1804 adult patients at 73 hemodialysis centres demonstrated partial immunity against *S. aureus* bacteremia for approximately 40 weeks, after which protection waned as antibody levels decreased (Shinefield *et al.* 2002).

Staphylococcal vaccine research may be divided into studies that target bacterial determinants whose genes are always or almost always present (such as capsule, fibronectin-binding protein and clumping factor A) and those that are variably present in populations of clinical isolates (including collagen-binding protein, enterotoxins and PBP2a, the altered PBP encoded by *mecA* and expressed by methicillin-resistant strains).

Staphylococcus aureus synthesizes poly-*N*-succinyl- β -1-6-glucosamine (PNSG) as a surface polysaccharide during human and animal infection, although few strains expressed PNSG *in vitro*. All *S. aureus* strains examined in one study carried genes for PNSG synthesis, and immunization protected mice against death from strains that produced little PNSG *in vitro* (McKenney *et al.* 1999). A considerable body of work has been undertaken to examine fibronectin-binding protein as a potential vaccine target, but a complicated story has emerged. The presence of antibodies to fibronectin-binding protein has been reported to lead to the following:

1. more rapid bacterial clearance from mouse peritoneum and liver after peritoneal inoculation (Rozalska and Wadstrom 1993);
2. a reduction in bacteria count on injured heart valve in an animal model of endocarditis (Schennings *et al.* 1993);
3. lowered bacterial count in rabbit blood and excised organs compared with controls following intravenous inoculation (Park *et al.* 1999).

FnBP vaccination also reduced disease severity in a mouse mastitis model (Mamo *et al.* 1994). However, blocking of the interaction between FnBPs and fibronectin appears to be limited to 50% inhibition *in vitro*. This may be because antibodies raised *in vivo* are predominantly to epitopes that are presented by the ligand–FnBP complexes (i.e. after binding has occurred). These have been termed ligand-induced binding sites. Mapping of immunodominant epitopes has been performed (Rozalska, Sakata and Wadstrom 1994; Sun *et al.* 1997), and current research directions include the generation of antibodies by using recombinant FnBP protein with preserved antigenic activity but reduced ligand-binding activity (Brennan *et al.* 1999; Huesca *et al.* 2000; Rennermalm *et al.* 2001). Vaccination against

ClfA has had mixed results. A DNA vaccine directed against ClfA (injection of plasmids expressing the fibrinogen-binding region A of ClfA) induced a strong and specific antibody response but did not protect mice against an intraperitoneal challenge of *S. aureus* (Brouillette *et al.* 2002). A second group reported that mice immunized with recombinant ClfA and challenged with *S. aureus* developed less severe arthritis than controls and that passive immunization of mice with rat and rabbit anti-ClfA antibodies protected against *S. aureus* arthritis and sepsis-induced death (Josefsson *et al.* 2001).

Passive transfer of collagen adhesin-specific antibodies or vaccination using a recombinant fragment of the *S. aureus* collagen adhesin has been shown to protect mice against sepsis-induced death following inoculation of the Cna-positive strain Phillips (Nilsson *et al.* 1998). Only around half of clinical isolates carry the gene encoding Cna, and therefore, clinical application of a vaccine to Cna is only realistic if this is just one of several targets. Vaccination of mice against PBP2a followed by sublethal dose of MRSA reduced the *S. aureus* counts in kidney compared with non-immunized controls (Ohwada *et al.* 1999; Senna *et al.* 2003). It is unclear whether there is cross-protection against the PBP2 of MRSA, or whether this would only be effective against MRSA, thereby limiting its usefulness.

Toxins have also been evaluated as target vaccine candidates. Immunization of mice with recombinant SEA devoid of superantigenic properties provided good protection against *S. aureus* sepsis (Nilsson *et al.* 1999), and vaccination against SEB provided protection from the effect of subsequent toxin challenge given intraperitoneally or mucosally (Stiles *et al.* 2001). However, many clinical isolates do not express SEA or SEB.

An alternative approach to the identification of *S. aureus* vaccine candidates has been reported, in which a comprehensive list of immunologically relevant proteins is identified. In brief, *S. aureus* proteins are displayed *in vitro* using an expression library and screened using antibodies in sera from patients. Many immunogenic antigens have been identified for further evaluation (Etz *et al.* 2002; Weichhart *et al.* 2003).

Coagulase-Negative Staphylococci

Roger G. Finch

Department of Microbiology and Infectious Diseases, The University of Nottingham and Nottingham City Hospital NHS Trust,
Clinical Sciences Building, Hucknall Road, Nottingham NG5 1PB, UK

INTRODUCTION

Coagulase-negative staphylococci (CONS) comprise an ever-expanding group of bacteria whose medical importance has emerged in the past three decades. They now count among the most frequent of nosocomial pathogens featuring prominently among blood culture isolates, often in association with intravascular devices, and as a cause of infection of more deep-seated prosthetic implants. Clinically, infection may be silent, overt and occasionally fulminant, and this reflects the diverse pathogenic profile of this group of organisms. CONS are also characterized by an unpredictable pattern of susceptibility to commonly used antibiotics. Multiple drug resistance is common and adds to the difficulties of treating these infections.

HISTORICAL ASPECTS

Staphylococcus aureus was first described by Rosenbech in 1884. Its pathogenic profile includes local invasion, systemic spread, toxin-mediated disease and increasing resistance to commonly used antibiotics. It was included among the group of pyogenic cocci, and hence, its former description, *S. pyogenes*. In contrast, CONS were considered for many years to be non-pathogenic commensal organisms of the skin. *Staphylococcus albus* was widely used to describe all CONS as distinct from the colonial appearance of the golden pigmented *S. aureus*. The first widely accepted pathogenic role of CONS was the association of *S. saprophyticus* (novobiocin-resistant CONS) with urinary tract infections (UTIs) in women (Pereira, 1962).

The widely held view that CONS were largely commensals and indeed contaminants of clinical specimens frustrated recognition of the pathogenic potential of this group of organisms for many years. However, by the 1980s CONS had clearly been identified with a wide variety of clinical problems such as bacteremia, endocarditis of both prosthetic and native heart valves, septic arthritis, peritonitis complicating continuous ambulatory peritoneal dialysis (CAPD), mediastinitis, pacemaker associated infections, cerebrospinal fluid (CSF) shunt device infections, prosthetic joint and other orthopaedic device infections, osteomyelitis, UTI and prostatitis (Kloos and Bennerman, 1994). While *S. saprophyticus* was clearly associated with the urinary tract, the predominant species among the remaining infections was *S. epidermidis*. However, many hospital diagnostic laboratories have used the species *S. epidermidis* description loosely to encompass all CONS, further frustrating recognition of the diverse microbial nature of CONS infections. This has changed in recent years largely as a result of increased awareness of the importance of CONS infections, together with the availability of commercial identification systems.

DESCRIPTION OF THE ORGANISM

Taxonomically, CONS, together with *S. aureus*, are members of the family Micrococcaceae. They are Gram-positive facultative anaerobes which appear in clusters, are non-motile, non-spore forming and catalase positive and in general do not produce the enzyme coagulase. A thin capsule may be detected in some strains.

CONS are divided into more than 30 species (Table 6.1) and more than a dozen subspecies, of which approximately half have been associated with humans (Kloos and Bennerman, 1994). The remainder are associated with domestic and other species of mammals. The relatedness of these species has been confirmed by guanine + cytosine ratios. DNA sequence homology of >50% has been used to group the species, although a number of species are too distantly related to fit into this arrangement.

Coagulase production is generally absent among CONS, although some strains of *S. intermedius* and *S. hyicus* are weak producers. Heat-stable thermonuclease is produced by *S. intermedius*, *S. hyicus*, *S. schleiferi* and some strains of *S. carnosus*, *S. epidermidis* and *S. simulans* and permits cleavage of nucleic acids.

Classification

CONS have been divided into various species based on a variety of characteristics including colonial morphology, coagulase and phosphatase production, acid formation from maltose, sucrose, D-mannitol, D-trehalose and D-xylose as well as susceptibility to novobiocin using

a 5- μ g disc (Pfaller and Herwald, 1988). More extensive biochemical testing is necessary to speciate less common strains such as *S. warneri*, *S. capitis*, *S. simulans* and *S. hominis*, although little call is made for this outside reference or research laboratories (Kloos, Schleifer and Götz, 1991). Table 6.2 summarizes the major differentiating biochemical features (Barrow and Feltham, 1993). *Staphylococcus intermedius* is coagulase positive as are many strains of *S. hyicus*.

PATHOGENICITY

Infection associated with implanted medical devices is currently the most important pathogenic consequence of CONS infection. This is recognized as a two-stage process initially of bacterial attachment, followed by cell division within an extracellular matrix to produce a biofilm. The process of bacterial attachment to cells and inanimate surfaces has been subject to much investigation (Tenney *et al.*, 1986). In the case of CONS, it is clear that the mechanism is complex, strain variable and affected by the nature of the solid surface and the environment in which attachment occurs (Figure 6.1).

Biomaterials are largely synthetic polymers but may occasionally be natural substances. Physicochemical factors affecting attachment include electrostatic forces and hydrophobicity. While more hydrophobic strains in general attach more readily to these surfaces, there is considerable variation which may be further affected by nutrient limitation, pH and variation in carbon dioxide tension (pCO₂) (Denyer *et al.*, 1990).

In addition to mechanisms surrounding device-associated infection, CONS are also known to express an increasing number of other virulence factors to varying degrees among the different species (Gemmel, 1986). These include hemolysins, phosphatases, thermonuclease, lipase, galactosidase, pyrrolidonyl arylamidase and various decarboxylases.

Attachment

The adherence of microorganisms to biomaterials varies in relation to the nature of the material and the surface characteristics of the microorganism. In addition to physicochemical properties, including hydrophobicity and polarity, the implanted medical device readily

becomes coated with host substances such as collagen, fibrinogen, fibronectin, vitronectin and laminin (von Eiff, Peters and Heilmann, 2002). Variation in binding affinities to these proteins can be demonstrated; *S. haemolyticus* binds more strongly than strains of *S. epidermidis* (Paulsson, Ljungh and Wadström, 1992). The binding of *S. epidermidis* to fibronectin may be linked to their ability to colonize damaged tissues (Wadström, 1989). In contrast, strains of *S. saprophyticus* associated with urine infections have a higher capacity to adhere to laminin. However, the importance of polymer conditioning with these various host proteins in promoting attachment still remains a source of controversy (Mack, 1999).

The search for a specific adhesin continues. A capsular immunodominant polysaccharide adhesin (PS/A) with a molecular weight of > 500 000 has been described (Tojo *et al.*, 1988; Mack *et al.*, 1994). Antibodies to PS/A have been shown to block adherence of *S. epidermidis* (strain RP-62A) to silastic catheter surfaces. The same adhesin has been demonstrated in other species such as *S. capitis* subsp. *ureolyticus*. Anti-adhesin antibodies have also been shown to enhance opsonophagocytosis by polymorphonuclear leukocytes. Another protein that may be associated with attachment is a 220-kDa surface antigen of *S. epidermidis*, which immunogold electron microscopy suggests could be fimbrial in nature (Timmerman *et al.*, 1991). In general adhesin-positive isolates have been shown *in vitro* to be more adherent to medical devices (Muller *et al.*, 1993). Autolysin-mediated attachment has also been described (Heilmann *et al.*, 1997). Cellular accumulation follows as a result of polysaccharide intercellular adhesin (PIA) (Heilmann *et al.*, 1996). Molecular and genetic studies have indicated that PIA, and possibly capsular PS/A, are encoded by the *ica* operon (Heilmann *et al.*, 1996; McKenney *et al.*, 1998).

The presence of *ica* gene appears to correlate with pathogenicity. Blood culture and device-associated isolates are significantly more likely to contain this gene compared with non-pathogenic controls (Ziebutr *et al.*, 1997; Fitzpatrick *et al.*, 2002). Such isolates are also more likely to possess the *mecA* gene (Frebourg *et al.*, 2000).

Slime

Staphylococci, including CONS, produce variable amounts of capsular material. External to this is extracellular slime material produced under certain circumstances of growth (Bayston and Rodgers, 1990), usually following attachment to a foreign surface.

Figure 6.1 Schematic model of the phases involved in *Staphylococcus epidermidis* biofilm formation and bacterial factors involved. Biofilm-associated (Bap) homologous protein (Bhp) whose homologous counterpart in *S. aureus* has been shown to be involved in *S. aureus* biofilm formation is labeled with a question mark. AAP=accumulation-associated protein; AtlE=autolysin; Fbe = fibrinogen-binding protein; PIA=polysaccharide intercellular adhesin; PS/A=polysaccharide/adhesin; SdrG = serine-aspartate-repeat-containing protein G; SSP-1/SSP-2 = staphylococcal surface proteins. Reproduced with permission of The Lancet Infectious Diseases.

Figure 6.2 Microcolony of coagulase-negative staphylococci growing within a biofilm on the internal surface of a central venous catheter. Reprinted with permission from Elsevier (The Lancet, 2002, Vol 2, pp 677–685).

The term glycocalyx encompasses both capsular and extracellular slime material within which the microorganisms grow to produce a biofilm. The importance of extracellular slime material and biofilm formation lies in the relationship of CONS to medical device-associated infections and colonization of the uroepithelium. Extracellular slime production appears to occur more readily with certain strains of CONS associated with foreign bodies and in particular indwelling medical devices (Figure 6.2). The function of slime has been much debated, but it is believed to act as an ion-exchange resin for nutritional purposes. Bacterial growth within a biofilm differs markedly from the planktonic state.

Chemical analysis of slime indicates that it is a glycoconjugate composed of glycerol phosphate, D-alanine, *N*-acetylglucosamine and usually glucose (Kotilainen *et al.*, 1990; Hussain, Hastings and White, 1991). It is now described as PIA. Production is strain variable and affected by circumstances of growth (Hussain *et al.*, 1992a). Class I and class II phenotypes have been described (Barker, Simpson and Christensen, 1990). The former demonstrate good slime production under aerobic conditions but not in anaerobic states, whereas class II produce little or no slime under either condition. Slime production has been measured qualitatively and quantitatively. The Congo Red agar test has been widely used for individual colony testing, while radiochemical analyses have also been described (Hussain *et al.*, 1992b). Slime production is now known to be under the genetic control of the *ica* gene cluster (Fey *et al.*, 1999).

Biofilm-associated CONS appear to be protected from a number of control mechanisms. Slime from CONS interferes with various components of phagocytosis (Johnson *et al.*, 1986). Leukocyte migration is inhibited, as is degranulation. Oxygen-dependent intracellular killing, as measured by chemiluminescence, is also impaired. In addition, complement and immunoglobulin G (IgG) opsonic phagocytosis and killing have also been shown to be inhibited (Noble, Grant and Hajen, 1990). It is thought that surface-exposed proteins may be important in this regard (Shiro *et al.*, 1994). Human T-cell lymphocyte proliferation is inhibited (Gray *et al.*, 1984). This may be a direct inhibitory effect or may be mediated by enhanced production of prostaglandin E2 (Stout *et al.*, 1992). In addition, slime production has been associated with increased production of interleukin I and tumor necrosis factor α (Beutler and Cerami, 1989; Dinarello, 1989) as have changes in Ig production as a result of impaired B-cell blastogenesis. While these phenomena are of interest, they do not clarify the exact molecular and genetic nature whereby slime production is inhibitory to host defenses.

Most reports have focused on *S. epidermidis* and have generally, but not universally, shown slime production to be linked with pathogenic potential in relation to device-associated infections. *Staphylococcus saprophyticus* can also produce slime; urea appears to be an essential

nutrient and is associated with biofilm production and the formation of urinary struvite and apatite stones (McLean *et al.*, 1985).

Iron-Scavenging Systems

Many bacteria have developed sophisticated iron-scavenging systems, as this element is essential to survival. Such systems have been well characterized for Gram-negative bacteria; however, their significance among Gram-positive pathogens is now emerging. *Staphylococcus epidermidis*-associated CAPD catheter-associated infections express two iron-regulated proteins in the cytoplasmic membrane when grown in used dialysate (Williams, Denyer and Finch, 1988). These have been shown to be antigenic and in a rat chamber model are immunodominant (Modun, Kendall and Williams, 1994). Furthermore, using lectin-binding studies human transferrin, but not transferrin from other species, has been shown to bind to a 42-kDa transferring receptor protein (Modun and Williams, 1999). This suggests that *S. epidermidis* has developed sophisticated iron-scavenging systems which include not only siderophores but also receptor and transporter systems to internalize this essential element (Cockayne *et al.*, 1998). Staphyloferrin A and B are siderophores which have been identified in *S. hyicus* and *S. epidermidis* (Lindsey, Riley and Mee, 1994).

EPIDEMIOLOGY

Normal Habitat

The distribution and concentration of CONS on the human skin and surface mucosae varies. The density of organisms ranges from 10^3 to 10^6 CFU/cm², with the lowest counts in the dry areas of the skin. They are particularly concentrated in the perineum, inguinal region, axillae and anterior nares. The distribution pattern is reflected in the relative frequency with which the various species are isolated from pathological specimens. For example, *S. capitis* subsp. *capitis* generally prefers the scalp and face. *Staphylococcus epidermidis* is the most widely distributed species on the skin and achieves the highest concentrations in moist skin areas. *Staphylococcus haemolyticus* and *S. hominis* are most numerous in the perineum, axillae and inguinal regions in association with apocrine glands. *Staphylococcus auricularis* is largely confined to the external auditory meatus. *Staphylococcus warneri* and *S. lugdunensis* are less frequent commensals than are other species, but when present they are widely distributed (Kloos and Bennerman, 1994).

The increasing importance of CONS as human pathogens has been recognized over the past 25 years. Prior to this, *S. epidermidis* was an uncommon pathogen, although *S. saprophyticus* was recognized as an occasional cause of community-acquired UTI in sexually active young women. However, community-acquired CONS infections are rare but may arise in patients who have been discharged from hospital following the insertion of prosthetic implants such as joints, heart valves and intracardiac patches. Infection by these organisms is generally a delayed expression of hospital-acquired infection. However, the recent growth in CAPD, earlier discharge of patients from hospital and interest in home intravenous drug therapy suggest that CONS infections will increase within the community.

Hospital

It is in the hospital setting that CONS infections have made their greatest impact. Many studies confirm the rising frequency of CONS infections (Sehaberg, Culver and Gaynes, 1991). This is demonstrated in surveys of nosocomial bacteremia; rates of 5–10% in the early 1980s increased to 25–30% in the 1990s for all nosocomial bacteremias (Bannerjee *et al.*, 1991). Currently CONS are now the leading cause of hospital-acquired bacteremia as demonstrated in the National

Nosocomial Infection Survey in the USA (Sehaberg, Culver and Gaynes, 1991). These surveys suggest infection rates of 5.2–38.6 cases per 10 000 admissions in one institution (Martin, Pfaller and Wenzel, 1989). This increase is greatest in patients within critical care areas such as the intensive care unit (ICU), hematology and oncology facilities, dialysis and other high-dependency units, although no service is entirely free of this problem. CONS bacteremia among neonatal ICUs has increased and is more common in the low birth weight infant of <1000 g (Freeman *et al.*, 1987). Nosocomial CONS bacteremia often prolongs hospitalization. Furthermore, there is an overall mortality of 30.5% and an attributable mortality of 13.6%, with a relative risk ratio for dying of 1.8 in comparison with controls (Martin, Pfaller and Wenzel, 1989).

One population of patients in whom CONS infections have figured prominently are those with malignant disease undergoing cytotoxic chemotherapy. Gram-positive infections are an increasing cause of neutropenic febrile episodes, among which CONS predominate (EORTC International Antimicrobial Therapy Cooperative Group, 1990). This not only reflects the use of intravascular devices such as Hickman catheters and dialysis lines (Quinn, Counts and Meyers, 1986) but also an absolute reduction in Gram-negative bacteremia as a result of improved chemoprophylactic regimens. More aggressive cytotoxic regimens also increase the risks of infection as a result of their effects on skin and mucous membranes.

While most nosocomial CONS infections are device associated, others have been clearly linked to infections at other sites such as skin and soft tissue, septic arthritis, mediastinitis, native valve endocarditis, ophthalmitis, pneumonia and meningitis (Kloos and Bennerman, 1994). In many situations CONS infection has been linked to surgical wound infection or mechanical ventilation. Although the possibility of contamination is high, it is important not to dismiss the isolation of CONS from a range of non-device-associated situations without assessing carefully the full aspects of a case.

Although most CONS infections arise from the host's normal flora, there is increasing evidence to suggest that some are the result of nosocomial spread. Studies have indicated transmission from staff to patients, while in other reports epidemic strains have been found circulating within high-dependency units such as a neonatal ICU (Huebner *et al.*, 1994). Part of the difficulty in defining the epidemiology of nosocomial CONS infections accurately has been the lack of good data concerning normal carriage rates of the various CONS species, and the factors that affect these. The increasing availability of various molecular typing systems has greatly improved this epidemiological data (Bingen, Denamur and Elion, 1994).

CLINICAL FEATURES

Infection with CONS rarely exhibits characteristic clinical symptoms or signs. Patients may have a fever which is usually low grade. Occasionally, infection may have more striking systemic features of the sepsis syndrome with multiorgan involvement. Other signs are those of infection at the affected site and are described below.

Intravascular Line Infections

CONS are the commonest cause of intravascular line infections (Goldman and Pier, 1993). Clinical evidence for sepsis includes inflammation, with or without a purulent discharge at the insertion site. Evidence of systemic infection and occasionally metastatic sepsis at other sites may be present. Endocarditis is always a concern with regard to infected, centrally placed vascular catheters.

Peripheral blood cultures are often collected simultaneously with cultures collected through the catheter and compared in an attempt to define a pathogenic role. As peripheral devices are more readily removed, they have been sampled in various ways.

Some recommend quantitative blood cultures in this situation, although this can only increase the risk of contamination. Semi-quantitative cultures of the distal (intravascular) section of peripheral venous catheters, cultured by rolling the cut off tip across an agar plate, have provided guidance in differentiating between contamination and true colonization; counts of >15 CFU have been used to indicate catheter-related sepsis (Maki, Weise and Sarafin, 1977). However, this approach is not usually of great practical value in the clinical management of such patients. Alternative approaches have included intraluminal brushings of the catheter *in situ* (Markus and Buday, 1989), semiquantitative cultures of the hub and skin (Cercenado *et al.*, 1990) and flushing of removed catheter systems, a section of which is then incubated in broth media; the ability to distinguish infection from contamination is poor and may therefore lead to confusion in the management of such patients.

Bacteremia and Endocarditis

CONS are now among the most frequent of blood culture isolates, especially in hospitalized patients. However, the risk of contamination with commensal CONS, either during collection or as a result of laboratory manipulations, cannot be entirely eliminated, despite the use of automated blood culture systems. As a result it is generally considered desirable to have evidence that a similar isolate be present in at least two sets of blood cultures collected from different sites at different times. In routine diagnostic laboratories, evidence of similarity is often restricted to colonial morphology, coagulase activity and antibiogram with or without biochemical testing.

The microbiological diagnosis of infective endocarditis affecting a prosthetic valve or implant, or indeed a native valve, presents a particular challenge. Here repeated isolation of a similar strain from samples collected from different venepuncture sites over a period of time and viewed in the context of the overall clinical picture provides the best evidence for active infection (Caputo *et al.*, 1987). Among CONS causing endocarditis, *S. epidermidis*, *S. capititis*, *S. warneri* and more recently *S. lugdunensis* predominate (Herchline and Ayers, 1991).

CSF Shunts/Valves

CSF-shunting systems include valves, ventriculoatrial and ventriculoperitoneal systems used in the management of hydrocephalus. Ventriculoperitoneal shunts are currently preferred. Unfortunately these are subject to microbial contamination, often at the time of insertion or subsequent manipulations, and they cause considerable difficulties with regard to early diagnosis and management. Those inserted in the first few months of life are at greatest risk of infection with rates of 10–20%, of which CONS accounts for approximately three-quarters of the infecting organisms (Bayston, 1994). Shunt infections may be internal when they affect the lumen of the shunt or less commonly external when the surgical insertion site and surrounding tissues become infected. Ventriculitis is common and requires examination of CSF for its diagnosis. Aspiration of CSF from the valve chamber of the shunt must be carried out carefully to avoid introducing infection; adequate skin disinfection is essential. Ventriculoperitoneal shunts may be associated with low-grade peritonitis. Bacteremia is a rare complication of ventriculoarterial shunt infection.

Dialysis Infections

CONS are the most common cause of dialysis-associated infections and together with *S. aureus* comprise the leading bacteria responsible for infection of either short-term or chronic dialysis catheter devices (Cheesbrough, Finch and Burden, 1986). The temporary use of double-lumen catheters for hemodialysis is often complicated by infection, usually with microorganisms of skin origin including CONS. These

infections may be clinically evident but are often covert and are only recognized once the catheter is removed and cultured. Microbial attachment, colonization and biofilm production are common and are particularly associated with CONS (Baddour *et al.*, 1986). The diagnosis is usually made clinically and supported by positive blood cultures which may be collected from a peripheral vein as well as through the device.

Arteriovenous fistulae created for hemodialysis are prone to infection during needle insertion. Staphylococci are the leading pathogens; *S. aureus* predominates but CONS may also occur. The risks from both these dialysis catheter-associated infections are recurrence and metastatic spread of infection. Diagnosis is largely based on clinical evidence of sepsis and positive blood cultures. Local evidence of inflammation with exudate formation may be present. Removal of dialysis catheters provides an opportunity to culture the endovascular and subcutaneous portions through techniques such as catheter rolling and flushing (Maki, Weise and Sarafin, 1977). Examination by scanning electron microscopy to visualize microcolony formation has been described within the research environment.

CONS are the most frequent cause of peritonitis in patients managed by CAPD (Working Party of the BSAC, 1987). The microbiological diagnosis is partly hampered by the low colony counts present in spent dialysate, which may be as few as <1 CFU/ml. Furthermore, the risk of contaminating samples at the time of collection or during processing, often with skin microorganisms, presents an added problem. The diagnosis is therefore based on clinical and microbiological evidence of peritonitis. The latter should include evidence of a minimum of 100 white blood cells per microliter. The cellular effluent is made up of polymorphonuclear cells and peritoneal macrophages (Verbrugh *et al.*, 1983). Direct Gram staining of spun dialysate yields a positive result in only about 15% of instances and thus lacks sensitivity. Because of the low bacterial counts, techniques aimed at improving the yield have been adopted. Centrifuged deposits and Millipore-filtered samples are used in some diagnostic laboratories. However, broth enrichment culture is now widely adopted as the simplest diagnostic approach, often using conventional blood culture systems (Working Party of the BSAC, 1987). Isolation, identification and antibiotic susceptibility should follow. Recurrent infections are not uncommon and reflect either persistence of the original infection, usually from continued colonization of the implanted Tenkhoff catheter, or reinfection with a different microorganism. An interval of 6 weeks between two episodes of infection is often used to distinguish recurrence from reinfection. However, this is an arbitrary separation which does not always stand up to close microbiological scrutiny. Hence it is important to retain isolates in case more detailed microbiological analysis becomes necessary.

Urine

Midstream specimens of urine (MSU) are generally adequate for the diagnosis of UTI. CONS count for approximately 10% of UTIs in young women. *Staphylococcus saprophyticus* and *S. epidermidis* are the most frequent CONS isolates (Latham, Running and Stamm, 1983). The risk of contamination of the sample can present difficulties when interpreting culture findings, particularly in the absence of pyuria. Standard quantitative microbiological techniques are satisfactory in indicating levels of significance. Counts of 10^5 CFU/ml are considered significant, but in patients with dysuria and frequency counts as low as 10^3 CFU/ml can also be found. CONS grows satisfactorily on standard laboratory media used in the diagnosis of UTI such as cysteine lactose electrolyte-deficient and MacConkey agar. Colonial morphology, coagulase negativity and resistance to a 5- μ g novobiocin disk is generally satisfactory for the routine identification of *S. saprophyticus*. Isolation in pure culture is usual, although repeat mixed cultures may occur. It is rarely necessary to resort to suprapubic aspiration of urine.

Soft Tissue and Deep Wound Samples

In the case of soft tissue and wound infections, aspirated material for culture on solid media is preferred. Surface swabs will almost certainly be contaminated by normal flora. Gram stain of infected material is valuable as a means of initial assessment and as an aid to interpretation of subsequent culture findings. In the case of infected medical implants such as joint prostheses, arthrocentesis and, when appropriate, surgical exploration, allow sampling of synovial fluid, the surrounding soft tissue as well as the bone cement interface. This permits a full range of cultures including tissue homogenates to be set up. When infected prosthetic valves are removed, vegetations and infected valve rings should be processed carefully to avoid laboratory contamination. Culturing tissue homogenates may improve the yield. Likewise, an infected joint prosthesis should also be subject to microbiological sampling and culture in order to provide the best information for eradicating deep-seated infection.

LABORATORY DIAGNOSIS

Specimens

CONS may be isolated from a wide range of laboratory specimens submitted for bacteriological analysis. However, difficulties in defining their pathogenic role are common. Repeated isolation from a normally sterile body site presents few problems when ascribing aetiology. However, the fact that CONS are ubiquitous members of the normal flora of the skin and surface mucosae inevitably leads to concerns with regard to contamination of samples collected from these sites or from regions contiguous or deep to such areas. Furthermore, the association of CONS with deeply situated medical device implants presents difficulties with sampling, processing and interpretation of cultures, should these become infected. In many clinical situations the risks associated with the removal of implanted medical devices, such as prosthetic hip joints and heart valves or CSF-shunting systems, present a major clinical dilemma in which the risks of removal must be carefully weighed against the failure to control the infectious process. Various procedures have been developed, aimed at increasing the sensitivity and specificity of laboratory diagnosis.

Media

CONS can be isolated using a variety of laboratory media such as blood agar, nutrient agar, tryptic soya agar, brain heart infusion agar and their broth equivalents. Colonies vary in diameter from 1 to 3 mm following overnight incubation in air. Morphological variation provides some assistance in identification and to some extent speciation. Colonies of CONS tend to be smaller than those of *S. aureus*, usually lack pigment and were formerly called *S. albus* because of their white appearance. *Staphylococcus lugdunensis* often appears creamy or yellow in colour. Occasional strains are sticky, reflecting slime production. In general the colonies are entire, complex and smooth. Colonial variation occurs; for example, those of *S. haemolyticus* are usually larger than *S. epidermidis*.

Speciation

Another laboratory dilemma includes the desirability of speciating CONS isolates accurately for diagnostic and epidemiological purposes. The lack of widely available, sensitive, reliable and economical typing systems creates difficulties in recognizing outbreaks of CONS infections.

A number of commercial miniaturized rapid identification systems have been produced. The API-STAPH and Vitek systems among others are increasingly widely used and have permitted ready speciation

by routine diagnostic laboratories of many commonly isolated species. These diagnostic kits, in conjunction with novobiocin susceptibility testing, provide speciation accuracy of 70–90% (Kloos and Bennerman, 1994). Occasional difficulties arise in speciating *S. warneri* and *S. haemolyticus*. Other systems are based on fatty acid analysis, high-resolution gas chromatography and ribotyping. However, for routine diagnostic purposes, such systems are generally unnecessary and relatively expensive, especially those which are combined with automated reading systems. Speciation still has limitations in establishing the epidemiology of clusters of CONS infections. However, they are useful in defining the nature of repeat isolates from blood, implanted medical devices and other sites when distinguishing contaminant from pathogen.

Finally the increasing problem of multi-drug resistance among CONS has implications for the range of susceptibility tests that should be provided. In turn, the necessity for therapeutic drug monitoring of vancomycin adds an additional complexity to management.

Antibiotic Susceptibility

The growing importance of CONS as a cause of human infection has been matched by an increasing problem of drug resistance. Multiply antibiotic-resistant strains of CONS are now commonly recognized either as colonizers or as pathogens. Evidence for cross-infection between patients and staff is accumulating and CONS, as part of the normal human flora, provide a reservoir in which antibiotic resistance can be spread to other CONS and other potentially pathogenic bacteria.

The majority of CONS are able to elaborate an inducible β -lactamase and hence are resistant to penicillin, while the production of a low-affinity penicillin-binding protein, PB2a, is responsible for resistance to methicillin and related anti-staphylococcal drugs (Chambers, 1987). The *mecA* gene is common to all staphylococci exhibiting methicillin resistance and is expressed heterotypically among a variable minority of isolates within a bacterial population. Recognition is sometimes difficult to detect, as the more resistant subpopulation is in the minority and grows more slowly. Detection is improved by using a higher inoculum and incubation at lower temperatures (30 °C); 2% NaCl and prolonged incubation also improve detection, although *mecA* gene probe is probably the most sensitive method (Archer and Pennell, 1990); however, detection does not necessarily correlate with gene expression. More than 80% of hospital-acquired CONS are methicillin resistant (Schulin and Voss, 2001), and of these, more than half will be resistant to other agents such as gentamicin, trimethoprim, erythromycin and clindamycin (Diekema *et al.*, 2001). Tetracycline, chloramphenicol and quinolone resistance is more variable. Methicillin resistant CONS should be considered to be multi-resistant unless there is *in vitro* evidence to the contrary (Archer and Climo, 1994).

Gentamicin resistance among CONS is usually enzymatic as a result of either acetylation [AAC (6')] or phosphorylation (APH 2') (Thomas and Archer, 1989). Such resistance may be plasmid or chromosomally mediated and is common to most aminoglycosides. This is of particular concern when treating infections such as infective endocarditis for which a β -lactam-aminoglycoside regimen is widely used.

Quinolone resistance was recognized shortly after the introduction of agents such as ciprofloxacin and ofloxacin (Kotilainen, Nikoskelainen and Huovinen, 1990). The widespread use of these agents within hospital populations led to a rapid decline in the susceptibility of CONS as a result of DNA gyrase (*gyrA*) mutation (Piddock, 1994). More recently, alterations to the *norA* gene have been linked to increased efflux of quinolones and other antibiotics (Piddock, 1994). Resistance rates vary throughout the world but are of the order of 7–22%. Cross-resistance to other quinolones is common and includes the more recently developed agents active against Gram-positive cocci.

Tetracycline resistance has declined owing to less frequent use in hospitals. Resistance rates of about 25–35% (Archer and Scott, 1991) occur and are related to either reflux or ribosomal resistance; while the

tet (K) gene is responsible for plasmid-mediated resistance (Bismuth *et al.*, 1990), the *tet M* gene is chromosomally carried and is responsible for resistance in minocycline, tetracycline and doxycycline, although minocycline often retains activity against other tetracycline-resistant strains.

Macrolide resistance is often linked to clindamycin and streptogramin resistance, as they share a similar target on the 50S ribosomal subunit, which is important in translocation and transpeptidation. The majority of methicillin-resistant CONS and even some methicillin-sensitive strains will be resistant to erythromycin and related compounds (Archer and Climo, 1994). Dissociated resistance between erythromycin and clindamycin is the result of differential induction of the *erm* gene (Jenssen *et al.*, 1987), although mutational resistance can occur during treatment with clindamycin. New macrolides – clarithromycin and azithromycin – appear to offer no advantage with regard to CONS, as *in vitro* activity is comparable and cross-resistance occurs (Hamilton-Miller, 1992).

Rifampicin is increasingly used to treat deep-seated CONS infection in combination with other antibiotics. CONS are usually highly sensitive, but rifampicin-resistant mutants occur spontaneously at a rate of approximately 1 in 10⁶ as a result of genetic mutation in coding for the subunit of DNA-dependent RNA polymerase. It is therefore important that use of this agent be limited and should be based on *in vitro* evidence of susceptibility.

Vancomycin is currently the glycopeptide of choice for the treatment of most serious CONS infections. To date, most CONS remain susceptible to 4 mg/l of vancomycin or less, although occasional strains of *S. haemolyticus* are resistant (Srinivasan, Dick and Perl, 2002). Vancomycin resistance among *S. epidermidis* isolates is even more uncommon, but concerns have been heightened following the detection of vancomycin-resistant *S. aureus*.

Teicoplanin is being increasingly used as an alternative to vancomycin in the treatment of a wide range of staphylococcal infections. However, CONS of reduced susceptibility (minimal inhibitory concentration >8 mg/l) among *S. epidermidis* and *S. haemolyticus* are now recognized (Bannerman, Wadiak and Kloos, 1991). Resistance to *S. haemolyticus* can be readily reduced *in vitro* and among *S. epidermidis* by stepwise exposure (Biavasco *et al.*, 1991). However, such strains are currently uncommon. Quinupristin-dalfopristin (von Eiff *et al.*, 2000) and linezolid (Henwood *et al.*, 2000) are two new agents licensed for the treatment of Gram-positive infections including those caused by susceptible CONS. Experience to date remains limited but is encouraging in the case of linezolid. However, despite *in vitro* susceptibility of many isolates, there is little evidence to suggest that the antibiotic treatment of medical device-associated infections has been improved. While *in vitro* susceptibility to various antibiotics can be demonstrated, biofilm-embedded microorganisms are less susceptible to the effects of antibiotic. Originally it was felt that the biofilm prevented drug penetration, but this is now known to be incorrect. Diffusion is often rapid, and concentrations are high in the case of vancomycin and rifampicin (Schulin and Voss, 2001). *In vitro* biofilm models of infection have shed some light on the activity of established drugs (Widmer *et al.*, 1990) and new agents such as quinupristin-dalfopristin (Gander and Finch, 2000) and linezolid (Gander *et al.*, 2002).

MANAGEMENT OF INFECTION

The clinical presentations of CONS infection vary widely according to the circumstances in which they express disease. In patients with deep-seated infections, such as those complicating a prosthetic hip implant, clinical features are usually localized to the joint with progressive pain, and eventually instability; constitutional symptoms are often absent. This contrasts with the patient in an ICU with multiple endovascular lines, in whom fever and persistent bacteremia should rapidly raise the suspicion of line-associated sepsis. Peritonitis

complicating CAPD is usually accompanied by a cloudy effluent dialysate and may precede clinical symptoms of peritonitis.

The diagnosis and management of CONS-associated infections presents major challenges. There is often difficulty in establishing a microbiological diagnosis, particularly in situations associated with deep-seated infection. Removal of an infected prosthetic device presents specific and individual problems; an implanted heart valve is less easily dealt with than an endovascular catheter which may be readily removed. The diagnostic problems are compounded by the occasional difficulties in confidently ascribing pathogenicity to organisms which are the most common laboratory or sampling contaminant. Furthermore, antibiotic choice is restricted owing to the frequency of multi-drug resistance. Finally, there may be uncertainty with regard to duration of therapy and the likelihood of success if prescribed in the continued presence of an infected medical device.

Urinary Tract Infection

Staphylococcus saprophyticus, and less commonly *S. epidermidis* and other species of CONS, account for about 10% of cases of UTI. *Staphylococcus saprophyticus* has a seasonal pattern peaking during the summer months (Hovelius and Mårdh, 1984). Although most commonly associated with acute cystitis in young women, the upper urinary tract or prostate may occasionally be involved. Acute cystitis can usually be treated with an appropriate antibiotic, although susceptibility guidance is desirable. Trimethoprim, nitrofurantoin or a quinolone such as norfloxacin are all appropriate choices, provided the organism is sensitive. Short-course therapy is now widely practised using a 3-day regimen with arrangements for checking MSU 6 weeks after treatment or earlier should symptoms fail to resolve.

Intravascular Line Infection

The range and complexity of intravascular lines in current medical use are reflected in the diverse nature of the infectious complications. One of the most widely used devices is the intravenous cannula of the Venflon variety. These may or may not have an integral injection port. Most are sited in peripheral veins for short-term vascular access. The complications include phlebitis and infection which are often inter-related and vary with the type of plastic, the length of the device and the site of insertion (Cheesbrough and Finch, 1985). Infection rates average 0.6 per 1000 device days (Safdar, Kluger and Maki, 2001). Evidence of infection at the exit site is usually managed by device removal with spontaneous resolution. Occasionally, cellulitis or septic phlebitis may occur, with the necessity for antibiotic therapy. Most respond to an anti-staphylococcal penicillin, such as flucloxacillin, although occasionally metastatic infection may arise with positive blood cultures. Antibiotic selection should then be governed by sensitivity testing but will usually include either a penicillase-stable penicillin or a glycopeptide such as vancomycin or teicoplanin.

Central venous catheters are used for a variety of purposes including pressure monitoring, infusion of fluids, blood or drugs and parenteral nutrition. Infectious complications are much more frequent, usually because of the multiple uses these systems are put to. Hickman, Broviac, Swan-Ganz and hemodialysis catheters are particularly subject to infectious complications from skin microorganisms (Cheesbrough, Finch and Burden, 1986; Goldman and Pier, 1993). Staphylococci including CONS predominate (Mermel *et al.*, 1991). There should be a low threshold for suspecting such an infection in any patient running a fever with a central line in place. Blood cultures should be obtained, and the exit site inspected and sampled (Linares *et al.*, 1985). It is occasionally helpful to draw blood cultures through the catheter (Moyer, Edwards and Farley, 1983).

The principles of treatment are the same as for peripheral devices (Bouza, Burillo and Muñoz, 2002). However, these devices are often essential to patient management, particularly to those patients in a

high-dependency unit, so that a trial of antibiotic therapy is often conducted before a decision to remove the device is made; ideally the catheter should be removed and resited. This approach is unwise where there is clinical evidence of local or disseminated sepsis. Antibiotic choice should again be guided by laboratory susceptibility testing. In the case of CONS infections, greatest reliance is now placed on vancomycin (Mermel *et al.*, 2001), with teicoplanin as an alternative choice (Graninger *et al.*, 2002). Another approach has been to combine systemic with locally administered antibiotic using relatively high concentrations of drug which is locked into the lumen of the catheter for several hours (Capdevila, 1998). Where drug intolerance or glycopeptide resistance is a problem, alternative agents include linezolid and rifampicin (in combination with another agent) according to *in vitro* susceptibility testing. This strategy will occasionally prove successful, but as stated, line removal is often necessary to eradicate infection. There is the risk of developing metastatic infection or endovascular infection such as right-sided endocarditis when the catheter tip is sited within the heart.

Infective Endocarditis

Staphylococci are the most frequent cause of prosthetic valve endocarditis (PVE) and, less commonly, the cause of native valve endocarditis (Caputo *et al.*, 1987; Tornos *et al.*, 1997). Although predominantly arising within 2 months following valve insertion, it has become increasingly apparent that endocarditis beyond this period may also be staphylococcal in nature. CONS figure prominently in both situations (Karchmer, 2000). The key clinical features of endocarditis include low-grade fever, a murmur and systemic embolization. There should be a low threshold for suspecting infective endocarditis in patients with prosthetic heart valves, intracardiac patches or ventricular support systems. The diagnosis is normally confirmed microbiologically by evidence of persistent bacteremia on blood culture.

The management of PVE includes prolonged high-dose intravenous bactericidal antibiotic and careful monitoring of clinical response supported by investigations such as echocardiography. Failure to control bacteremia, a changing murmur, conduction abnormalities suggesting a septal abscess, progressive heart failure and major embolic phenomena are all indications for urgent valve replacement.

The antibiotic regimen should be guided by laboratory information on the nature and susceptibility of the infecting organism. In the case of CONS endocarditis an anti-staphylococcal penicillin such as flucloxacillin in combination with gentamicin, with or without the addition of rifampicin, is commonly prescribed for a period of 6 weeks (Wilson *et al.*, 1995). In those allergic to penicillin an appropriate cephalosporin or vancomycin is widely used, again in association with gentamicin. Teicoplanin provides an alternative to vancomycin (Galletto *et al.*, 1986), although failures have been reported (Gilbert, Wood and Kimbrough, 1991). The latter will require careful monitoring of blood levels to avoid drug toxicity, especially to the kidney. Treatment of PVE requires a minimum of 6 weeks of therapy with careful follow-up to detect relapse. PVE complicates approximately 2–3% of procedures. Prevention requires careful surgical technique with practices similar to those adopted for prosthetic joint insertion (q.v.). Perioperative antibiotic prophylaxis regimens vary, but a broad-spectrum cephalosporin such as cefuroxime is generally suitable. If surgery is prolonged, a second dose may need to be administered. Where there are concerns about possible MRSA infection complicating surgery, some centers are including a glycopeptide (Maki *et al.*, 1992).

CAPD Peritonitis

Peritonitis is the commonest complication of CAPD. The infecting organisms often arise from the skin of the patient and gain access to the Tenkhoff catheter during bag changes. Less commonly the catheter exit site becomes infected. There is considerable individual variation

in the frequency of such infections. Patients need to be educated in the practice of sterile technique and observed to ensure good practices, as repeated episodes of peritonitis can alter the efficiency of the peritoneal surface as a dialysis membrane.

The principles of management have evolved over the past decade or so. Systemic antibiotics are less able to achieve sufficiently high therapeutic concentrations within the infected peritoneal cavity than those administered directly with the dialysate. The latter is the preferred route of administration, although in patients with systemic features of sepsis one or two doses of antibiotic are given intravenously at the start of therapy (Report of BSAC, 1987; Vas, 1994).

The choice of agent should be guided by microbiological information (Keane *et al.*, 2000). However, the initial empirical regimen takes account of the importance of skin staphylococci and in particular CONS. Vancomycin plus gentamicin is the most widely adopted combination, although caution may be necessary in those patients with some residual renal function (Shemin *et al.*, 1999). Alternatives have included cefuroxime, quinolones, other cephalosporins and carbapenems. While the drug has frequently been given into each dialysate bag, it is now recognized that alternate bag therapy, or even the overnight dwell bag, may be adequate for the control of such infections (Ad Hoc Advisory Committee, 1993; Keane *et al.*, 2000). However, before varying the regimen it is important to monitor response to treatment clinically by observing the clearing of the dialysate bag. Microbiological information may permit subsequent simplification of the regimen to a single drug. Treatment is usually continued for a period of 7–10 days when managing CONS infections, but longer periods for infections caused by yeasts or Gram-negatives such as *Pseudomonas aeruginosa* will be required (Report of BSAC, 1987).

Patients should be monitored to detect early relapse. Should this occur within a 6-week period, then careful consideration should be given to whether the Tenckhoff catheter is heavily colonized with bacteria within a biofilm. This makes eradication of infection extremely difficult, and catheter change is often necessary for its clearance. Traditionally this required a period of hemodialysis following peritoneal catheter removal and the subsequent insertion of a new Tenckhoff device. However, removal and insertion of a new catheter as a single procedure has proved successful under cover of appropriate antibiotic therapy and has the advantage of avoiding unnecessary hemodialysis and a further surgical procedure to insert a new catheter as a delayed procedure (Ad Hoc Advisory Committee, 1993).

CSF-Shunt Infections

The management of CSF shunt infections is a specialized problem requiring close collaboration between experienced neurosurgical and microbiological services and an individualized decision as to whether this should be managed surgically or non-surgically (Bayston, 2001). Surgical treatment requires shunt removal and reshunting, with or without a period of external ventricular CSF drainage. An alternative approach includes shunt removal and regular ventricular taps in selected patients. However, both approaches run the risk of either ventriculitis from retrograde spread of organisms through the external ventricular drainage system or from direct puncture, which of itself may result in pencephalic cysts (Mayhall *et al.*, 1984). Another approach has been to remove the infected shunt and replace it immediately with a fresh system. However, this can be technically difficult and the risk of infecting the new shunt, despite appropriate antibiotic cover, may occur.

The antibiotic management of CSF-shunt infections depends upon the causative microorganisms, their known susceptibility to antibiotics and the ability to deliver the antibiotic in sufficient concentrations to the site of the infection (Bayston *et al.*, 1995). Furthermore, the ability of many microorganisms to form microcolonies and exist within a biofilm presents further difficulties with regard to eradicating these infections.

Various antibiotics have been used, such as flucloxacillin, cephalosporins such as cefuroxime, fusidic acid and erythromycin and to a lesser extent clindamycin. The modest inflammatory response in the CSF produced by infections such as CONS presents further difficulties in achieving adequate concentrations of β -lactam agents within the CSF. Furthermore, these drugs are only active against dividing cells, and within an infected CSF shunt, cells are often dividing extremely slowly. Greatest reliance is therefore currently placed on the use of vancomycin, with or without rifampicin (Bayston, 2001). It is important that the infecting organism be identified carefully, and in the case of CONS the laboratory evidence should suggest a true infection rather than the presence of a contaminating organism.

Intraventricular administration of antibiotics is usually essential to achieve sufficient bactericidal concentrations to sterilize an infected shunt and the ventricular CSF (Wen *et al.*, 1992). In the case of ventriculoperitoneal shunts, infection is also present within the peritoneal cavity (although often clinically inapparent) and systemic antibiotics should also be given.

Vancomycin has achieved greater importance in the management of multiple antibiotic-resistant staphylococcal shunt infection. A daily dose of 20 mg of vancomycin administered intraventricularly has proved effective and safe (Bayston, Hart and Barniecoat, 1987; Bayston, 2001). CSF concentrations of between 200 and 300 mg/l are achieved. Systemic antibiotic is also given, and oral rifampicin is preferred when dealing with staphylococcal infections. The response to treatment is measured clinically and by repeated CSF examinations. CONS infections generally disappear within 4–5 days. CSF levels of antibiotic should be measured preferably to ensure adequate bactericidal concentrations. A decision whether to attempt medical eradication of infection or to reshunt requires assessment of all factors relevant to the case.

Prosthetic Joint Infections

Many thousands of total hip arthroplasties and total knee procedures are performed annually. The majority give rise to a few complications. However, the development of a wound infection, and more seriously infection of the prosthesis, can result in failure of the prosthetic implant (Fitzgerald *et al.*, 1977; Norden, 1994). Infection rates for total hip replacements vary between 0.6 and 2%. The rate for total knee arthroplasties is approximately twofold higher. Underlying problems such as diabetes mellitus, rheumatoid arthritis, advanced age and infection remote from the operation site are all recognized risk factors of infection which may arise by direct implantation through the open wound, or as a result of hematogenous spread, or less commonly as a result of the reactivation of latent infection in a previously infected operative site (Berbari *et al.*, 1998). Infections are reduced in frequency by the use of prophylactic antibiotics in the perioperative period and by high-efficiency particulate air (HEPA) exhaust ventilation systems in the operating theatre suite (Lidwell *et al.*, 1982; Salvati *et al.*, 1982). The use of exhausted suits for the operating team are in additional refinement but have not been widely adopted.

The diagnosis of joint infection can be difficult and may be delayed, as local symptoms often occur late (Inman *et al.*, 1984). Loosening of the prosthesis is a late sign. Systemic signs of infection are often lacking in the early stages. Monitoring the erythrocyte sedimentation rate (ESR) can be valuable. The role of isotope scans for diagnosis remains controversial (Owen *et al.*, 1995). Early acute infections are more likely to be caused by *S. aureus* and associated with poor wound healing and local evidence of infection. Infections delayed beyond a 3-month period are more usually associated with low-grade pathogens such as CONS and other skin bacteria such as *Propionibacterium* spp. Infection should be suspected if there is persistent joint pain and a raised ESR.

The management of prosthetic joint infections needs to be individualized and is a balance between medical and surgical treatment.

Prolonged antibiotic therapy for periods ranging from 1 to 12 months according to response is widely practised. Alternatively, this is often given following removal of the infected prosthesis and wound debridement. The choice of agent should be guided by microbiological data but should be directed at Gram-positive cocci including CONS in the absence of any laboratory information. Drugs such as flucloxacillin, co-amoxiclav or a cephalosporin are commonly used. These may be given parenterally for the first few weeks until there is clinical evidence of response including a falling ESR. Surgical drainage of any infected material should be part of the early management, while early resection of an obviously infected arthroplasty should not be delayed. A replacement implant should only be considered once all evidence of local infection has disappeared.

Prevention of prosthetic joint infections requires careful consideration of the operative environment, which should include a satisfactory ventilation system, preferably with a HEPA filtration arrangement (Lidwell *et al.*, 1984). Meticulous preparation of the operative site and observance of all aspects of sterile technique are essential. Double glove techniques and operator isolator systems have their devotees. Patients should be free of infection at other sites and in particular the skin.

The use of antibiotic prophylaxis is now well established and in general when given as a short perioperative course is effective in encouraging a sterile operative site. The combined benefits of clean air within the operating room and short-course perioperative antibiotic prophylaxis have been associated with the lowest complication rates of <1%. Among the agents selected, flucloxacillin and the cephalosporins have proved the most popular (Hill *et al.*, 1981; Norden, 1991). Cefuroxime, cephadrine and cefazolin possess anti-staphylococcal activity, which is a primary consideration, although the increasing frequency of antibiotic resistance has led to alternative choices such as co-amoxiclav (Nelson, 1987). Other techniques such as joint irrigation and antibiotic-impregnated bone cement have been used by some but have not been universally adopted (Espeshaug *et al.*, 1997).

Section Two

Gram-Positive Bacilli

Corynebacterium spp.

Aruni De Zoysa and Androulla Efstratiou

Health Protection Agency, Centre for Infections, Department of Respiratory and Systemic Infections, London, UK

INTRODUCTION

Diphtheria is one of the most important diseases of bacterial aetiology. The causative organism is toxin-producing *Corynebacterium diphtheriae*, which infects the tissues of the pharynx (Lehmann and Neumann, 1896). Diphtheria is an ancient disease that probably existed even in the times of Hippocrates (Andrews *et al.*, 1923; Harries, Mitman and Taylor, 1951; Lloyd, 1978; English, 1985). The first modern clinical descriptions were made by Joost van Lom (Lommius) in 1560 and Baillou (Ballonius) in 1576 (Andrews *et al.*, 1923). They referred to the disease as 'quinsy' and 'croup', respectively. The first epidemic of the disease was described in Spain, where it was called 'morbus suffocans' or 'garrotillo' as suffocation brought by the disease resembled garrotting, the Spanish method of executing criminals (Rosen, 1954). The disease occurred in distinct waves: 1583–1618, 1630, 1645 and 1666. From Spain the disease spread to Italy in 1618, where it was known as 'male in canna' or 'gullet disease'. It first broke out in Naples and then spread to southern Italy including Sicily. Towards the end of the seventeenth century the disease died down; however, as the eighteenth century evolved, diphtheria again became prevalent in Europe and broke out in Britain and America. The first major epidemic of the eighteenth century occurred between 1735 and 1740 in New England, where it was commonly known as 'throat distemper' (Douglass, 1736; Andrews *et al.*, 1923; Rosen, 1954). In 1735, New Hampshire lost a thousand citizens (5% of the total population) to the disease and in New England there were about 5000 deaths (2.5% of the population) (English, 1985).

Diphtheria was first recognised as a distinct clinical entity by the French pathologist and clinician Pierre Bretonneau in 1826 (Semple, 1859; Rosen, 1954). Bretonneau coined the term diphthérite to cover a contagious condition, characterised by the presence of a false membrane in the pharynx or larynx. The word diphthérite is derived from the Greek word *diphthera* (δίφθερα), meaning leather or hide. Following Bretonneau's treatise, there was much speculation about the cause of the disease. In 1883, Edwin Klebs reported that two types of microorganisms existed in the diphtheritic membrane, chain-producing cocci and bacilli, and Klebs was unable to find the bacilli in the blood or organs of individuals who had died from the disease. He reported that they were confined to the membrane (Andrews *et al.*, 1923; Dolman, 1973). In 1884, Friedrich Loeffler proved that it was the bacillus and not the cocci, which were described previously by Klebs, that caused diphtheria (Loeffler *et al.*, 1908; Andrews *et al.*, 1923). He developed a new stain (methylene blue) and a new culture medium (blood agar) and used this to demonstrate the presence of the organism in post-mortem material from cases of diphtheria. He demonstrated that cultures of the organism were highly pathogenic in

laboratory animals by showing that it killed guinea pigs and small birds. Loeffler showed that the organism retained its virulence after repeated passage from guinea pig to guinea pig. He found that the organism was confined to the membrane and that it did not invade the body (confirmed Klebs findings). He postulated that the bacillus released a toxin capable of causing tissue damage away from the respiratory mucosa (Loeffler *et al.*, 1908). In 1888, Roux and Yersin, working at the Pasteur Institute, proved him correct by demonstrating that, when a sterile filtrate derived from broth cultures of the bacillus was injected into animals it caused all the symptoms, which would be produced if a live culture were injected. In 1890, von Behring and Kitasato produced serum antibodies in animals against the toxin and demonstrated that the serum could protect susceptible animals against the disease (von Behring and Kitasato, 1890). In 1901, von Behring won the Nobel Prize in medicine for his work on the development of antitoxin.

The first use of toxin-antitoxin mixtures to immunise children against diphtheria was reported by von Behring in 1913. Also in 1913, Bela Schick introduced an intradermal test, which was able to detect the presence or absence of circulating antitoxin (MacGregor, 2000). In 1923, Glenny and Hopkins showed that formalin treatment of diphtheria toxin (DT) abolished its toxicity but left its antigenicity intact. They coined the term toxoid for the non-toxic, antigenic material. It was useful as an immunising agent in animals in combination with antitoxin (Glenny and Hopkins, 1923). Around the same time, a stable, non-toxic diphtheria toxoid, which could be used for immunising humans, was finally produced by Ramon by the action of formalin on crude toxin, followed by incubation at 37 °C for several weeks (Relyveld, 1995). The initial clinical trials were extremely successful as it reduced the fatalities among those immunised to nearly zero (English, 1985). The observation by Glenny and others that the immunogenicity of the toxoid could be improved by precipitation with aluminium compounds led to a new generation of toxoids (Dixon, Noble and Smith, 1990). At first, alum-precipitated toxoid was used, but this has now been replaced by preparations in which purified toxoid is precipitated onto aluminium phosphate (Dixon, Noble and Smith, 1990).

DESCRIPTION OF THE ORGANISM

Genus *Corynebacterium*

The genus *Corynebacterium* was first proposed by Lehmann and Neumann in 1896 (Skerman, McGowan and Sneath, 1980) to include the diphtheria bacillus and other morphologically similar organisms.

The genus name is derived from the Greek words *koryne*, meaning club, and *bacterion*, little rod (Schwartz and Wharton, 1997). The genus *Corynebacterium* is presently composed of 46 species (and two taxon groups), 31 of which are medically relevant (Funke and Bernard, 1999). *Corynebacterium* species are commonly found in soil and water and reside on the skin and mucous membranes of humans and animals. *Corynebacterium diphtheriae* is the major human pathogen in this genus. Other potentially toxigenic corynebacterial species include *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*.

The cell wall of corynebacteria contains meso-diaminopimelic acid and short-chain mycolic acids with 22–36 carbon atoms (Collins, Goodfellow and Minnikin, 1982; Collins and Cummins, 1986). The *Corynebacterium* species *Corynebacterium amycolatum* and *Corynebacterium kroppenstedtii* are the only species that do not possess mycolic acids in the cell wall (Collins, Burton and Jones, 1988; Collins *et al.*, 1998). Palmitic (C_{16:0}), oleic (C_{18:1ω9c}) and stearic (C_{18:0}) acids are the main cellular fatty acids in all corynebacteria. The G+C content of *Corynebacterium* spp. varies from 46 mol% in *Corynebacterium kutscheri* to 74 mol% in *Corynebacterium auris* (Funke *et al.*, 1997). Other microscopic characteristic features of the genus *Corynebacterium* include morphology, showing straight-to-slightly-curved rods with tapered ends and sometimes club-shaped forms; snapping division producing angular and palisade arrangements (Chinese lettering); Gram-positive staining (some cells stain unevenly); formation of metachromatic granules (which is visualised with Loeffler's methylene blue stain or Albert's stain); non-motile, non-capsulate and non-sporing; facultatively anaerobic growth (some are aerobic); and catalase production (Collins and Cummins, 1986). In 1995 Pascual *et al.* and Ruimy *et al.* outlined the phylogenetic relationships within the genus *Corynebacterium*, creating an extensive database for 16S rRNA gene sequences for the delineation of new species (Pascual *et al.*, 1995; Ruimy *et al.*, 1995).

Corynebacterium diphtheriae

Corynebacterium diphtheriae is the causative agent of diphtheria. Humans are its only host, and there is no known environmental reservoir of infection (MacGregor, 2000). *Corynebacterium diphtheriae*, when lysogenised by certain bacteriophages, produces DT. Colonies of *C. diphtheriae* grown on Hoyle's tellurite medium appear black or grey because of the reduced tellurite. However, other bacteria (e.g. streptococci and staphylococci) also grow as black colonies. When grown on a medium described by Tinsdale (1947) and modified by Moore and Parsons (1958), *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis* produce a well-delineated brown halo around the greyish-black colonies (only rarely may streptococci, staphylococci and some other bacteria show this phenomenon). A brown halo results when H₂S is produced by the action of cysteinase on L-cystine and potassium tellurite is reduced to metallic tellurium. Halo formation also depends on the organism acidifying the medium. Another feature that sets *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis* apart from most other corynebacteria that might be isolated from humans is their inability to hydrolyse pyrazinamidase.

There are four biotypes of *C. diphtheriae*: var. *gravis*, var. *mitis*, var. *belfanti* and var. *intermedius* (Anderson *et al.*, 1933; Chang, Laughren and Chalvardjian, 1978; Funke *et al.*, 1997), differentiated on the basis of cultural and biochemical differences (including colony morphology) (Krech, 1994). In practice, *C. diphtheriae* var. *intermedius* is the only biotype that is distinguished easily on the basis of colony morphology. *Corynebacterium diphtheriae* strains of the biotype *intermedius* are lipophilic and require lipids (e.g. hydrolysis on Tween 80 medium) for optimal growth. On routine medium, *intermedius* strains produce tiny (0.5–1 mm in diameter), grey, discrete, translucent colonies (Ward, 1948; Efstratiou and Maple, 1994; Clarridge, Popovic and Inzana, 1998). Strains of biotype *gravis* and *mitis* are

non-lipophilic, and they produce larger (1.5–2 mm in diameter), denser, grey, opaque colonies that are indistinguishable. A weak β-haemolysis is observed with *mitis* strains and a few *gravis* strains. Differences in the Gram stain morphology for each biotype have been described by Noble and Dixon in 1990: strains of the *mitis* biotype are usually long, pleomorphic, but rigid club-shaped rods; biotype *gravis* are usually short, coccoid or pyriform rods; and *intermedius* strains are highly pleomorphic, ranging from very long to very short rods (Noble and Dixon, 1990).

Strains of *C. diphtheriae* biotype *intermedius* are distinguished from biotype *mitis* strains because the former is dextrin positive. Biotypes *mitis* and *gravis* are distinguished by their glycogen and starch reactions (*gravis* strains are positive for both). *Corynebacterium diphtheriae* biotype *belfanti* is nitrate negative; otherwise, they resemble *mitis* strains. The *intermedius* biotype seems to be the least common biotype.

PATHOGENESIS

Diphtheria Toxin and its Mode of Action

The major virulence determinant of *C. diphtheriae* is diphtheria toxin (DT), the cause of the systemic complications seen with diphtheria. The DT gene is carried by a family of closely related bacteriophages (corynebacteriophages) that integrate into the bacterial chromosome and convert non-toxigenic, non-virulent *C. diphtheriae* strains into toxigenic, highly virulent species (Freeman, 1951; Uchida, Gill and Pappenheimer, 1971). Therefore, DT is only secreted by strains of *C. diphtheriae* lysogenically infected with a temperate bacteriophage (Freeman, 1951). Several different types of lysogenic corynebepages have been recognised (β *tox*⁺, γ *tox*⁺ and ω *tox*⁺), with the β-corynebepage being the most common. Some of these phages are also capable of lysogenising *C. ulcerans* and *C. pseudotuberculosis*.

DT is a protein molecule with a molecular weight (*M_r*) of 58 350 Da (Pappenheimer, 1977; Collier, 1982). The toxin is synthesised as a single polypeptide chain consisting of 535 amino acid residues. It contains four cysteine (C) residues and has two internal disulphide bonds that link C186 to C201 (links fragment A to B) and C461 to C471 (contained within fragment B). Treatment of DT with trypsin selectively cleaves the peptide bond at arginine (R) residue R190, R192 or R193, which are positioned in the protease-sensitive loop, to generate an amino-terminal fragment A (21 150 Da) and a carboxyl-terminal fragment B (37 200 Da) which remain covalently linked by the disulphide bond between C186 and C201 (Drazin, Kandel and Collier, 1971; Gill and Pappenheimer, 1971), and reduction of this disulphide bridge separates the toxin into fragments A and B. Studies performed on the three-dimensional structure of the molecule (Choe *et al.*, 1992; Bennett and Eisenberg, 1994) have shown that the toxin may be divided into three separate domains:

1. the amino-terminal C (catalytic) domain, responsible for ADP-ribosylation of elongation factor 2 (EF-2) which blocks protein synthesis;
2. the centrally located transmembrane or translocation (T) domain [composed of nine α-helices (TH1–TH9)], responsible for insertion into membranes at acidic pH, formation of channels and translocation of the C-domain across endosomal membranes for delivery to the cytosols;
3. the carboxyl-terminal R-domain, responsible for binding of DT to the heparin-binding epidermal growth factor (HB-EGF) precursor that functions as the DT receptor on susceptible cells (Morris *et al.*, 1985; Naglich *et al.*, 1992; Naglich, Rolf and Eidels, 1992).

The HB-EGF receptor is a protein on the surface of many types of cells. The occurrence and distribution of the HB-EGF receptor on cells determine the susceptibility of an animal species, and certain

cells of an animal species, to the DT. More receptors are found on the heart and nerve cells than other cell types; hence, in severe forms of the disease, cardiac failure and neurological damage occurs (Efstratiou *et al.*, 1998).

The intoxication of a single eukaryotic cell by DT involves at least four steps. First, the toxin binds to a specific receptor (HB-EGF receptor) on susceptible cells and enters the cell by receptor-mediated endocytosis (Morris *et al.*, 1985; Naglich *et al.*, 1992). The pH within the endosome becomes more acidic and triggers the partial unfolding of the protein, which exposes the hydrophobic regions of the B fragment (helices 8 and 9, the innermost layer of the transmembrane domain), and the translocation domain of DT inserts into the endosomal membrane and forms a channel through which translocation of the A fragment (C-domain) occurs [the A fragment is cleaved from the B fragment (transmembrane and receptor-binding domains), and it translocates into the cytoplasm] (Kagan, Finkelstein and Colombini, 1981; Hu and Holmes, 1984; Moskaug, Sandvig and Olsnes, 1988; Papini *et al.*, 1993). Fragment A is a NAD⁺-binding enzyme that catalyses the transfer of the ADP-ribosyl group to a post-translationally modified histidine residue termed diphthamide, present in the cytoplasmic EF-2 of eukaryotic cells (Brown and Bodley, 1979; Van Ness, Howard and Bodley, 1980). The resulting EF-2-ADP-ribose complexes are inactive and therefore cause inhibition of protein synthesis and, ultimately, cell death. In the absence of fragment B, the A fragment is non-toxic, as it cannot cross the plasma membrane to reach the cytoplasm. It has been demonstrated *in vitro* that a single molecule of fragment A in the cytoplasm is enough to kill one eukaryotic cell (Yamaizumi *et al.*, 1978). The minimal lethal dose for humans and sensitive animals (monkeys, rabbits and guinea pigs) is below 0.1 µg/kg of body weight (Pappenheimer, 1984).

Regulation of DT Production

Production of DT by toxigenic strains of *C. diphtheriae* is affected greatly by the composition of the growth medium (Mueller, 1940, 1941; Mueller and Miller, 1941). Studies carried out during the 1930s showed that optimal yields of DT are obtained when *C. diphtheriae* is grown under conditions of iron limitation and that DT production is inhibited severely when grown under high iron conditions (Pappenheimer and Johnson, 1936).

Studies on the regulation of DT production began in the 1970s. In 1974, Murphy and colleagues reported that the DNA from *tox*⁺ β-coryneophage directed the synthesis of DT and other phage-encoded proteins and that addition of *C. diphtheriae* extracts to this system inhibited the synthesis of DT, but not the production of other phage-encoded proteins (Murphy *et al.*, 1974). This led to the hypothesis that *C. diphtheriae* contained a factor that acted as a negative controlling element in the regulation of toxin production. Fourel *et al.* in 1989 provided evidence for the presence of a chromosome-encoded DT repressor (Fourel, Phalipon and Kaczorek, 1989). These investigators observed that proteins in crude extracts from *C. diphtheriae* grown under high iron conditions were able to bind specifically to the *tox* operator and protect it from DNase I digestion. As protection of the *tox* operator required the presence of iron in the reaction, it was assumed that the binding factor was the DT repressor. In 1992, Krafft *et al.* demonstrated that an iron-dependent repressor, which inhibits the transcription of the *tox* gene of the β-coryneophage under high iron growth conditions, was encoded by the *C. diphtheriae* genome (Holmes, 1975; Murphy, Skiver and McBride, 1976; Murphy, Bacha and Holmes, 1979; Krafft *et al.*, 1992).

The gene for the DT repressor (*dtxR*) was cloned by Boyd *et al.* in 1990 and Schmitt and Holmes in 1991. DNA sequence analysis indicated that the *dtxR* gene encodes a *M_r* 25 316 polypeptide consisting of 226 amino acids (Boyd, Oza and Murphy, 1990; Schmitt and Holmes, 1991a,b). Each DtxR monomer has three domains. Domain 1 (residues 1–73) is located at the amino terminal and contains

a helix-turn-helix motif, which is required for binding DNA. Domain 2 (residues 74–144) is responsible for dimerisation and possesses two metal-binding sites (site 1, the ancillary site is composed of ligands H79, E83, H98, E170 and Q173, and site 2, the primary site consists of M10, C102, E105 and H106 and the main chain carbonyl oxygen of C102). Domain 3 (residues 145–226) is located at the carboxyl terminal. It exhibits an SH3-like fold and has greater flexibility than domains 1 and 2 (Qiu *et al.*, 1995). Domain 3 is not resolved in most crystal structures of DtxR, and its function is unknown.

EPIDEMIOLOGY

Overview of Diphtheria since 1940

In the prevaccine era, diphtheria was a much feared childhood disease found in temperate climates. Widespread implementation of childhood immunisation in the 1940s and 1950s led to a marked decrease in the incidence of diphtheria in Western Europe, the United States and Canada (Galazka, Robertson and Oblapenko, 1995). However, since 1989, there has been a major resurgence of the disease in Europe, mainly within countries of the former Soviet Union. The diphtheria epidemic in the Newly Independent States (NIS) of the former USSR began in the Russian Federation in 1990 and affected all 15 NIS countries by the end of 1994. In Russia, the highest incidences were seen in Moscow and Saint Petersburg, where the outbreak first began. (Hardy, Dittman and Sutter, 1996; Efstratiou, Engler and De Zoysa, 1998). In 1990, 1431 diphtheria cases were reported in the NIS (1211 of these cases were from the Russian Federation). The number of cases reported increased to 5729 by 1992 and to 19 453 by 1993. In 1994, 47 324 cases were reported, and it reached a peak of 49 994 in 1995 (WHO, 2002).

In 1995, aggressive diphtheria control strategies were implemented (i.e. mass immunisation of the whole population), and as a result, the number of cases decreased by 60% in 1996 to 20 078. The decreasing trend continued in 1997 (7149 cases were reported in the NIS), and in 1998, 2610 cases were reported in the NIS. There has been excellent progress in the control of diphtheria in Armenia, Azerbaijan, Estonia, Kazakhstan, Lithuania, Moldova and Uzbekistan. Diphtheria control has improved in Belarus, Georgia, Kyrgyzstan, Russian Federation, Tajikistan, Turkmenistan and Ukraine. However, continued efforts and close monitoring are still required. Diphtheria still remains a major concern in Latvia, as there has been an increase in the number of reported cases from 42 in 1997 to 81 in 1999 and to 264 cases in 2000. The total number of cases reported to the World Health Organization (WHO) from the NIS in 2000 was 1573 (WHO, 2002). This outbreak has been the largest diphtheria outbreak in the developed world in recent years. Since the epidemic began, more than 170 000 cases and 4000 deaths have been reported to the WHO Regional Office for Europe (Roure, 1998). Also, importations from the NIS to other European countries such as Finland, Estonia, Germany, Norway, Poland, Bulgaria, Belgium, Greece and the United Kingdom have been reported. Over 20 imported cases of diphtheria in adults have been reported in the above countries (De Zoysa *et al.*, 1993; Efstratiou, 1995; Rey, Patey and Vincent-Ballereau, 1996; Dittman, 1997; Claridge, Popovic and Inzana, 1998; Wharton *et al.*, 1998).

Figure 7.1 illustrates the diphtheria global annual reported incidence and DTP3 coverage between 1980 and 2001. The decline in reported diphtheria cases in the 1980s is consistent with the reported increasing DTP3 coverage. The sudden increase in incidence during the 1990s is due to the massive epidemic that occurred in the former Soviet Union. During the 1990s, outbreaks were also reported in Algeria, Iraq, Laos, Mongolia, Sudan and Thailand. Figure 7.1 shows only those cases reported to the WHO, and therefore, these figures probably underestimate the true incidence of the disease, as for many countries figures are unavailable.

Figure 7.1 Diphtheria global annual reported incidence and DTP3 coverage, 1980–2001.

Molecular Epidemiology

Limitations of the phenotypic methods led to the development of molecular typing schemes for *C. diphtheriae*. In 1983, Pappenheimer and Murphy demonstrated the resolving power of molecular methods when they analysed *C. diphtheriae* isolates using DNA restriction fragment length polymorphism (RFLP) with different DNA probes for different areas of the toxin gene (Pappenheimer and Murphy, 1983). In 1987, Rappuoli *et al.* used an insertion element of *C. diphtheriae* as a DNA probe to characterise Swedish strains from a diphtheria outbreak in an alcoholic and drug-abusing population (Rappuoli, Perugini and Ratti, 1987), and in 1989, Coyle *et al.* studied the molecular epidemiology of the three biotypes of *C. diphtheriae* in the Seattle outbreak by analysing RFLPs with three DNA probes (Coyle *et al.*, 1989).

Since then, several new molecular subtyping methods have been developed and successfully applied to epidemiological investigations of diphtheria (De Zoysa *et al.*, 1995; De Zoysa and Efstratiou, 1999, 2000). Currently, ribotyping is the gold standard for typing *C. diphtheriae*, and molecular subtyping of *C. diphtheriae* by using ribotyping has identified significant genetic diversity within the species and has led to the identification of a unique clonal group that emerged in Russia in 1990 at the beginning of the Eastern European epidemic (De Zoysa *et al.*, 1995; Popovic *et al.*, 2000).

As a result of extensive collaborative typing studies amongst the European Laboratory Working Group on Diphtheria (ELWGD), a database of ribotype patterns has been set up at the Institut Pasteur, Paris, France, using the software Taxotron® (Grimont *et al.*, 2004). This database allows international exchange and dissemination of typing data, specifically on the origin of outbreak strains and their relationship to endemic and epidemic strains worldwide (Efstratiou *et al.*, 2000).

The Diphtheria European and Global Network

The ELWGD was formed at the initiative of the WHO European Office in July 1993 as a result of the epidemic situation in Eastern Europe. The main objectives of the ELWGD were, firstly, to establish a network of collaborating laboratories to monitor the microbiological surveillance of diphtheria, secondly, to standardise methodologies for laboratory diagnosis in epidemic areas and, thirdly, to standardise the

typing techniques, leading to the establishment of a microbiological surveillance system for all isolates of *C. diphtheriae* in the European Region and beyond.

In 1994, an international microbiological surveillance for all *C. diphtheriae* isolates from sporadic cases within the European Region was initiated with collaboration from the members of the ELWGD. Typing results obtained essentially by the laboratory in the United Kingdom facilitated the establishment of a standard technique (ribotyping) for typing *C. diphtheriae*, and the ribotyping results obtained were used for the establishment of a database of ribotype patterns.

The ELWGD plays a major role in the strengthening of laboratory diagnostics. The group provides advice to WHO and other agencies on laboratory diagnosis and molecular epidemiology of *C. diphtheriae*. In response to the diphtheria epidemics, a WHO manual on laboratory diagnosis of diphtheria has been produced, which complements the WHO manual on control and case management (Efstratiou *et al.*, 2000). The Diphtheria Surveillance Network (DIPNET) established in 2001 (Kelly and Efstratiou, 2003) is the definitive expansion of the ELWGD and encompasses key epidemiologists and microbiologists from most of the European Union (EU) member states, associated countries and beyond. The integration of ELWGD and DIPNET has established rapid communication between the laboratory network, public health specialists and WHO, which should lead to a standardised surveillance system for diphtheria and related infectious diseases in Europe.

CLINICAL MANIFESTATIONS

Diphtheria is usually classified according to the site of manifestation (i.e. tonsillar, pharyngeal, nasal and non-respiratory). Humans are the only natural host for *C. diphtheriae*, and the organism spreads by airborne upper respiratory tract droplets or direct contact with respiratory secretions of symptomatic individuals or exudate from infected skin. Dust and clothing also contribute to transmission as the organism may survive up to 6 months in dust and fomites. The incubation period is 2–5 days, occasionally longer. Infection is usually associated with low-grade fever, and systemic complaints early in the infection are minimal. Symptoms depend on the location and duration of the infection before treatment. Concentration of bacteria increases over time, resulting in the release of increasing amounts of DT. Therefore, early recognition and treatment are critical to reduce complications

associated with toxin dissemination. Classically, diphtheria affects the respiratory tract, although diphtheritic infections of several other sites (skin, eyes, ears, vagina and endocardium) have been described (MacGregor, 2000).

Faucial Diphtheria

Faucial diphtheria is the most common clinical presentation and involves infection of the posterior structures of the mouth, tonsils and proximal pharynx. Symptoms may be mild in vaccinated patients, whereas unvaccinated patients tend to have more severe disease. The onset is usually abrupt, with low-grade fever (rarely $>39^{\circ}\text{C}$), malaise, sore throat, mild pharyngeal injection and the development of a membrane typically on one or both tonsils (Plate 4). The membrane gradually thickens and extends over the tonsillar pillars, uvula, soft palate, oropharynx and nasopharynx. Initially, the membrane is white and smooth but later becomes grey with patches of green and black necrosis. The extent of the membrane correlates with the severity of symptoms: localised tonsillar disease is often mild, but involvement of the posterior pharynx, soft palate and periglottic areas is associated with profound malaise, weakness, prostration, cervical adenopathy and swelling. Gross swelling of the cervical lymph nodes gives rise to a bullneck appearance, causing respiratory stridor (Dobie and Tobey, 1979; MacGregor, 2000; Demirci, 2001; Singh and Saba, 2001).

Anterior Nasal Diphtheria

Infection of the anterior nares results in mucoid or serosanguineous nasal discharge accompanied by few constitutional symptoms. Shallow ulceration of the external nares and upper lip are characteristic. This form of diphtheria is most common in infants (MacGregor, 2000; Demirci, 2001; Singh and Saba, 2001).

Laryngeal and Tracheobronchial Diphtheria

Laryngeal diphtheria occurs as a result of membrane extension. Symptoms include hoarseness, dyspnoea, respiratory stridor and a brassy cough. Rapid diagnosis, intubation or tracheostomy is required to relieve airway obstruction; otherwise, or the patient may rapidly die of asphyxiation. The disease may progress, if enough toxin enters the blood stream, causing severe prostration, striking pallor, rapid pulse, stupor and coma. These effects may result in death within a week of onset of symptoms (Claridge, Popovic and Inzana, 1998).

Systemic Complications of Diphtheria

Systemic complications occur because of DT. The absorbed toxin causes delayed damage at distant sites. Although the toxin is toxic to all tissues, it has its most striking effects on the heart (myocarditis) and the cranial nerves. These complications may occur from 1 to 12 weeks after disease onset.

Cardiac Toxicity

Evidence of myocarditis is found in up to two-thirds of patients with respiratory diphtheria (Boyer and Weinstein, 1948). Clinically significant cardiac dysfunction is observed in 10–20 of patients (Morgan, 1963; Ledbetter, Cannon and Costa, 1964). Cardiac toxicity correlates directly with the extent and severity of local disease and generally occurs within 1–2 weeks after the onset of the illness. The DT damages the Purkinje system, and the toxin also causes necrosis of cardiac muscle cells, which results in acute congestive heart failure and circulatory collapse (MacGregor, 2000).

Neurologic Toxicity

Neurologic toxicity is also proportional to the severity of the primary infection. Mild disease only occasionally produces neurotoxicity, but up to 75% of patients with severe disease develop neuropathy. Symptoms develop 10–28 days after the onset of respiratory disease. Two types of neuropathies are seen. The first, cranial nerve involvement, is usually limited to the ninth and tenth nerves, resulting in aspiration, difficulty in swallowing, nasal regurgitation and loss of the gag reflex (Dobie and Tobey, 1979). Less often, oculomotor and facial nerves become impaired. This type of neuropathy tends to occur later in the course of illness and resembles Guillain–Barré syndrome. Patients have quadriplegia associated with hyporeflexia. Microscopic examination of affected nerves shows degeneration of myelin sheaths and axon cylinders. After treatment of the infection, slow but complete neurologic recovery follows (MacGregor, 2000). The frequency of complications such as myocarditis and neuritis was directly related to the time between the onset of symptoms and administration of anti-toxin and to the extent of membrane formation.

Cutaneous Diphtheria

Corynebacterium diphtheriae causes clinical skin infections characterised by chronic non-healing ulcers with a dirty grey membrane particularly in the tropics (Livingood, Perry and Forrester, 1946; Höfler, 1991). Primary infection of the skin with *C. diphtheriae* does occur; however, more commonly, the organism superinfects pre-existing skin lesions (Liebow *et al.*, 1946), including underlying dermatoses, lacerations, burns, insect bites and impetigo. Primary cutaneous diphtheria begins as a tender pustule and enlarges to an oval punched-out ulcer with a membrane and oedematous rolled borders (Liebow *et al.*, 1946; Höfler, 1991) (Plate 5). Group A streptococci and *Staphylococcus aureus* are often isolated concurrently. It has also been reported that toxigenic strains of *C. ulcerans* have been associated with mimicking classical cutaneous diphtheria (Wagner *et al.*, 2001). Skin infections may vary in severity, but toxin-induced complications are usually uncommon. Cutaneous infections induce high levels of antitoxin antibody and, therefore, appear to act as natural immunising events (Gunatillake and Taylor, 1968; Bray *et al.*, 1972; Hewlett, 1985). They also serve as a reservoir for the organism under conditions of both endemic and epidemic respiratory tract diphtheria. Cutaneous infections have been shown to contaminate the environment and to induce throat infections more efficiently than pharyngeal colonisation. Also, bacterial shedding from cutaneous infections continues longer than from the respiratory tract (Belsey *et al.*, 1969; Koopman and Campbell, 1975; Belsey and LeBlanc, 1975).

Other Sites of Infection

The organism may uncommonly infect other sites such as the eye, genitalia and the ear. The eye may be infected through the nasolacrimal duct from the nose or directly by droplets during the performance of tracheotomy (Harries, Mitman and Taylor, 1951). Patients may develop conjunctival diphtheria as the only manifestation of diphtheria. An acute catarrhal condition of the eye may occur; a filmy exudate or a membrane may also develop inside the lower palpebral conjunctiva and rapidly spread over the eye (Hogan, 1947), which may result in the necrosis of the conjunctiva and severe damage to the cornea. Diphtheritic infections of the vulva and vagina have also been reported (Eigen, 1932; Wallfield and Litvak, 1933; Grant, 1934).

Infections Caused by Non-toxigenic *C. diphtheriae*

Non-toxigenic *C. diphtheriae* has been known to cause significant local disease and, since 1922, some times systemic infection even in

the absence of toxin production (Jordan, Smith and Neave Kingsbury, 1922). There have been reports of classical diphtheria associated with non-toxicogenic *C. diphtheriae* (Edward and Allison, 1951; Rakhmanova *et al.*, 1997). However, these reports are doubtful, as patients carry toxigenic and non-toxicogenic strains at the same time (Simmons *et al.*, 1980). Therefore, it is likely that a toxigenic strain was present, but not identified from patient samples. There have also been several reports of endocarditis due to non-toxicogenic *C. diphtheriae* (see below). Two cases who accidentally ingested non-toxicogenic *C. diphtheriae* var. *mitis* in a laboratory developed sore throat with tonsillar membrane (Barksdale, Garmise and Horibata, 1960). A non-toxicogenic strain of *C. diphtheriae* var. *gravis* was also documented as the causative organism in an outbreak of infection in a boy's residential school in 1975. The organism was isolated from 7 of 19 boys and from 24 asymptomatic carriers (Jephcott *et al.*, 1975).

Non-toxicogenic isolates are often isolated from cases of pharyngitis. Wilson *et al.* in 1992 reported a cluster of cases of pharyngitis in homosexual men attending a genitourinary medicine clinic (GUM) in London. However, their role here is uncertain, as the pharyngitis may have been caused by a concurrent viral or streptococcal infection (578 homosexual men were screened for pharyngeal isolates, *C. diphtheriae* was isolated from 6 patients and streptococci were isolated from 55 patients). Four reports (Jephcott *et al.*, 1975; Wilson *et al.*, 1990, 1992; Sloss and Faithfull-Davies, 1993) that examined the occurrence of non-toxicogenic *C. diphtheriae* in throat swabs showed that it was not possible to state whether non-toxicogenic *C. diphtheriae* was the cause of pharyngitis or whether it was a mere coloniser, especially in the absence of a control group. A study carried out on 238 throat isolates (Reacher *et al.*, 2000) showed that non-toxicogenic *C. diphtheriae* was reported as the predominant organism in 72% of the cases. β -Haemolytic streptococci were also isolated from 28% of the cases, and viral culture of the throat was undertaken in only 4% of the cases. Sore throat was reported in 211 of the 238 cases. The data indicated that non-toxicogenic *C. diphtheriae* is frequently perceived as a pathogen. However, very little is known about the pathogenicity of non-toxicogenic *C. diphtheriae*. It has been suggested that the organism may have an affinity for attaching to vascular endothelium (Belko, Wessel and Malley, 2000).

***Corynebacterium diphtheriae* Endocarditis and Septicaemia**

Endocarditis due to *C. diphtheriae* was first reported by Howard in 1893 (Howard, 1893). Endocarditis and septicaemia caused by *C. diphtheriae* are often considered a rarity. Toxin production does not appear to be important in these invasive infections as most of the cases reported were caused by non-toxicogenic strains, and immunisation with the toxoid offers no protection. Endocarditis caused by non-toxicogenic strains of *C. diphtheriae* commonly occurs in previously healthy patients who do not have any predisposing factors for endocarditis. Endocarditis can be a devastating disease, with a high incidence of complications and mortality. Most of the cases do not have a coexisting respiratory infection. Therefore, the route of infection is usually obscure. Possible predisposing factors include pre-existing heart disease including mitral insufficiency, and prosthetic valves, intravenous drug use and malignancy. *Corynebacterium* spp. isolated in blood cultures are often classified as contaminants, and this may delay the diagnosis of endocarditis. Also, because of the absence of underlying cardiac risk factors in many of these patients, physicians may not initially consider the possibility of endocarditis. These factors may explain the high morbidity and case fatality rate associated with this disease.

LABORATORY DIAGNOSIS OF DIPHTHERIA

Diphtheria is no longer easily diagnosed on clinical grounds because of the lack of familiarity with the clinical features. Mild cases of the

disease resemble streptococcal pharyngitis, and the classical pseudo-membrane of the pharynx may not develop, particularly in people who have been vaccinated (Bonnet and Begg, 1999). Because the disease is rare, many clinicians may never encounter a case and therefore miss clinical diagnosis (Bowler *et al.*, 1988). Therefore, diagnosis relies on the laboratory isolation and identification of toxigenic *C. diphtheriae*. It is therefore of utmost importance for the laboratory to provide accurate and rapid information to confirm or eliminate a suspected case of diphtheria. However, bacteriological diagnosis should be regarded as complementary to, and not as a substitute for, clinical diagnosis of diphtheria (Efstratiou and Maple, 1994).

Identification of Potentially Toxicogenic *C. diphtheriae*

The currently recommended microbiological procedure for the laboratory diagnosis of diphtheria is shown in Figure 7.2.

Specimen Collection and Transport

Because diphtheria is primarily an upper respiratory tract infection, ear, throat, nasopharyngeal and nasal swabs should be taken. Also, if membranous material is present, it should be submitted for examination. The only other common form of diphtheria is cutaneous diphtheria, which is clinically indistinguishable from pyodermas. Swabs should be taken from the affected area of the skin. Any crusted material should be removed and the swabs taken from the base of the lesion (Efstratiou and Maple, 1994; Clarridge, Popovic and Inzana, 1998; Efstratiou and George, 1999; Efstratiou *et al.*, 2000).

Once swabs have been taken, they should be transported to the laboratory immediately. The laboratory should be notified ahead of time of a suspected diagnosis of diphtheria. If the specimen cannot be transported to the laboratory immediately, the use of a transport medium such as Amies (Amies, 1976), which was described in 1976, is recommended (Efstratiou and Maple, 1994; Efstratiou and George, 1999).

Primary Isolation

Culture specimens should be initially plated out on blood agar and Hoyle's tellurite agar and incubated at 35–37 °C. Tellurite-containing media suppress the growth of commensals and allow the growth of *C. diphtheriae* and some other corynebacteria as well as staphylococci and yeasts. They have the rare ability to reduce tellurite salts, producing dull black colonies (Efstratiou *et al.*, 2000). *Corynebacterium diphtheriae* grows most rapidly on Loeffler medium, which is a lipid-rich medium, and Gram stains from colonies grown on Loeffler are the best for demonstrating metachromatic granules. However, diagnosis of diphtheria based solely upon direct microscopy of a smear is unreliable. Potentially toxicogenic species of corynebacteria (*C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis*) are differentiated by the use of rapid screening tests such as detection of the enzyme cysteinase (using Tinsdale medium) and the absence of pyrazinamidase activity (Colman, Weaver and Efstratiou, 1992; Efstratiou and Maple, 1994). On Tinsdale medium, the three potentially toxicogenic species of corynebacteria produce black colonies surrounded by a brown halo. The use of Tinsdale medium for primary culture is not recommended, because the medium is highly selective and, therefore, increases the probability of false negatives, mainly with specimens that contain small numbers of organisms (Efstratiou and Maple, 1994; Efstratiou and George, 1999).

After isolation of pathogenic strains, identification is carried out by the use of a series of simple biochemical tests. The biochemical characteristics of the potentially toxicogenic corynebacteria (four biotypes of *C. diphtheriae*, *C. ulcerans* and *C. pseudotuberculosis*) and other coryneforms that may be present in throat or wound swabs are described in Table 7.1. Commercial identification kits such as the

API Coryne system (API bioMérieux, Marcy-l'Étoile, France) and Rosco Diagnostica tests (Rosco Diagnostica, Taastrup, Denmark) are readily available, and the results obtained are highly accurate and reproducible. All tests are described in detail in a WHO manual (Efstratiou and Maple,

1994). The four biotypes of *C. diphtheriae* (var. *gravis*, var. *mitis*, var. *belfanti* and var. *intermedius*) are classified on the basis of morphological and biochemical properties (Table 7.2). The biochemical tests that distinguish *C. diphtheriae* from other corynebacteria and coryneforms are as

Table 7.2 Differences in the morphological appearances of typical colonies of *C. diphtheriae* on tellurite blood agar (after 48 h of incubation aerobically)

Biotype	Colony morphology
<i>C. diphtheriae</i> var. <i>gravis</i>	Dull, dry grey, opaque colonies, 1.5–2 mm in diameter with a matte surface. Colonies are friable, they tend to break into small segments when touched with a straight wire. They can also be pushed across the surface of the medium without breaking. Non-haemolytic usually
<i>C. diphtheriae</i> var. <i>mitis</i>	Grey, opaque colonies, 1.5–2 mm in diameter with an entire edge and smooth surface. Variation in size is a common characteristic. They tend to exhibit a small zone of β -haemolysis on blood agar
<i>C. diphtheriae</i> var. <i>intermedius</i>	Small, grey, discrete, translucent colonies, 0.5–1 mm in diameter

follows: production of catalase and cysteinase, reduction of nitrate (except biotype *belfanti*, which is nitrate negative), absence of urease and pyrazinamidase and fermentation of glucose, maltose and starch (only biotype *gravis* ferments starch).

Detection of Toxigenicity

The test for toxigenicity is the most important test for the microbiological diagnosis of diphtheria and should be performed without delay on any suspect isolate that is found by routine screening or while investigating a suspect case of diphtheria (Brooks and Joynson, 1990). The *in vivo* toxin test using guinea pigs was the gold standard for testing toxin production since the end of the last century. However, the expense, the risk of accidental self-inoculation, slowness of the test in producing a result and the increasing unacceptability of *in vivo* tests in many countries led to a decline in the use of this test. An alternative gold standard for the *in vivo* assay is the *in vitro* Vero cell assay, which is based on the cytotoxicity of DT to cultured Vero cells (Efstratiou *et al.*, 1998). Engler *et al.* (1997) and Reinhardt, Lee and Popovic (1998) developed modified Elek tests, which produce results in 16–24 h. Other *in vitro* methods that are currently used include a polymerase chain reaction (PCR) assay for detecting the 'A' portion of the toxin gene (Pallen, 1991; Hauser *et al.*, 1993; Pallen *et al.*, 1994; Aravena-Roman, Bowman and O'Neill, 1995; Mikhailovich *et al.*, 1995; Nakao and Popovic, 1997), a rapid enzyme immunoassay (EIA) (Engler and Efstratiou, 2000) and a rapid immunochromatographic strip (ICS) test (Engler *et al.*, 2002).

MANAGEMENT, PREVENTION AND CONTROL OF *C. DIPHTHERIAE* INFECTIONS

Antitoxin has been used to treat diphtheria for over 100 years (MacGregor, 2000). Diphtheria antitoxin is a hyperimmune serum produced in horses. The antitoxin only neutralises circulating toxin that has not bound to the tissues, and therefore, it is critical that diphtheria antitoxin be administered as soon as a presumptive diagnosis has been made, without waiting for bacteriological confirmation.

Delayed administration increases the risk of late effects such as myocarditis and neuritis (Begg, 1994).

Because antitoxin is derived from horse serum, tests with a trial dose to exclude hypersensitivity to horse proteins should be carried out before administration. All patients should be tested by applying a 1:100 dilution of diphtheria antitoxin onto the underside of the forearm by scratching or pricking. If the result is negative, 0.02 ml of antitoxin diluted 1:1000 in saline is injected intracutaneously, with adrenaline available for immediate administration. If an immediate reaction occurs, the patient should be desensitised progressively with higher doses of antiserum (MacGregor, 2000).

The dose of antitoxin depends upon the severity of the disease and the site and the extent of the membrane. Table 7.3 summarises the dose range for various clinical situations (Bonnet and Begg, 1999). Many countries use this scheme; however, there may be variations, which have been recommended by manufacturers of antitoxin or the national health authorities. Antitoxin therapy is probably of no value for cutaneous disease; however, some authorities recommend using 20 000–40 000 units because there have been reports of toxic sequelae (Farizo *et al.*, 1993).

Antibiotics are necessary to eliminate the bacterium and prevent spread, but it is not a substitute for antitoxin treatment. Killing the organism by antibiotic therapy has three benefits:

1. toxin production is terminated;
2. local infection is improved;
3. spread of organism to uninfected contacts is prevented (MacGregor, 2000).

Antibiotics such as penicillin, erythromycin, clindamycin, rifampicin and tetracycline are effective. Penicillin and erythromycin appear to be the agents of choice. Intramuscular administration of procaine penicillin G (25 000–50 000 U/kg-day for children and 1.2 million units/day for adults, in two divided doses) is recommended or parenteral course of erythromycin (40–50 mg/kg-day, with a maximum of 2 g/day) until the patient can swallow comfortably, at which point erythromycin in four divided doses or oral penicillin V (125–250 mg four times daily) may be substituted. Antibiotic treatment should be continued for 14 days (Bonnet and Begg, 1999).

Prevention of diphtheria depends primarily on widespread routine vaccination with diphtheria toxoid (MacGregor, 2000). Control and prevention of diphtheria epidemics require the following:

1. *High vaccine coverage in target groups.* Achieving and maintaining high coverage in children through routine immunisation. Furthermore, mass immunisation of adults older than 25 years, belonging to high-risk groups (alcoholics, homeless, armed forces and health care workers) with diphtheria toxoid-containing vaccines (preferably Td, diphtheria–tetanus vaccine with reduced amount of diphtheria toxoid).
2. *Early diagnosis and proper management (immediate treatment and hospitalisation) of diphtheria cases.* Prompt recognition of suspected diphtheria cases; prompt and qualified collection and shipment of specimens for laboratory examination; prompt standard treatment with diphtheria antitoxin antibiotics; and notification of the case to the local health authorities.

Table 7.3 Dose of antitoxin recommended for various types of diphtheria

Type of diphtheria	Dose (units)	Route
Nasal	10 000–20 000	Intramuscular
Tonsillar	15 000–25 000	Intramuscular or intravenous
Pharyngeal or laryngeal	20 000–40 000	Intramuscular or intravenous
Combined types or delayed diagnosis	40 000–60 000	Intravenous
Severe diphtheria, e.g. with extensive membrane and/or severe oedema (bullneck diphtheria)	40 000–100 000	Intravenous or part intravenous and part intramuscular

3. *Rapid investigation of close contacts of people with diphtheria and their effective standardised treatment to prevent secondary cases.* Clinical surveillance for 7 days from the last date of contact with the case; treatment with antibiotics for 7 days; and immunisation with booster dose of diphtheria/tetanus toxoid if their immunisation is incomplete or unknown (Dittmann and Roure, 1994).

Immunity to Diphtheria

Acquired immunity to diphtheria is primarily due to toxin-neutralising antibody (antitoxin). Antibodies to fragment B of the DT are able to neutralise the effect of toxin and protect against disease. Diphtheria antitoxin production [primarily of immunoglobulin G (IgG) antibody] may be induced by the natural toxin during clinical infection or in the carrier state or by immunisation with diphtheria toxoid (Todar, 1997; Canada CDR, 1998). Diphtheria toxoid is a formaldehyde-inactivated preparation of DT, adsorbed onto aluminium salts to increase its antigenicity (WHO, 1998). DTP vaccine (diphtheria toxoid combined with pertussis vaccine and tetanus toxoid) is the core vaccine in childhood immunisation programmes. The vaccine is used in preschool children for primary and reinforcing immunisation, whereas a combined diphtheria-tetanus vaccine in the form DT is used for booster doses in preschool children (7 years and younger) and its adult form Td (which has a reduced amount of diphtheria toxoid) is used for booster doses in older children, adolescents and adults. There are three main DTP immunisation schedules in widespread use in different countries:

1. three doses: three primary doses of DTP vaccine given during the first year of life;
2. four doses: primary series of three doses reinforced with one booster dose administered usually at the age of 2–3;
3. five doses: primary series of three doses reinforced with the first booster at the age of 2 and second booster given before entering school at the age of 4–6 (WHO, 1998).

The three-dose schedule is mainly used in the African region, South-east Asia and in the Western Pacific region. The four-dose schedule is used in most European countries, and the five-dose schedule is used mainly in the American region (WHO, 1998). In the United Kingdom, five doses are currently recommended: a primary series of three doses at 2, 3 and 4 months of age and a booster dose at school entry or 3 years after primary immunisation, and since 1994, a booster dose at 15–19 years has been recommended (PHLS CDR, 1994; Begg and Balraj, 1995).

In the prevaccine era, circulation of *C. diphtheriae* strains was common and the occurrence of diphtheria case high. This enabled adults to acquire natural immunity by subclinical infection. Most newborn infants passively acquire antibodies from their mothers via the placenta, which provided protection during the first 6 months after birth (Zingher, 1923; Hardy, 1998; Galazka, 2000). However, after widespread childhood immunisation, diphtheria became rare and exposure to these organisms was uncommon. Immunity induced by childhood immunisation usually wanes, and if adults are not exposed to toxigenic organisms to acquire natural immunity and if they do not receive booster doses of diphtheria toxoid, they become susceptible to the disease (Brainerd *et al.*, 1952; Galazka and Robertson, 1996; Galazka and Tomaszunas-Blaszczyk, 1997). Several studies have shown that many adults in industrialised countries have low antibody levels and are susceptible to diphtheria (Weiss, Strassburg and Feeley, 1983; Christenson and Böttiger, 1986; Simonsen *et al.*, 1987; Cellei *et al.*, 1989; Maple *et al.*, 1995; Edmunds *et al.*, 2000; Egemen *et al.*, 2000; Marlovits *et al.*, 2000; von Hunolstein *et al.*, 2000). The age group with the lowest levels of immunity varies from country to country and probably depends on the year that childhood immunisation programme was implemented on a routine basis (Galazka and Robertson, 1996; Edmunds *et al.*, 2000).

According to internationally accepted definitions, an antibody titre of >0.1 IU/ml gives long-term protection against diphtheria, a titre of 0.1 IU/ml gives full protection, a titre between 0.01 IU/ml and 0.09 IU/ml gives basic protection and a titre of less than 0.01 IU/ml indicates no protection against diphtheria. Several assays have been developed to determine the diphtheria antitoxin level in serum (Efstratiou and Maple, 1994), and among these, the *in vivo* toxin neutralisation test is regarded as the gold standard. However, it is laborious, time consuming and expensive; therefore, equally accurate *in vitro* cell-culture methods have been developed. These assays measure the ability of serum from an individual to neutralise the cytopathic effects of pure DT in a tissue-culture system and thus measure functional antibodies. Assays that are cheaper and simpler to perform than the neutralisation tests include enzyme-linked immunosorbent assay (ELISA) and passive haemagglutination tests. However, they lack sensitivity for serum samples containing <0.1 IU/ml of antitoxin (Efstratiou and George, 1999).

OTHER POTENTIALLY TOXIGENIC CORYNEBACTERIA

Corynebacterium ulcerans

Corynebacterium ulcerans was first isolated in 1926 from throat lesions by Gilbert and Stewart (Gilbert and Stewart, 1926). Colonies of *C. ulcerans* resemble those of *C. diphtheriae* biotype *gravis*. They are dry, waxy and grey-white, with light haemolysis, and are 1–2 mm in diameter after 24 h. Microscopically, the organism is pleomorphic, with predominantly coccoid forms and some rod forms. On Tinsdale medium, it produces brownish-black colonies with distinct halos, which are indistinguishable from *C. diphtheriae* colonies. *Corynebacterium ulcerans* is urease positive and nitrate negative and ferments glucose, maltose and glycogen (von Graevenitz, Coyle and Funke, 1998; Efstratiou and George, 1999; Funke and Bernard, 1999). The ability to hydrolyse urea and the lack of nitrate reduction distinguish *C. ulcerans* from *C. diphtheriae* (Table 7.1). *Corynebacterium ulcerans* when lysogenic for a *tox*⁺ carrying phage, produces two exotoxins in varying proportions (Petrie and McLean, 1934; Carne and Onon, 1982). One is identical to *C. diphtheriae* toxin, which is neutralised by diphtheria antitoxin and can be detected by the Elek test. The other is identical to *C. pseudotuberculosis* toxin, phospholipase D (PLD), which is unaffected by diphtheria antitoxin. *Corynebacterium pseudotuberculosis* toxin PLD is discussed in more detail in the section *Corynebacterium pseudotuberculosis*.

Corynebacterium ulcerans is a veterinary pathogen and causes mastitis in cattle and other domestic and wild animals (Fox and Frost, 1974; Hommez, 1999). Toxigenic strains of *C. ulcerans* have been associated with classical diphtheria (Fakes and Downham, 1970; Meers, 1979; CDC, 1997; Ahmad, Gainsborough and Paul, 2000) as well as milder symptoms (Bostock *et al.*, 1984; Hart, 1984; Barrett, 1986; Pers, 1987; Kisely *et al.*, 1994). At least three deaths have been attributed to such infection (Leek, 1990; Anonymous, 2000; Wellinghausen *et al.*, 2002). Usually, human infections are acquired through contact with animals or by ingestion of unpasteurised dairy products (Bostock *et al.*, 1984; Hart, 1984; Barrett, 1986). However, such risk factors were not identified for three cases of classical diphtheria in the United Kingdom, caused by *C. ulcerans*, which suggests that there may be other routes of infection (White *et al.*, 2001). Recently, in the United Kingdom, toxigenic *C. ulcerans* was isolated from domestic cats with bilateral nasal discharge (Anonymous, 2002a; Taylor *et al.*, 2002).

Corynebacterium pseudotuberculosis

Corynebacterium pseudotuberculosis (previously known as *Corynebacterium ovis*) was called the Preisz–Nocard bacillus in honour of the researchers who first isolated the organism in the early 1890s from necrotic kidney of a sheep (Lipsky *et al.*, 1982). Colonies are

yellowish white, opaque and convex with a matted surface and are about 1–2 mm in diameter after 48 h and produce slight β -haemolysis. Like *C. ulcerans*, *C. pseudotuberculosis* is urease positive. The organism is similar to both *C. diphtheriae* and *C. ulcerans* in its production of halos on Tinsdale media and failure to hydrolyse pyrazinamidase (Table 7.1). *Corynebacterium pseudotuberculosis* comprises two biovariants, *equi* and *ovis*, that are distinguished by the ability of biovariant *equi* to reduce nitrate (Songer *et al.*, 1988). The most discriminating biochemical tests for distinguishing *C. pseudotuberculosis* from *C. ulcerans* are the hydrolysis of glycogen by *C. ulcerans* and the lipid-stimulated growth of *C. pseudotuberculosis*.

Corynebacterium pseudotuberculosis also harbours the DT, and nearly all strains produce dermonecrotic toxin or PLD. PLD is a potential virulence factor of *C. pseudotuberculosis*. It is a protein much smaller than the DT (molecular weight 14 000). Over 10% of the *C. pseudotuberculosis* isolates produce the DT (Maximescu *et al.*, 1974); however, there have not been any clinical cases of diphtheria attributed to infection with *C. pseudotuberculosis* (MacGregor, 2000).

Corynebacterium pseudotuberculosis causes caseous lymphadenitis in sheep and goats, ulcerative lymphangitis in horses and cutaneous abscesses and lesions in many other animal species (Yeruham *et al.*, 1997; Moller *et al.*, 2000; Watson and Preece, 2001). Infections of humans have also been recorded in farm workers and veterinarians exposed to infected animals, usually manifesting as lymphadenitis (Goldberger *et al.*, 1981; Richards *et al.*, 1985; House *et al.*, 1986; Mills *et al.*, 1997; Peel *et al.*, 1997).

OTHER CORYNEBACTERIA

Corynebacterium pseudodiphtheriticum

Corynebacterium pseudodiphtheriticum, previously known as *Bacillus pseudodiphtheriticum*, was probably first isolated by von Hoffman in 1888 from throats of humans (MacGregor, 2000). The current name *C. pseudodiphtheriticum* was given by Bergey *et al.* in 1925 (Lipsky *et al.*, 1982). Colonies of *C. pseudodiphtheriticum* are non-haemolytic, white, slightly dry with entire edges and 1–2 mm in diameter after 48 h of incubation at 37 °C. The organism is non-fermentative, reduces nitrate and hydrolyses urea.

Corynebacterium pseudodiphtheriticum is part of the oropharyngeal bacterial flora and is associated with respiratory disease mainly in immunosuppressed patients (Cimolai *et al.*, 1992; Freeman *et al.*, 1994; Ahmed *et al.*, 1995; Manzella *et al.*, 1995). It also causes pneumonia or bronchitis in non-immunocompromised hosts (Miller *et al.*, 1986; Ahmed *et al.*, 1995; Manzella *et al.*, 1995). Most of the cases reported have been in patients with endotracheal intubation. Therefore, there is a possibility that the intubation procedure introduces the organism into the lower respiratory tract (Freeman *et al.*, 1994). The organism also causes endocarditis and has been isolated from draining wounds (Lindner, Hardy and Murphy, 1986; Hatch, 1991; Morris and Guild, 1991; Wilson *et al.*, 1992).

Corynebacterium xerosis

Corynebacterium xerosis is a commensal of human skin and mucous membranes (von Graevenitz, Coyle and Funke, 1998). It has been reported that, in the past, *Corynebacterium striatum* strains were misidentified as *C. xerosis* (Coyle *et al.*, 1993). In the past, differentiation of *C. xerosis* from *C. striatum* relied on a few biochemical tests. Both organisms are positive for glucose and sucrose fermentation and are negative for urease production, esculin hydrolysis and mannitol and xylose fermentation. They are distinguished primarily by fermentation of maltose by *C. xerosis* but not *C. striatum*. True *C. xerosis* colonies appear yellowish, dry and granular with irregular edges,

whereas *C. striatum* colonies are white, moist and smooth. Other characteristics that may be helpful in differentiating *C. xerosis* from *C. striatum* are the following: hydrolysis of tyrosine and rapid fermentation of sugars (24–36 h) by strains of *C. striatum*. *Corynebacterium xerosis* strains do not hydrolyse tyrosine and ferment sugars slowly (72–96 h) (Martinez-Martinez *et al.*, 1995).

Furthermore, Funke *et al.* in 1996 demonstrated that nearly all isolates identified as *C. xerosis* in the routine clinical laboratory in the past in fact represent *C. amycolatum* strains. They concluded that *C. xerosis* strains are very rare and that nearly all *C. xerosis* strains that appeared in the literature before 1996 may have been misidentified *C. amycolatum* strains. Characteristics that differentiate *C. amycolatum* from *C. xerosis* are the following: *C. amycolatum* strains produce white-grey colonies, lack mycolic acids, show weak or no leucine arylamidase activity, produce large amounts of propionic acid from glucose fermentation and are resistant to the vibriocidal agent 0/129, whereas *C. xerosis* strains, as mentioned above, produce yellowish colonies, express mycolic acids and leucine arylamidase activity, produce lactic acid from glucose fermentation and are susceptible to 0/129 (Funke *et al.*, 1996a). Therefore, as *C. xerosis*, *C. striatum* and *C. amycolatum* strains have been misidentified in the past, the pathogenic role of these organisms is unclear.

Corynebacterium imitans

Corynebacterium imitans is a new species, and the only strain described to date was isolated in 1997 from a nasopharyngeal specimen of a child suspected of having throat diphtheria, and the same strain was isolated from three adult contacts (Funke *et al.*, 1997). This was the first well-documented case of person-to-person transmission of a *Corynebacterium* other than *C. diphtheriae* in a non-hospital environment. Colonies of *C. imitans* are 1–2 mm in diameter, white-grey in colour and shiny and creamy with entire edges after 24 h incubation at 37 °C. The organism is cysteinase negative and tellurite positive. It is catalase positive and nitrate and α -glucosidase negative, and pyrazinamidase activity is weak. Urea, esculin and tyrosine are not hydrolysed. Acid is produced from D-arabinose, ribose, D-glucose, D-fructose, D-mannose, maltose, lactose, L-fucose and weakly from sucrose. *Corynebacterium imitans* is differentiated from *C. diphtheriae* by the following tests: negative nitrate reduction, weak pyrazinamidase activity, positive alkaline phosphatase, a positive CAMP test and susceptibility to 0/129. The strain isolated did not produce DT, and the toxin gene was not detectable.

Corynebacterium jeikeium

Corynebacterium jeikeium was first described by Hande *et al.* in 1976, as the cause of four cases of septicaemia in immunocompromised patients, and it consists of the isolates previously designated as CDC coryneform group JK bacteria (Jackman *et al.*, 1987).

Corynebacterium jeikeium exists as part of the normal skin flora in hospitalised patients (Gill *et al.*, 1981; Larson *et al.*, 1986; Soriano and Fernandez-Roblas, 1988), and it may survive in the hospital environment for long periods of time (Telander *et al.*, 1988). *Corynebacterium jeikeium* isolates are pleomorphic, club-shaped Gram-positive rods, arranged in V forms or palisades. On blood agar, these organisms form discrete pinpoint colonies that are greyish-white, glistening and non-haemolytic. The biochemical reactions that differentiate *C. jeikeium* from other corynebacteria are the inability to produce urease, reduce nitrate or readily ferment most carbohydrates (ferments glucose, galactose and, sometimes, maltose). The API Coryne identification system may incorrectly identify *C. jeikeium* because of insufficient acid formation from glucose and maltose (von Graevenitz, Coyle and Funke, 1998). The organism is catalase positive and oxidase negative, and no halo is produced on Tinsdale medium (Coyle, Hollis and Groman, 1985; Jackman *et al.*, 1987). It is

a strict aerobe, with no growth occurring anaerobically (Jackman *et al.*, 1987).

Most infections have occurred in immunocompromised patients with malignancies, patients with medical devices (vascular or implanted access catheters), patients who are hospitalised for long periods, those who have breaks in their integument and those who have had therapy with broad-spectrum antibiotics (Coyle and Lipsky, 1990). Cutaneous infection by *C. jeikeium* was reported by Dan *et al.* in 1988. The following have been reported as being associated with *C. jeikeium* infections: neutropenia (Rozdzinski *et al.*, 1991), prosthetic and native heart valve endocarditis (Vanbosterhaut *et al.*, 1989; Ross *et al.*, 2001), osteomyelitis (Weller, McLardy-Smith and Crook, 1994), meningitis with transverse myelitis (Johnson, Hulse and Oppenheim, 1992) and cerebral ventriculitis (Knudsen, Nielsen and Espersen, 1994).

Corynebacterium urealyticum

The name *Corynebacterium urealyticum* was proposed in 1986 to describe *Corynebacterium* group D2 (Soriano *et al.*, 1986); however, this name was not validated until 1992 (Pitcher *et al.*, 1992). *Corynebacterium urealyticum* is Gram-positive rods that may appear coccoidal after prolonged incubation and are arranged in V forms or palisades. Colonies are non-haemolytic, pinpoint, whitish, smooth and convex. The organism is a strict aerobe, with no growth occurring on blood agar incubated anaerobically (Pitcher *et al.*, 1992). *Corynebacterium urealyticum* strains are catalase positive, produce pyrazinamidase, have very strong urease activity and are oxidase negative, nitrate negative and asaccharolytic. They may be differentiated from *C. jeikeium* by their inability to oxidise sugars and by their urease production.

Corynebacterium urealyticum has been documented to cause acute or chronic (encrusted) infections of the lower urinary tract if an underlying renal or bladder disease is present (Soriano *et al.*, 1990). The organism may also cause infection in the upper part of the urinary tract, resulting in pyelonephritis or pyeloureteritis (Aguado, Ponte and Soriano, 1987), particularly in immunocompromised or post-renal-transplant patients with surgical complications (Nadal, Schwöbel and von Graevenitz, 1988; Aguado *et al.*, 1993). There have been reports of *C. urealyticum* causing infections other than urinary tract infections, such as endocarditis (Ena *et al.*, 1991), bacteremia (Marshall, Routh and MacGowan, 1987; Soriano *et al.*, 1993; Wood and Pepe, 1994), osteomyelitis (Chomarar Breton and Dubost, 1991), soft-tissue infection (Saavedra *et al.*, 1996) and wound infection (Soriano *et al.*, 1993). Most *C. urealyticum* strains are multiresistant to antibiotics. *Corynebacterium urealyticum* is often resistant to β -lactams and aminoglycosides and susceptible to vancomycin.

Listeria and *Erysipelothrix* spp.

Kevin G. Kerr

Department of Microbiology, Harrogate District Hospital, Harrogate, UK

INTRODUCTION

In 1918 a bacterium resembling *Erysipelothrix rhusiopathiae* was isolated from the cerebrospinal fluid of a soldier serving in France. This isolate was deposited in the Institut Pasteur, Paris, but it was to be many years before this bacterium was recognised as *Listeria monocytogenes*.

In 1924 Murray and colleagues, during the investigation of an epizootic among experimental animals, isolated a bacterium from the lymph glands of affected animals which, when injected into healthy animals, induced a monocytosis and was accordingly given the name *Bacillus monocytogenes*. Three years later in South Africa, Pirie who was studying carriage of *Yersinia pestis* by rodents isolated a bacterium from the livers of gerbils, which he named *Listerella hepatolytica*. This bacillus was found to be indistinguishable from *B. monocytogenes*, and Pirie later proposed the name *L. monocytogenes*.

In 1929 Nyfeldt isolated *L. monocytogenes* from blood cultures of a patient with glandular fever and was convinced he had isolated the causative agent of infectious mononucleosis. Not surprisingly, other investigators were unable to substantiate his claim. Over the ensuing years, anecdotal reports of human listeriosis in both neonates and adults continued to appear in the literature, but the consensus was, however, that listeriosis was an extremely rare zoonotic pathogen. The pioneering work of Reiss and colleagues, and of Heinz Seeliger in the 1950s, encompassed the first truly systematic studies of human listeriosis; but it was not until three decades later, following a series of well-publicised outbreaks, that *L. monocytogenes* was catapulted from relative obscurity into the microbiological limelight. Since that time it has become the focus of much attention from a number of scientific disciplines, not only because of the public health importance of *L. monocytogenes* but also because the bacterium has become to be regarded as an important experimental model for facultative intracellular parasitism.

THE GENUS LISTERIA

General Description of the Genus

The intragenetic and intergenetic relatedness of the genus *Listeria* has been the subject of much debate. At first considered as a member of the family Corynebacteriaceae, primarily because of morphological characteristics, later chemotaxonomic studies demonstrated that *Listeria* spp. are quite distinct from the corynebacteria. It was not until 1984, however, that partial sequencing of 16S rRNA unambiguously confirmed the phylogenetic place of the genus *Listeria* in the *Clostridium-Bacillus-Lactobacillus* group, with *Brochothrix thermosphacta* as its nearest neighbour.

The genus *Listeria* as originally described was monotypic, with *L. monocytogenes* the sole member. In the ensuing years a further seven species were recognised: *L. ivanovii* (previously *L. monocytogenes* serovar 5), *L. innocua*, *L. welshimeri*, *L. seeligeri*, *L. murrayi*, *L. grayi* and *L. denitrificans*. *Listeria denitrificans* has been since reclassified as *Jonesia denitrificans*. *Listeria murrayi* and *L. grayi* were once considered sufficiently distinct from other *Listeria* spp. to warrant the creation of a new genus, *Murraya*, but have now been assigned to a single species *L. grayi*. Most recently, *L. ivanovii* has been divided into two subspecies: subsp. *ivanovii* and subsp. *londoniensis*. Of the non-*monocytogenes* species, only *L. ivanovii* is recognised as a human pathogen (Cummins, Fielding and McGlauchlin, 1994).

The genomes of *L. monocytogenes* and *L. innocua* have been sequenced with the former having a genome 2.94 Mbp long with 2583 open-reading frames and a mol% G + C of 39. *Listeria innocua* has a genome 3.01 Mbp in length with 2973 open-reading frames and a mol% G + C content of 37 (Glaser *et al.*, 2001). Of particular note is the fact that many of the proteins encoded by these bacteria bear a striking similarity to *Bacillus subtilis*. *Listeria monocytogenes* is found in an extraordinarily diverse range of habitats, and it is thus unsurprising that 331 genes encoding different transport proteins (11.6% of all predicted genes) and 209 transcriptional regulators have been identified in the bacterium (Glaser *et al.*, 2001).

Between 0 and 79% of *L. monocytogenes* isolates carry plasmids of various sizes. Although most of these are cryptic, cadmium resistance is plasmid associated and plasmids specifying for resistance to single or multiple antimicrobials have also been reported (Poyart-Salmeron *et al.*, 1992; Hadorn *et al.*, 1993). Plasmid carriage is much more predominant in isolates of *L. monocytogenes* belonging to serogroup 1 (Harvey and Gilmour, 2001).

Listeria spp. are short (0.4–0.5 × 0.5–2.0 μm) Gram-positive rods. They are nonacid fast and do not produce spores. At 20 °C they are motile by means of peritrichous flagella, but motility is not observed in cultures incubated at 37 °C. They are facultatively anaerobic and grow over a wide temperature range of 0–45 °C (optimum 30–36 °C), although growth at very low temperatures is slow. Growth over a wide pH range occurs, with some strains growing at pH 9.6, but is optimal at neutral to slightly alkaline pH. Key biochemical and other characteristics are listed in Tables 8.2 and 8.3.

The major antigenic determinants of *Listeria* spp. are the somatic (O) and flagellar (H) antigens. The current serotyping scheme, based on these antigens, distinguishes six serogroups (1/2, 3, 4, 5, 6 and 7) further subdividable into serovars for all species except *L. grayi* and *L. ivanovii*. While *L. ivanovii* and *L. welshimeri* can be readily differentiated from *L. monocytogenes* on serotyping, other species may share one or more antigens with *L. monocytogenes*. For example, some isolates of *L. seeligeri* may be antigenically indistinguishable from those belonging to *L. monocytogenes* to serogroup 1/2. It should

also be noted that, although 13 serovars of *L. monocytogenes* are recognised currently, in excess of 90% of clinical isolates belong to only three serovars –1/2a, 1/2b and 4b, thereby limiting the value of this technique in epidemiological studies.

PATHOGENESIS

Apart from the very rare exception of direct inoculation via skin or conjunctiva, it is most likely that in the adult the bacteria gain access to the host via the gastrointestinal tract. In the case of the fetus, infection in the majority of cases arises from haematogenous seeding of the placenta and only a few cases are thought to be acquired *intra partum* as the neonate exits the birth canal. Late onset neonatal listeriosis is acquired through direct or indirect person-to-person transmission.

Although it has been suggested that co-infection with another gastrointestinal pathogen may predispose to invasion of the gut by *L. monocytogenes*, it is now known that the bacterium can specify its own uptake by mammalian cells, including those which are non-professional phagocytes. The expression of cell-surface-associated proteins, of which internalin (Inl) A and B are the best characterised, are of key importance in this process. Another protein (p60), the product of the *iap* gene, recently renamed *cwhA* (cell-wall hydrolase) was originally thought to play a significant role in this context, but its contribution to invasiveness has since been downplayed (Pilgrim *et al.*, 2003).

Following internalisation by the host cell, the bacterium lyses the membranes of the phagosomal vacuole. Lysis is mediated by listeriolysin O, a haemolysin which is related to other cholesterol-dependent pore-forming toxins (CDTX) such as streptolysin O. Two phospholipases, PlcA and B, are also deemed to be important in allowing *L. monocytogenes* to escape from phagosomal vacuoles. Once free in the host cell cytoplasm, the protein ActA promotes actin accumulation and polymerisation resulting in the formation of an actin tail at a pole of the bacterium, and it is propelled in a pseudopod-like structure into an adjacent cell whereupon it is then phagocytosed. The bacterium escapes from the resulting double-membrane vacuole through production of listeriolysin and PlcA and B. Key virulence genes of *L. monocytogenes* are located on a 8.2-kb pathogenicity island, LIPI, and are transcriptionally regulated by the product of the *prfA* gene (PrfA). PrfA also partially regulates expression of internalin A and B which are located on a separate pathogenicity island (Roberts and Wiedmann, 2003).

The minimum infectious dose of *L. monocytogenes* for humans remains to be determined, although counts of the bacterium from foodstuffs implicated in most sporadic and epidemic cases are typically in excess of 10^6 CFU g^{-1} . Putative interstrain differences in virulence have been identified – for example, human strains of *L. monocytogenes* associated with asymptomatic carriage express a truncated InlA (Olier *et al.*, 2003). Comparative genomics have also revealed serovar-specific genes which will permit further investigation of differences in virulence and may help to explain why most cases of human listeriosis are caused by serovar 4b (Doumith *et al.*, 2004).

EPIDEMIOLOGY

The Environment

Listeria monocytogenes has been isolated from a very wide range of environmental sources including dust soil and sewage. Although it is often considered that *L. monocytogenes* in soil and vegetation results from faecal contamination by animals, Weis and Seeliger (1976) noted that the bacterium was isolated in greatest numbers from plants and soil from uncultivated areas, whereas the lowest numbers were obtained from agricultural areas.

Listeria monocytogenes can survive for extended periods in the environment. It can survive for up to 1500 days in certain types of soil and can persist and multiply in water, being isolated from surface water of canals and lakes as well as estuarine environments. The bacterium has also been isolated from raw and treated sewage. When sprayed on agricultural land, numbers of *L. monocytogenes* do not significantly decrease over time, leading to concern that crops grown in soil treated with sewage sludge may become contaminated with the bacterium (Garrec, Picard-Bonnaud and Pourcher, 2003). Similarly, aquatic environments may become contaminated by the addition of animal manure or human soil as occurs in several countries.

Listeria monocytogenes can also be found in the environment of food production facilities and retail outlets. The formation of biofilm, which is strain dependent, may be important in this respect (Borucki *et al.*, 2003). The bacterium has also been isolated from the domestic environment, but the significance of this in relation to human listeriosis is uncertain (Beumer *et al.*, 1996).

Food

Following the recognition that listeriosis is frequently a food-borne infection there have been few foods which have not escaped the attention of microbiologists seeking *L. monocytogenes*. Studies to determine the extent of listerial contamination of a given food product often yield different results. The reasons for this are complex and reflect, at least in part, geographic, seasonal and other differences as well as variations in isolation protocols. Marked differences in experimental technique also account for the discrepancies in the results of investigations into the growth, survival and heat tolerance of *L. monocytogenes* in foods.

Listeria monocytogenes has been associated with a wide variety of food products, particularly unpasteurised milk and dairy products, principally surface-ripened (soft) cheese. Hard cheese, because of the decrease in pH and a_w , which occur during ripening is much less likely to become contaminated during manufacture. It should be noted that soft cheeses made from pasteurised milk can become contaminated during production (Bind, 1989).

Listeriosis has been associated with the consumption of poultry, and recent surveys have shown that up to 62% of uncooked chicken specimens sampled at retail level may be contaminated with the bacterium (Miettinen *et al.*, 2001). The prevalence of *L. monocytogenes* in cooked chicken, as might be expected, is lower than that for raw products; nevertheless, both anecdotal reports and case-control studies have implicated cooked chicken in human listeriosis. Other meat products, both raw and cooked, may also be contaminated with the bacterium.

Listeria monocytogenes has also been detected in a wide range of other foodstuffs including pâté, vegetables (including prepacked salads), seafood – particularly crab meat and smoked fish – and both commercial and institutional cook-chill products. Contamination of ready-to-eat foods may also occur at the retail level (Gombas *et al.*, 2003).

Animals and Human Carriers

At least 50 species of wild, zoo and domestic animals and birds have been shown to harbour *L. monocytogenes*. Rates of faecal carriage in cattle, sheep and goats vary widely but may be very high, even in listeriosis-free herds.

Early studies investigating faecal carriage in humans suggested that up to 70% of selected populations may excrete *L. monocytogenes* for short periods, but these reports must be viewed with caution, as many of the isolates, given contemporary identification criteria, would not now be recognised as *L. monocytogenes*. More recent reports suggest that faecal carriage is much less frequent, occurring in approximately 3% of healthy individuals. Several studies have attempted to identify

factors associated with carriage of the bacterium, such as H2 receptor antagonist therapy, but results from investigations should be interpreted with care, as the only long-term prospective study (Grif *et al.*, 2003) has indicated that faecal carriage may not only be intermittent but also short-lived (maximum of 4 days).

Carriage of *Listeria* spp. in the vagina has been investigated but does not seem to occur outside the setting of recent maternofetal listeriosis.

Human Infection

For many years, *L. monocytogenes* was considered a rare zoonotic pathogen. The first cases of presumed food-borne listeriosis were reported as long ago as 1951. Similar reports continued to appear in the ensuing two decades but failed to make an impact in the wider scientific and medical communities, presumably because the East German and Czechoslovak researchers had little contact with fellow investigators in the West. It was not until the large outbreaks in the 1980s that systematic studies of the epidemiology of *L. monocytogenes* infection were initiated. These studies resulted in the perception in many countries that the incidence of listeriosis was increasing. However, the question as to whether this represented a true increase or merely greater awareness of the disease among clinicians, bacteriologists and public health agencies remains unanswered. While there can be no doubt that improved diagnostic techniques and surveillance and reporting systems had improved, most authorities now believe that there was a real increase in the number of cases. The reasons for this are complex but reflect, at least in part, the growing number of individuals with conditions which render them vulnerable to *L. monocytogenes* infection as well as major changes in food production, distribution, retailing (such as the introduction of refrigerated products with extended shelf lives) and dietary habits.

Recognition of these factors leading to improved food production and retailing practices, increased microbiological and public health surveillance coupled with changes in consumer awareness relating to high-risk foods, especially in the most vulnerable patient groups, may well be responsible for the decrease in the incidence of listeriosis reported by several countries, although outbreaks continue to occur.

Listeria monocytogenes as a Food-Borne Pathogen

Evidence that contaminated food is the principal route of transmission of *L. monocytogenes* comes from three main sources: investigation of outbreaks (Table 8.1), case-control studies and individual case reports.

Even before the well-publicised outbreaks in North America and Europe in the 1980s, epidemics of listeriosis were well recognised. Several of these involved large numbers of individuals (in the 1966 outbreak in Halle, Germany, there were 279 cases), but insufficient data were collected to allow precise identification of the source of these outbreaks. Recognition of outbreaks is hampered by a number of

factors including the long incubation period in some cases of listeriosis, geographically wide distribution of implicated food products or food products not sold through conventional retail channels (CDC, 2001) as well as a failure to recognise that food-borne listeriosis may manifest with a clinical picture of gastroenteritis similar to that of salmonellosis or campylobacteriosis (as discussed later). Indeed, it is possible that some outbreaks have only come to light because of fortuitous circumstances (Linnan *et al.*, 1988) or through molecular epidemiological surveillance (Anon., 2003).

Case-control studies and anecdotal reports of human listeriosis have incriminated a variety of contaminated foodstuffs, such as soft cheese and undercooked poultry, as the source of infection. The investigation of sporadic cases is often difficult, as the incubation time for food-borne listeriosis may be very long compared with that for other food-borne pathogens (mean 3–4 weeks).

In contrast to classical food-borne listeriosis, there is increasing recognition that *L. monocytogenes* can cause a self-limited febrile gastroenteritis syndrome with a short incubation time (typically 24 h) (Frye *et al.*, 2002). Foods implicated in this form of listeriosis include turkey meat, sweet corn and tuna salad, chocolate milk, smoked fish and corned beef (Sim *et al.*, 2002).

Person-to-person transmission outside the hospital setting has never been convincingly demonstrated, but nosocomial spread of *L. monocytogenes* is well recognised, particularly on neonatal units, typically following introduction of a case of early onset sepsis onto the ward, which is followed by late onset cases several days later (Colodner *et al.*, 2003). Routes of transmission include contaminated resuscitation equipment, rectal thermometers and mineral oil applied to the skin of newborns. In other outbreaks, transmission of the bacterium by health care personnel or mothers appears to have occurred. Nosocomial listeriosis may also be food borne in origin (Graham *et al.*, 2002).

Zoonotic cases of listeriosis are uncommon and have presentations which differ from the more commonly recognised syndromes and include cutaneous lesions, conjunctivitis and pneumonia. There is no convincing evidence that *L. monocytogenes* can be transmitted by sexual intercourse. Transmission via blood transfusion, although theoretically possible given the psychrotrophic nature of the bacterium, has never been reported.

Molecular Epidemiology of *L. monocytogenes*

The limitations of conventional typing systems such as serotyping, which is poorly discriminative, and bacteriophage typing, available at only a few centres and limited by the non-typeability of many isolates, have long been known. Accordingly, molecular techniques have been applied and have contributed much to the understanding of *L. monocytogenes* infection. Methods include restriction fragment length polymorphism analysis, PCR-based techniques, such as random amplification of polymorphic DNA (RAPD), multilocus enzyme electrophoresis, amplified fragment length polymorphism and ribotyping. Pulsed-field gel electrophoresis is generally regarded as the gold standard typing method for *L. monocytogenes*, although

multilocus sequence typing may prove to be a more discriminative technique (Revazishvili *et al.*, 2004). In addition, surveillance using molecular techniques has been used to identify hitherto unrecognised outbreaks and clusters of infection (Anon., 2003; Sauders, Fortes and Morse, 2003) and to distinguish between relapsing and recurring listeriosis.

CLINICAL MANIFESTATIONS OF *L. MONOCYTOGENES* INFECTION

Listeriosis in Pregnancy

This syndrome accounts for approximately one-third of all cases of listeriosis, although the proportion may be much higher in epidemics. Although most frequently documented in the third trimester, listeriosis in earlier stages of pregnancy has also been reported. However, as early fetal loss is very often incompletely investigated, the number of cases occurring in the first trimester of pregnancy may be underestimated.

Bacteraemia is the most common manifestation of listeriosis in pregnancy and is classically accompanied by an episode of flu-like illness with fever, headache and myalgia. Associated low back pain may suggest a urinary tract infection. In up to 45% of cases, however, the pregnant woman may be asymptomatic with the first indication of infection being the abortion or stillbirth of the foetus or neonatal listeriosis in a live-born child.

The idea that maternal genital listeriosis is a cause of repeated abortion was first proposed over 40 years ago, but there is no compelling evidence to uphold it.

In contrast to adult listerial infections, complications in pregnant women are very rare and are usually seen in the context of underlying illness such as systemic lupus erythematosus or AIDS and, in the overwhelming majority of women, infection is self-limiting.

Evidence that untreated *L. monocytogenes* bacteraemia in the gravid female does not inevitably lead to transmission of infection to the foetus is accumulating, especially if appropriate antimicrobial chemotherapy is administered (Mylonakis, Paliou and Hohmann, 2002).

Neonatal Listeriosis

Somewhat analogous to neonatal sepsis with Lancefield group B streptococci, neonatal listeriosis can be divided into early and late onset groups with the former being defined as sepsis manifesting within 5 days of birth, but typically presenting within 48 h post partum. Late onset disease develops 5 or more days after birth, with a mean age of onset of 14 days. Mortality is high, up to 60 and 25% for the early- and late-onset forms, respectively.

Early onset disease results, in the most cases, from *in utero* transmission of *L. monocytogenes* from a bacteraemic mother. Ascending vaginal infection is very uncommon. The classical manifestation of early onset disease is granulomatosis infantisepticum characterised at autopsy by widely disseminated granulomas in several organs. Although noted frequently in early reports, it has been much less commonly observed by later investigators. More typical of this form of the disease is septicaemia often accompanied by pneumonic involvement or meningitis (Mylonakis, Paliou and Hohmann, 2002). Maculopapular or papulovesicular rashes are also seen. In practice, however, it is often difficult to distinguish between early onset listeriosis and other forms of neonatal sepsis on clinical grounds alone.

In contrast to the early onset form of the disease, infants who manifest the late onset form are usually healthy at birth. It has been suggested that affected infants are colonised at birth, but as a result of unexplained factors, the onset of infection is delayed. Much more likely, however, is that nosocomial acquisition has occurred as is borne out by

numerous reports of clusters of late onset listeriosis. Late onset disease is characterised by meningitis or meningoencephalitis, seen in up to 90% of cases. Onset may be more insidious than with the early form of the infection, with poor feeding, irritability and fever common presenting symptoms.

Listeriosis in Adults

Listeriosis in adults is frequently seen against a background of immune suppression, particularly where cell-mediated immunity is affected, e.g. lymphoreticular neoplasms, antirejection regimens in solid organ transplantation and autologous and allogeneic bone marrow transplantation in which the disease occurs typically as a late complication (Rivero *et al.*, 2003). Listeriosis may follow therapy with corticosteroids, chemotherapeutic agents, such as fludarabine, and the anti-tumour necrosis factor- α agents infliximab and etanercept (Slifman *et al.*, 2003). Early in the AIDS pandemic, *L. monocytogenes* was not considered to be a significant pathogen in HIV-infected individuals, and several plausible explanations for this, including the antilisterial activity of co-trimoxazole used for *Pneumocystis jiroveci* prophylaxis, were advanced. Later studies, however, demonstrated that listeriosis is 150–300 times more common in HIV-positive patients than in matched control groups from the general population. Other chronic diseases such as alcoholism and diabetes mellitus also predispose to *L. monocytogenes* infection.

The fact that invasive listeriosis can develop in previously apparently healthy individuals is often overlooked. Indeed, in several published series, approximately one-third of cases had no apparent predisposing factor (e.g. Skogberg *et al.*, 1992). Immunocompetent individuals are also susceptible to the febrile gastroenteritis syndrome associated with consumption of *L. monocytogenes*-contaminated foodstuffs.

In invasive listeriosis, reported mortality rates vary widely according to age, sex, underlying illnesses and it is thus extremely difficult to useful comparisons between published studies. Nevertheless, overall mortality rates of 35–45% are typical. Several investigators have reported decreasing mortality rates, perhaps because of more increased awareness of the infection leading to more vigorous bacteriological investigations and antimicrobial therapy in immunocompromised patients.

Adult invasive listeriosis can be categorised into three groups according to clinical manifestations: central nervous system (CNS) disease which accounts for as much as 75% of all cases, primary bacteraemia and a miscellaneous group which embraces an ever-widening spectrum of localised infections.

Neurological Infection

Meningitis, with or without focal neurological signs, is the most common form of CNS listeriosis. As with other pyogenic meningitides, listerial meningitis is usually acute in onset with high fever, nuchal rigidity and photophobia, but there are other additional features such as movement disorders, including tremors and/or ataxia. Seizures also appear to be more common than in other types of meningitis.

The most common non-meningitic form of the CNS listeriosis is encephalitis, most frequently affecting the rhombencephalon. This has a characteristic biphasic course: a nonspecific prodrome of headache, nausea, vomiting and fever, followed by progressive asymmetrical cranial nerve palsies, cerebellar signs or hemiparesis and impairment of consciousness. Prognosis is poor with significant rates of neurological sequelae in survivors. Given the frequency of CNS involvement, it is surprising that listerial brain abscesses, which can be single or multiple, are rare, accounting for only 1% of cases of CNS disease (Cone *et al.*, 2003). All cases reported thus far appear to be haematogenous in origin with no evidence of spread from contiguous sites.

Bacteraemia

Primary bacteraemia is the second most common manifestation of invasive listeriosis in nonpregnant adults, occurring in 25–50% cases. There are no distinguishing clinical features associated with this form of listeriosis. Patients may be profoundly hypotensive with an overall clinical picture which mimics Gram-negative endotoxic shock which may be accompanied by the adult respiratory distress syndrome.

Miscellaneous Syndromes

A variety of other clinical syndromes are associated with invasive adult listeriosis. Infections of the locomotor system include osteomyelitis and septic arthritis which may affect both native and prosthetic joints. Pulmonary infection, in contradistinction to neonatal listeriosis, is rare, although cases of pneumonia or empyema have been reported. Hepatic involvement in listeriosis is also uncommon, although hepatic abscesses, both single and multiple, are recognised with the former almost exclusively occurring in patients with insulin-dependent diabetes (Bronniman *et al.*, 1998). Hepatitis in liver transplant recipients has also been described (Vargas *et al.*, 1998). Spontaneous bacterial peritonitis caused by *L. monocytogenes* has been reported in both cirrhotic and non-cirrhotic patients (Jammula and Gupta, 2002) as has peritonitis in patients undergoing continuous peritoneal dialysis (Tse *et al.*, 2003).

Listeria endocarditis occurs on both native and prosthetic valves, and although often an aggressive infection characterised by the development of complications, such as paravalvular abscess formation, some cases respond to medical therapy alone (Fernández Guerrero *et al.*, 2004). Infections of arteriovenous shunts, intravenous cannulae and prosthetic vascular grafts have also been recorded.

Ocular infections, although rare, have been described by several investigators. These infections are difficult to manage and are often sight threatening, although prompt intervention with appropriate antimicrobials may be associated with an improved outcome (Lohmann *et al.*, 1999). Primary cutaneous listeriosis is infrequently reported and is usually seen in veterinarians or farm workers after accidental inoculation of the skin following exposure to animals.

LABORATORY DIAGNOSIS

Diagnosis of listeriosis on clinical grounds alone is problematic, partly because there are few, if any pathognomic signs, and partly because it is such a rare infection and is often not considered in the differential diagnosis.

Direct Detection of *L. monocytogenes* in Clinical Material

Gram staining of specimens from normally sterile sites may suggest a diagnosis of listeriosis. Short Gram-positive rods may be seen in both intracellular and extracellular locations, but it should be remembered that the bacteria may appear filamentous, coccoid or even Gram negative, especially in cerebrospinal fluid from patients with partially treated meningitis. It should also be noted that analysis of CSF specimens may not yield a typical pyogenic picture; in up to 30% of cases there is no hypoglycorrhachia and there may be no predominance, or even an absence, of polymorphs (Niemann and Lorber, 1980).

A large number of systems which detect listerial antigens, such as enzyme-linked immunosorbent assay or reversed passive latex agglutination or DNA using hybridisation of PCR-based techniques, are available commercially but these have been developed for the

identification of *Listeria* spp. in foodstuffs (USDA/CFSAN, 2003a) and there is only very limited experience of these methodologies in the clinical laboratory (Lohmann *et al.*, 1999).

Serological Diagnosis of Listerial Infection

Detection of antibodies to listeriolysin has on occasion proved useful in the investigation of outbreaks as well as seroprevalence studies (Dalton *et al.*, 1997), but the technique is not widely available and has yet to find a place in the diagnostic laboratory for the investigation of sporadic cases of listeriosis.

Isolation of *L. monocytogenes* from Clinical Material

Listeria monocytogenes is easily isolated from specimens obtained from normally sterile sites, and the bacterium will grow on most commonly used nonselective media after 24–48 h of incubation at 37 °C. Blood agar is preferred as *L. monocytogenes* is β -haemolytic, although it should be noted that rare nonhaemolytic strains occur (USDA/CFSAN, 2003b). Isolation of *L. monocytogenes* from clinical (or food/environmental) specimens likely to be contaminated with competing microflora requires the use of selective differential media such as Oxford or PALCAM (polymyxin acriflavine lithium chloride ceftazidime individual aesculin mannitol) agars, both of which are commercially available. On these media, aesculin-hydrolysing colonies such as *Listeria* spp. are surrounded by a black aesculetin pigment (which may diffuse widely throughout the medium, making it difficult to identify aesculin-hydrolysing colonies). With the exception of the uncommonly encountered *L. grayi*, *Listeria* spp. do not ferment mannitol and this property is made use of in PALCAM agar which contains a mannitol/phenol red indicator system. Several commercially produced chromogenic agars for the isolation of *Listeria* spp. are available but experience with these products outside of food microbiology laboratories is limited. Food or contaminated clinical material may also be incubated in a one- or two-step enrichment process, using an enrichment broth, such as Fraser broth or buffered *Listeria* enrichment broth, which again are commercially available, before subculture onto a selective/differential medium. Cold enrichment of contaminated specimens at 4 °C is now regarded as obsolete.

Identification of *L. monocytogenes*

There are several reasons as to why *L. monocytogenes* may be misidentified in the clinical laboratory other than the well-recognised tendency of the bacterium to be labelled as a diphtheroid which may lead to an isolate being discarded as a contaminant. Zones of β -haemolysis may not be obvious on first inspection and may require removal of a colony from the plate for this to become apparent. In addition, *L. monocytogenes* may cross-react with antigens in some, but not all, commercially available kits for the grouping of β -haemolytic streptococci (Farrington *et al.*, 1991). Furthermore, tests for motility are sometimes carried out only at 20 °C without simultaneously testing for absence of motility at 37 °C. It should also be noted that only a minority of the motile population may exhibit the characteristic of the so-called tumbling leaf motility when viewed in hanging drop preparation. Very rarely, tests for catalase may be negative (Elsner *et al.*, 1996).

Although biochemical identification of *Listeria* spp., using traditional biochemical and other techniques as outline in Tables 8.2 and 8.3, should be well within the capability of most clinical laboratories, a number of commercially produced identification systems can be used, such as the API *Listeria* (Bille *et al.*, 1992). These are, however, primarily designed for the food microbiology laboratory, and it is unlikely, given the infrequency of isolation of *L. monocytogenes*

in the clinical setting, that the routine diagnostic laboratory would find it cost effective to employ these methods. However, many commonly used manual (e.g. API CORYNE) or automated identification systems (VITEK 2) likely to be in use in clinical laboratories are capable of identifying putative *Listeria* isolates to species level, although additional tests may be required to complete the identification process.

The CAMP (Christie Atkins and Munch-Petersen) test, originally employed in the identification of *Streptococcus agalactiae* has been modified for use in the characterisation of *Listeria* spp. The test relies upon synergism of haemolysis between cultures of *L. monocytogenes* and *Staphylococcus aureus* and *L. ivanovii* and *Rhodococcus equi* (*L. seeligeri* may also give a weakly positive CAMP test with *S. aureus*) (Figure 8.1). In the test *S. aureus* or *R. equi* is streaked across a 5% (v/v) sheep blood agar plate and the β-haemolytic *Listeria* isolate is streaked at 90° to the latter. Plates are incubated in air at 37 °C for 24 and 48 h. With *L. ivanovii* and *R. equi*, an easily identifiable arrowhead zone of haemolysis is observed. With *S. aureus* and *L. monocytogenes* (and also *L. seeligeri*), synergistic haemolysis also occurs, but this is less obvious and a more blunt zone is observed. It must be emphasised that, for the test to be successful, freshly prepared sheep blood agar should be used. The red cells should be washed twice in phosphate-buffered saline to remove inhibitors of haemolysis before use. Not all strains of *S. aureus* and *R. equi* are suitable for the CAMP test, and culture collection strains are recommended for this purpose [NCTC 1803 or NCTC 7428 (ATCC 49444) and NCTC 1621

Figure 8.1 CAMP test with *Listeria monocytogenes* (top) and *L. ivanovii* (bottom). Hatched areas represent zones of haemolysis.

(ATCC 6939), respectively]. Similarly, known isolates of *L. monocytogenes* (and other species if available) should be included as controls. Finally, it should be acknowledged that some strains of *L. monocytogenes* may also give a positive CAMP reaction with both *S. aureus* and *R. equi*, although the synergistic haemolysis seen with the latter is usually less pronounced than that seen with *L. ivanovii*.

MANAGEMENT OF INFECTION

Despite *in vitro* susceptibility to a wide range of agents (except the cephalosporins and fosfomycin), the outcome of antimicrobial therapy in invasive listeriosis is often disappointing, partly because of delays in the initiation of appropriate therapy as the diagnosis is not considered sufficiently early in the course of the illness and partly because so many patients with listeriosis have predisposing conditions such as

immunosuppression. Moreover, *L. monocytogenes* is a facultative intracellular parasite, and many agents have poor intracellular penetration. Even if penetration does occur, compounds may be unstable or exhibit reduced activity in this milieu. Information on the most effective regimens for the management of listeriosis are derived from *in vitro* data, animal models and clinical reports, but methodologies vary greatly between studies and results are often conflicting. There remain no controlled trials in this field.

Despite poor intracellular penetration and a widely held view that β -lactams are only bacteriostatic against *L. monocytogenes* in intracellular locations, the aminopenicillins, amoxicillin and ampicillin are regarded as the drugs of choice in invasive listeriosis, albeit at higher than usual doses of 8–12 g per day in divided doses. Many authorities recommend the addition of an aminoglycoside, such as gentamicin at 5–7 mg/kg as a single daily dose, to this regimen, as *in vitro* data suggest this is a synergistic combination and also because of favourable clinical experience of this combination as cited in published series (Safdar and Armstrong, 2003a). Animal models using liposomal or nanoparticle-bound ampicillin have yielded encouraging results, although these have yet to be evaluated in the clinical setting.

The optimal duration of antimicrobial therapy for listeriosis remains to be determined; this is not altogether surprising, given the wide range of clinical manifestations and large number of predisposing conditions, but a general recommendation would be at least 2 weeks for primary bacteraemia and listeriosis in pregnancy and at least 3 weeks for meningitis and neonatal infection. Shorter courses are associated with relapsing infection. Endocarditis may require up to 6 weeks of therapy.

For patients unable to tolerate an ampicillin \pm aminoglycoside regimen, co-trimoxazole is considered acceptable second-line therapy, on account of both *in vitro* synergy of the combination at concentrations readily achievable in serum and CSF and encouraging clinical outcomes as reported in the literature.

The choice of antimicrobial for patients where neither ampicillin nor co-trimoxazole can be used is problematic. Experience with vancomycin-based regimens has been disappointing (Safdar and Armstrong, 2003a), and although other agents such as carbapenems, newer fluoroquinolones, linezolid and quinupristin/dalfopristin have good *in vitro* activity against *L. monocytogenes*, clinical experience with these compounds remains limited (Weston *et al.*, 1998; Grumbach, Mylonakis and Wing, 1999).

Acquired antimicrobial resistance in clinical isolates is relatively uncommon (Safdar and Armstrong, 2003b), although tetracycline resistance in isolates carrying the *tetM* gene has been reported as has plasmid-mediated resistance (conferred by the *dfrD*) gene (Charpentier *et al.*, 1995; Charpentier, Gerbaud and Courvalin, 1999). Carriage of plasmid conferring resistance to multiple antimicrobials has also been reported (Hadorn *et al.*, 1993).

ERYSIPELOTHRIX RHUSIOPATHIAE

Introduction

Although Koch cultured a bacterium *Erysipelothrix muriseptica* from the blood of septicaemic mice in 1880, it was not until 8 years later that Löffler published the first accurate description of *E. rhusiopathiae*, which he isolated from a pig which had died from swine erysipelas. In the intervening period, Pasteur and Dumas (and later Thullier) used a strain of the bacterium which had been passaged through rabbits to immunise swine against erysipelas – the first time active immunisation by a live attenuated vaccine had been demonstrated. The bacterium was first identified by Rosenbach as a human pathogen in 1909 when he reported its isolation from a patient with localised cutaneous lesions to which he gave the name erysipeloid to distinguish them from those of human erysipelas.

Description of the Organism

Erysipelothrix spp. are facultative anaerobes which grow over a wide temperature range, with an optimum of 30–37 °C. They are nonmotile, asporogenous, nonacid fast, short Gram-positive rods (0.2–0.4 μ m in diameter and 0.8–2.5 μ m in length). They occur singly but, according to growth conditions, may be observed as chains, clusters or filamentous forms. Growth is favoured under alkaline conditions (range pH 6.7–9.2, optimum 7.2–7.6). Biochemical characteristics are discussed later and in Table 8.3. Until recently the genus *Erysipelothrix* contained only one species, *E. rhusiopathiae*, but chemotaxonomic and DNA studies have identified two other species, *E. tonsillarum* and *E. inopinata*, neither of which have been implicated as human pathogens.

For many years serotyping was used both as a tool for taxonomic and epidemiological analysis, but this has been rendered obsolescent with the introduction of molecular typing techniques such as ribotyping and RAPD-PCR.

Pathogenesis of *Erysipelothrix rhusiopathiae* Infection

Virulence factors of *E. rhusiopathiae* remain underinvestigated, particularly those which may be of importance in human infection. Putative virulence factors have included neuraminidase, hyaluronidase and adherence to mammalian cells, but the ability to survive intracellularly within phagocytic cells is probably of most importance (Shimoi, 2000).

EPIDEMIOLOGY

Ecology of *Erysipelothrix rhusiopathiae*

Erysipelothrix rhusiopathiae is distributed widely and has been isolated from a number of environmental sources such as soil and sewage effluent. The primary reservoir for the bacterium is, however, mammals and saltwater fish and crustaceans and, to a lesser extent, freshwater fish and avian species in which it can behave as either commensal or pathogen. Particularly important in this respect are pigs in which *E. rhusiopathiae* infection is associated with a number of syndromes including swine erysipelas, septicaemia and polyarthritis (which resembles rheumatoid arthritis in humans). Infection in pigs as well as other farmed animals and birds is of considerable economic importance to the agricultural industry.

Human Infection

There is no carrier state in humans. Although infections associated in humans are apparently rare, difficulties in the microbiological diagnosis, coupled with the rapid response of this condition to many antimicrobials and the fact that the disease is not notifiable, may lead to an underestimation of the true number of cases.

Given the reservoirs of this bacterium, it is not surprising that individuals who have frequent contact with animals, poultry, fish and their related products, such as farmers, abattoir workers, fishermen and butchers, are the most at risk of *Erysipelothrix* infection. In most instances of infection it is likely that the bacterium is acquired through cutaneous inoculation either through direct penetration of the skin with a sharp object or through contamination of a pre-existing skin lesion.

In some cases, no history of animal or fish contact can be elicited, while in others consumption of raw fish, shellfish or undercooked pork has been associated with subsequent systemic infection. There is no evidence that person-to-person transmission occurs.

CLINICAL FEATURES

The most common form of *E. rhusiopathiae* infection in humans, accounting for around 90% of cases, reported is the cellulitis known as erysipeloid. Most cases are occupationally related and follow puncture wounds or inoculation of cuts or abrasions. Very uncommonly, infection may follow dog bites. There is no convincing evidence to support earlier assertions that the bacterium can penetrate intact skin. After an incubation of 2–7 days, the lesions which are usually (but not exclusively) located on the hands or forearms develop. These typically have a blue or purplish colouration and a sharply defined edge and are often described as being intensely itchy or burning. Lesions may spread proximally with central clearing. Systemic symptoms are uncommon and, although there may be swelling and complaints of stiffness in adjacent joints, aspirates are sterile on culture. The differential diagnosis includes erysipelas caused by *S. pyogenes* and staphylococcal cellulites, although in these syndromes the incubation time is shorter and constitutional signs and lymphadenopathy are more frequent.

A more severe form of cutaneous infection, in which the cellulitis spreads more widely, often in conjunction with the appearance of lesions at other sites, occurs rarely. Despite the frequency of systemic symptoms in these cases, blood cultures are rarely positive when traditional manual systems are used. A case of necrotising fasciitis caused by *E. rhusiopathiae* has also been reported (Simoniescu *et al.*, 2003).

The most serious manifestation of *E. rhusiopathiae* infection is endocarditis (Gorby and Peacock, 1988). Approximately 40% of patients give a history of preceding or coexisting skin lesions. Most cases occur on native valves in individuals without a history of valvular disease. Very rarely consumption of raw or undercooked seafood or pork has anteceded endocarditis. Males are more likely to be affected than females, presumably reflecting occupational exposure to the bacterium, and there is a predilection for the aortic valve. Presentation can be acute but is more likely to have an insidious onset (mean duration to diagnosis 6.6 weeks). The course of infection is often characterised by valve destruction (30% cases require valve replacement) which along with embolic events may account for the higher mortality rate of this infection when compared with endocarditis caused by other bacteria. Bacteraemia without endocarditis also occurs usually, but not exclusively, in immunocompromised individuals, particularly those with chronic liver disease and in patients receiving glucocorticosteroids (Fakoya *et al.*, 1995).

Erysipelothrix rhusiopathiae is also associated with a range of other infections including septic arthritis in both immunocompromised and immunocompetent (Ruiz *et al.*, 2003; Vallianatos, Tilentzoglou and Koutsoukou, 2003) and peritonitis in chronic ambulatory peritoneal dialysis (Dunbar and Clarridge, 2000).

LABORATORY DIAGNOSIS

PCR-based methods have been described but have found only limited use in the clinical laboratory (Brooke and Riley, 1999). Similarly, serological tests and antibody detection techniques have been little employed outside the veterinary setting. Accordingly, diagnosis of *E. rhusiopathiae* infection in humans remains dependent on the isolation and identification of the bacterium from clinical material.

The bacterium will grow readily on standard blood culture media in cases of septicaemia or endocarditis. Swabs are unsuitable for the diagnosis of erysipeloid, and aspirates, or preferably skin biopsies, from the edge of the lesion should be obtained. As the number of bacteria in these lesions may be small, enrichment for up to 2 weeks in glucose serum broth is recommended with frequent subcultures to blood agar. Primary and subcultures should be incubated at 37 °C in 5–10% CO₂. For isolation from heavily contaminated specimens, selective media are available (Bratberg, 1981).

After 24 h of incubation, colonies are pinpoint, but extended incubation permits the observation of two colonial types. Smooth (S)

colonies are 0.5–1.5 mm in diameter, are convex and have a transparent bluish appearance. These are traditionally associated with isolates from acute infection, whereas rough (R) colonies, which are larger, flatter, opaque and with a rough irregular edge, are classically associated with chronic conditions. However, intermediate forms occur and both S and R forms can be isolated from a single specimen (Dunbar and Clarridge, 2000). On blood agar a narrow zone of α -haemolysis may be observed on prolonged incubation, and as *E. rhusiopathiae* is catalase negative, misidentification of these colonies as viridans group streptococci may occur. In addition, granules in the bacilli may resemble those of diphtheroids and smears made from older colonies may appear Gram negative.

The biochemical and other tests outlined in Table 8.3 can be used to identify the bacterium in the clinical laboratory, although this may be more easily achieved using commercially available systems, e.g. the API CORYNE kit.

When identifying *E. rhusiopathiae* and *L. monocytogenes* from environmental and food specimens, it is important to distinguish these bacteria from the Gram-positive genera *Brochothrix* and *Kurthia*. In practice this is not difficult as *Brochothrix* does not grow above 30 °C and *Kurthia* spp. are obligate aerobes and oxidase positive.

In clinical material, *E. rhusiopathiae* can be distinguished from *Lactobacillus* spp. by hydrogen sulphide production and from *Corynebacterium* spp. by failure to produce catalase and resistance to vancomycin. *Listeria* spp. can be distinguished from the former on the grounds of motility and catalase test and from the latter on testing for motility. [*Leifsonia aquatica* (formerly *Corynebacterium aquaticum*) is motile but, unlike *Listeria* spp., is negative in the Voges–Proskauer test.]

MANAGEMENT OF ERYSIPELOTHRIX INFECTION

Although the lesions of erysipeloid may resolve spontaneously, the time to resolution may be prolonged and relapses may occur and antimicrobial therapy is therefore recommended. Additionally, this may prevent progression to bacteraemia and/or endocarditis.

Given the relative infrequency of *E. rhusiopathiae* infection, it is not surprising that there have been no clinical trials to determine optimal antimicrobial therapy. Although there are several reports of the *in vitro* antimicrobial susceptibility of the bacterium, these have often involved small numbers of strains and different testing methods and there is a paucity of information regarding the clinical relevance of these data. However, the majority of isolates appear susceptible to penicillin, cephalosporins and imipenem as well as fluoroquinolones. The bacterium remains exquisitely susceptible to penicillin (MIC $\leq 0.01 \mu\text{g ml}^{-1}$) which remains the drug of choice. Of the other β -lactams, imipenem appears the most active agent. *In vitro* susceptibility to erythromycin, tetracycline and chloramphenicol is variable. Although generally regarded as resistant to aminoglycosides, Schuster, Brennan and Edelstein (1993) report an isolate with an MIC to gentamicin of $1 \mu\text{g ml}^{-1}$. Of particular note is the resistance of *E. rhusiopathiae* to vancomycin (but not necessarily teicoplanin), as this agent may be used in the empiric therapy of prosthetic valve endocarditis. There is no evidence that the genes for glycopeptide resistance in enterococci have been acquired from *E. rhusiopathiae* (Patel, 2000).

Although penicillin is regarded as the agent of choice for *E. rhusiopathiae* infection, there is very limited reported experience of the management of penicillin-hypersensitive patients, but ciprofloxacin appears highly active against the bacterium *in vitro* and has been used with the management of *E. rhusiopathiae* endocarditis in a patient who could not tolerate penicillin (MacGowan *et al.*, 1991).

Optimal dosing regimens and duration of therapy remain ill defined. Benzylpenicillin for 4–6 weeks has been recommended for therapy of serious *E. rhusiopathiae* infections, although shorter courses of 2 weeks of intravenous therapy followed by 2–4 weeks of oral therapy have been used with success (Reboli and Farrar, 1989).

Bacillus spp. and Related Genera

Niall A. Logan and Marina Rodríguez-Díaz

Department of Biological and Biomedical Sciences, Glasgow Caledonian University, Glasgow, UK

HISTORICAL INTRODUCTION

The organism now known as *Bacillus subtilis* was first described as '*Vibrio subtilis*' by Christian Ehrenberg in 1835. Nearly 30 years later Casimir Davaine (1864) gave the name '*Bacteridium*' to the organism associated with anthrax infection – *la maladie charbonneuse* – but the name *Bacillus* was first applied to these organisms by Ferdinand Cohn (1872), who included the three species of rod-shaped bacteria, *B. subtilis* (type species), *B. anthracis* and the now unidentifiable *B. ulna*. Cohn (1876), Koch (1876) and Tyndall (1877) independently discovered that certain bacteria could spend part of their lives as the dormant cellular structures now known as endospores. The first two of these authors recognized the significance of these structures in the epidemiology of anthrax, and Koch's study of the life history of *B. anthracis* proved the germ theory of disease and so marked the genesis of clinical bacteriology. Winter (1880) was the first to include 'propagation through spores' in the description of the genus, and Prazmowski (1880) was the first to use sporulation as a differential (i.e., taxonomic) characteristic; he proposed the genus name *Clostridium* for organisms that differed from *Bacillus* in having spindle-shaped sporangia. Over the next 40 years at least 30 keys for the classification of bacteria were produced, and although many of these used the presence of spores as a character, there were many that did not. It was not until the Committee of the Society of American Bacteriologists on Characterization and Classification of Bacterial Types reported in the early volumes of the *Journal of Bacteriology* (Winslow *et al.*, 1917, 1920) that satisfactory and largely uncontested definitions of the bacterial groups emerged. The defining feature of the family *Bacillaceae* was 'Rods producing endospores', and the Committee used the requirement of oxygen and sporangial shape for differentiation between *Bacillus* and *Clostridium*, the other genus in the family. This description was applied in the first and second editions of *Bergey's Manual of Determinative Bacteriology* (Bergey *et al.*, 1923, 1925), and so the definition of the genus *Bacillus* as aerobic endospore-forming rods had become widely established by the 1920s.

The first major study of *Bacillus* was undertaken by Ford and colleagues (Laubach, Rice and Ford, 1916; Lawrence and Ford, 1916). They allocated 1700 strains to 27 species but produced an incomplete classification, particularly owing to the absence of adequate differential tests. The next scheme appeared 30 years later when Smith, Gordon and Clark (1946) published a monograph that dealt with 625 strains. Subsequently this work was expanded to include 1134 strains and to cover all known aerobic spore formers (Smith, Gordon and Clark, 1952). The work of these authors was thorough; they collected strains widely and studied rod, spore and sporangial morphologies as well as many physiological characters. They placed their organisms in three groups according to their spore and sporangial shapes. Their approach contrasted with the tendency at

that time to describe new species on the basis of a single strain differing from the description of an existing taxon by a single character, and the soundness of the work was established when the scheme was successfully applied to 246 strains isolated by Knight and Proom (1950) from soil and to 400 isolates from clinical specimens, laboratory dust and soil (Burdon, 1956). An updated and expanded version of the Smith *et al.* scheme was published by Gordon, Haynes and Pang (1973), and this classification, despite attempts to split the genus (Gibson and Gordon, 1974), was widely followed until the early 1990s.

During this period the number of recognized species in the genus declined from its peak number of 146, in the 1939 (fifth) edition of *Bergey's Manual of Determinative Bacteriology*, to 22, with 26 of uncertain status in the 1974 (eighth) edition and to only 31 species in the ICSB Approved Lists of Bacterial Names (Skerman, McGowen and Sneath, 1980). Despite this relatively small number of species, however, it was generally agreed that the genus *Bacillus* was heterogeneous. The range of DNA base composition acceptable in a homogeneous genus is widely agreed to be no more than 10%, whereas that found in *Bacillus* was over 30% (Claus and Berkeley, 1986). This gave confirmation of heterogeneity, and numerical studies such as that by Logan and Berkeley (1981) also indicated that the genus might be divided into five or six genera.

Accordingly, *Bacillus* has now been divided into more manageable and better-defined groups on the basis of 16S rDNA sequencing studies, but this and other molecular characterization techniques have also allowed the recognition of many new species. Ten new genera have been proposed so far: *Alicyclobacillus* (Wisotzkey *et al.*, 1992), which contains six species of thermoacidophiles; *Paenibacillus* (Ash, Priest and Collins, 1993), containing 41 species and including organisms formerly called *B. polymyxa*, *B. macerans* and *B. alvei* and the honey bee pathogens *B. larvae* and *B. pulvifaciens* (now both subspecies of *P. larvae*); *Brevibacillus* (Shida *et al.*, 1996), containing 11 species and including organisms formerly called *B. brevis* and *B. laterosporus*; *Aneurinibacillus* (Shida *et al.*, 1996), with *A. aneurinilyticus* and two other species; *Virgibacillus* (Heyndrickx *et al.*, 1998) with *V. pantothenicus* and four other species; *Gracilibacillus* and *Salibacillus* (Wainø *et al.*, 1999), which each contain two species of halophiles; *Geobacillus* (Nazina *et al.*, 2001) with ten species of thermophiles including *B. stearothermophilus*; *Ureibacillus* (Fortina *et al.*, 2001) with two round-spored, thermophilic species and single-membered *Marinibacillus* (Yoon *et al.*, 2001b). *Salibacillus* has subsequently been merged with *Virgibacillus* (Heyrman *et al.*, 2003).

Sporosarcina contains the motile, spore-forming coccus *S. ureae*, which is closely related to *B. sphaericus*, and five rod-shaped, round-spored species, including *B. pasteurii*, that have now been placed in this genus (Yoon *et al.*, 2001a). Other genera of aerobic endospore formers, not derived from *Bacillus*, are: *Sulfobacillus*, *Amphibacillus*,

Halobacillus, *Ammoniphilus*, *Thermobacillus*, *Filobacillus*, *Jeotgalibacillus* and *Lentibacillus*, but these and *Alicyclobacillus*, *Gracilibacillus*, and *Ureibacillus* strains are unlikely to be encountered in a clinical laboratory, and clinical isolates of *Geobacillus* and *Sporosarcina* have not been reported; so these genera will not be considered further.

Bacillus continues to accommodate the best-known species such as *B. subtilis* (the type species), *B. anthracis*, *B. cereus*, *B. licheniformis*, *B. megaterium*, *B. pumilus*, *B. sphaericus* and *B. thuringiensis*. It still remains a large genus, with nearly 80 species, as losses of species to other genera have been balanced by proposals for new *Bacillus* species (six species await transfer to *Geobacillus* and *Paenibacillus*). Members of the *B. cereus* group, *B. anthracis*, *B. cereus* and *B. thuringiensis*, are really pathovars of a single species (Turnbull *et al.*, 2002).

Unfortunately, taxonomic progress has not revealed readily determinable features characteristic of each genus. They show wide ranges of sporangial morphologies and phenotypic test patterns. Many recently described species represent genomic groups disclosed by DNA–DNA pairing experiments, and routine phenotypic characters for distinguishing some of them are very few and of unproven value. New species and subspecies of aerobic endospore formers are regularly described (47 in the 3 years January 2000 to January 2003, during which period no proposals for merging species had been made), but often on the basis of very few strains. The habitats and physiologies of most of these recently described organisms are such that only in extraordinary circumstances would they be of clinical interest, but several of the remainder, in addition to the well-established pathogens *B. anthracis* and *B. cereus*, must be considered because they do occasionally cause clinical problems and the frequency of recognition of these problems is increasing.

DESCRIPTIONS OF ORGANISMS

Although the production of resistant endospores in the presence of oxygen remains the defining feature for *Bacillus* and the new genera derived from it, the definition was undermined by the discoveries of *B. infernus* and *B. arseniciselenatis*, which are strictly anaerobic (Boone *et al.*, 1995; Switzer Blum *et al.*, 1998), and spores have not been observed in *B. halodenitrificans*, *B. infernus*, *B. selenitireducens*, *B. subterraneus* and *B. thermoamylovorans*.

Nonetheless, those species of *Bacillus* and related genera likely to be isolated in a clinical laboratory are rod-shaped, endospore-forming organisms which may be aerobic or facultatively anaerobic. They are usually Gram positive (in young cultures), but sometimes Gram variable or frankly Gram negative. They are mostly catalase positive and may be motile by means of peritrichous flagella. Most species are mesophilic, but *Bacillus* contains some thermophiles and psychrophiles, *Aneurinibacillus* and *Brevibacillus* both contain thermophilic species, and *Paenibacillus* contains one psychrophilic species.

Although the aerobic endospore-forming genera are physiologically heterogeneous, containing some species that do not sporulate readily, all the clinically significant isolates reported to date are of species that grow, and often sporulate, on routine laboratory media such as blood agar or nutrient agar, at 37 °C. It is unlikely that clinically important, but more fastidious, strains are being missed for want of appropriate growth conditions. Occasional isolates are sent to reference laboratories as *Bacillus* species because they are large Gram-positive rods, even though spores have not been seen, or sometimes because poly- β -hydroxybutyrate granules or other inclusion bodies have been mistaken for spores.

Bacillus anthracis and *B. cereus*

These are the two *Bacillus* species of greatest medical and veterinary importance, and together with *B. mycoides*, *B. thuringiensis*, *B. weihenstephanensis* (a psychrophile) and their more distant relative *B. pseudomycoides*, they form the *B. cereus* group.

The colonies of this group are very variable (Figure 9.1a–c) but usually recognizable nonetheless. They are characteristically large (2–7 mm in diameter, and usually near the top end of this range) and vary in shape from circular to irregular, with entire to undulate, crenate or fimbriate (medusa head) edges; they have matt or granular textures and have been likened to little heaps of ground glass. Smooth and moist colonies are not uncommon, however.

Although colonies of *B. anthracis* and *B. cereus* can be similar in appearance (Figure 9.1a,b), those of the former are generally smaller, are nonhemolytic, may show more spiking or tailing along the lines of inoculation streaks and are very tenacious as compared with the usually more butyrous consistency of *B. cereus* and *B. thuringiensis* colonies so that they may be pulled into standing peaks with a loop. The edges of *B. anthracis* colonies are often described as medusa head, but this is a character to be found throughout the *B. cereus* group. *Bacillus cereus* itself has colonies that are butyrous and cream to whitish in colour. The white colonies often contain spores. On blood agar, which is usually vigorously hemolysed, the colonies may be tinged with pigments derived from hemoglobin degradation. Fresh cultures characteristically smell mousy. *Bacillus mycoides* colonies are characteristically rhizoid or hairy looking, adherent and readily cover the whole surface of an agar plate.

Bacillus anthracis cells are Gram-positive, nonmotile rods, 1.0–1.2 \times 3.0–5.0 μ m. They commonly appear as long, entangled chains, but some strains of *B. cereus* and *B. mycoides* (which is nonmotile) may look similar. Fresh isolates of *B. anthracis*, and laboratory strains grown on serum-containing agar in the presence of carbon dioxide, produce a poly- γ -D-glutamic acid capsule. Spores are ellipsoidal, central or nearly so and do not cause the sporangium to swell. This organism is a chemoorganotroph and grows above 15–20 °C and below 40 °C; its optimum temperature is about 37 °C.

Bacillus cereus cells are Gram positive and similar in size to those of *B. anthracis* but are usually motile, and single organisms, pairs and short chains are more common than in *B. anthracis* cultures. Capsules are not formed, but spore and sporangial morphology are similar to those of *B. anthracis* (Figure 9.2a). *Bacillus cereus* is chemoorganotrophic and grows above 10–20 °C and below 35–45 °C with an optimum temperature of about 37 °C.

Bacillus thuringiensis can be distinguished from *B. cereus* by the production of parasporal crystals that may be toxic for insects and other invertebrates. These crystals may be observed in sporulated cultures (after 2–5 days incubation) by phase-contrast microscopy (Figure 9.2b) or by staining with malachite green. The spores may lie obliquely in the sporangium, as might happen in *B. cereus*.

Vegetative cells of all members of the *B. cereus* group may, when grown on a carbohydrate medium, accumulate poly- β -hydroxybutyrate, and their cytoplasm appears vacuolate or foamy.

Other Species

Outside the *B. cereus* group, aerobic endosporeformers show a very wide range of colonial morphologies, both within and between species (Figure 9.1). Colonial appearance varies from moist and glossy, through granular, to wrinkled. Shape varies from round to irregular, sometimes spreading, with entire, through undulate or crenate, to fimbriate edges. Diameters range from 1 to 5 mm. Colours commonly range from buff or creamy grey to off-white, and strains of some species may produce yellow, orange or pink pigment. Hemolysis may be absent, slight or marked, partial or complete. Elevations range from effuse, through raised, to convex. Consistency is usually butyrous, but mucoid and dry; adherent colonies are not uncommon. Despite this diversity, colonies of these organisms are not generally difficult to recognize, and some species have characteristic, yet seemingly infinitely variable, colonial morphologies, as with the *B. cereus* group. *Bacillus subtilis* (Figure 9.2h) and *B. licheniformis* produce similar colonies which are exceptionally variable in appearance and often

Figure 9.1 Colonies of aerobic endospore-forming bacteria on blood agar (a–c and g–l) and nutrient agar (d–f) after 24–36 h at 37 °C. Bar markers represent 2 mm. Figure 9.1 (Continued).

Figure 9.2 Photomicrographs of aerobic endospore-forming bacteria viewed by phase-contrast microscopy. Bar markers represent 2 μm . (a) *Bacillus cereus*, broad cells with ellipsoidal subterminal spores, not swelling the sporangia; (b) *B. thuringiensis*, broad cells with ellipsoidal subterminal spores, not swelling the sporangia and showing parasporal crystals of insecticidal toxin (arrowed); (c) *B. circulans*, ellipsoidal subterminal spores, swelling the sporangia; (d) *B. coagulans*, ellipsoidal subterminal spores, swelling the sporangia; (e) *B. megaterium*, broad cells with ellipsoidal and spherical subterminal and terminal spores, not swelling the sporangia and showing polyhydroxybutyrate inclusions (arrowed); (f) *B. pumilus*, slender cells with cylindrical subterminal spores not swelling the sporangia; (g) *B. sphaericus*, spherical terminal spores, swelling the sporangia; (h) *B. subtilis*, slender cells with ellipsoidal central and subterminal spores, not swelling the sporangia; (i) *Brevibacillus brevis*, ellipsoidal subterminal spores, one swelling its sporangium slightly; (j) *B. laterosporus*, ellipsoidal central spores with thickened rims on one side (arrowed), swelling the sporangia; (k) *Paenibacillus alvei*, cells with tapered ends, ellipsoidal paracentral to subterminal spores, not swelling the sporangium; (l) *P. polymyxa*, ellipsoidal paracentral to subterminal spores, slightly swelling the sporangia.

Figure 9.2 (Continued).

appear to be mixed cultures; colonies (Figure 9.1d) are irregular in shape, are of moderate (2–4 mm) diameter, range from moist and butyrous or mucoid, with margins varying from undulate to fimbriate, through membranous with an underlying mucoid matrix, with or without mucoid heading at the surface, to rough and are crusted as they dry. The licheniform colonies of *B. licheniformis* tend to be quite adherent. *Bacillus circulans* was so named because a protoplasm-like, circular motion of the interior of its colonies was observable by

low-power microscopy. Rotating and migrating microcolonies showing spreading growth (Figure 9.1e) were observed macroscopically in about 13% of strains received as *B. circulans* (Logan, Old and Dick, 1985), but the species is exceptionally heterogeneous and the strains with motile colonies have now been allocated to *Paenibacillus glucanolyticus*, *P. lautus*, and some unidentified *Paenibacillus* species. Clinical isolates previously identified as strains of *B. circulans* (Figure 9.2c) may therefore be *Paenibacillus* species. Motile microcolonies

with spreading growth are also characteristic of *P. alvei* (Figures 9.1f and 9.2k); plate cultures of this species will readily grow across the entire agar surface and commonly have an unpleasant smell.

Other species that have been encountered in the clinical laboratory include *B. coagulans* (Figure 2d), *B. megaterium* (Figures 9.1g and 9.2e), *B. pumilus* (Figures 9.1h and 9.2f), *B. sphaericus* (Figures 9.1i and 9.2g), *B. brevis* (Figures 9.1j and 9.2i), *B. laterosporus* (Figures 9.1k and 9.2j), *P. macerans* and *P. polymyxa* (Figures 9.1l and 9.2l), and they do not produce particularly distinctive growth; it must be appreciated that few species have colonies sufficiently characteristic or invariant to allow tentative identification, even by the experienced worker.

Microscopic morphologies, particularly of sporangia (Figure 9.2), are much more helpful than colonial characters in distinguishing between all these non-*B. cereus* group species. Vegetative cells are usually round ended, but cells of *P. alvei* may have tapered ends (Figure 9.2k). The large cells of *B. megaterium* (Figure 9.2e) may accumulate poly- β -hydroxybutyrate and appear vacuolate or foamy when grown on glucose nutrient agar. Overall, cell widths vary from about 0.5 to 1.5 μm and lengths from 1.5 to 5 μm . Most strains of these species are motile. Spore shapes vary from cylindrical (Figure 9.2f,k), through ellipsoidal (Figure 9.2a–d,h–j,l), to spherical (Figure 9.2e,g), and bean- or kidney-shaped, curved cylindrical and pear-shaped spores are occasionally seen. Spores may be terminally (Figure 2g,d,e), subterminally (Figure 9.2a–c,f,h,i,k,l) or centrally positioned (Figure 9.2f,j) within sporangia and may distend it (Figure 9.2c,d,g,i,j,l). Although there is some within-species and within-strain variation, spore shape, position and size tend to be characteristic of species and may allow tentative identification by the experienced worker. One species, *B. laterosporus*, produces very distinctive ellipsoidal spores, which have thickened rims on one side, so that they appear to be laterally displaced in the sporangia (Figure 9.2j).

All these species are mesophilic and will grow well between 30 and 37 °C; minimum temperatures for growth lie mostly between 5 and 20 °C, maxima mostly between 35 and 50 °C. For more information on growth temperatures, see Claus and Berkeley (1986).

NORMAL HABITATS

Bacillus anthracis

Long before this organism was recognized as the cause of anthrax, it was understood that putting animals to graze in certain places was likely to lead to an outbreak of the disease. At one time this was attributed to the persistence of spores in the soil, introduced from infected animals. This does not, however, explain the regular, seasonal outbreaks in some areas (anthrax districts) and the long intervals between infections in others. The spores remain viable in soil for many years, and their persistence does not depend on animal reservoirs so that *B. anthracis* is exceedingly difficult to eradicate from an endemic area. *Bacillus anthracis* continues to be generally regarded as an obligate pathogen. Its continued existence in the ecosystem appears to depend on a periodic multiplication phase within an animal host, with its environmental presence reflecting contamination from an animal source at some time (Lindeque and Turnbull, 1994); however, some authorities believe that self-maintenance may occur within certain soil environments (Cherkasskiy, 1999).

Other Species

Most aerobic endospore forming species are saprophytes widely distributed in the natural environment, but some species are opportunistic or obligate pathogens of animals, including humans, other mammals and insects. *Bacillus anthracis* is, to all intents and purposes, an obligate

pathogen of animals and humans. The habitats of most species are soils of all kinds, ranging from acid through neutral to alkaline, hot to cold and fertile to desert, and the water columns and bottom deposits of fresh and marine waters. Their endospores readily survive distribution in soils, dusts and aerosols from these natural environments to a wide variety of other habitats, and Nicholson *et al.* (2000) have considered the roles of *Bacillus* spores in the natural environment. Some species appear to be ubiquitous contaminants of man, other animals, their foodstuffs, water and environments, natural, domestic, industrial and hospital. Their wide distribution is in part owing to the extraordinary longevity of their endospores, which show much greater resistance to physical and chemical agents, such as heat, cold, desiccation, radiation, disinfectants, antibiotics and other toxic agents, than their counterpart vegetative cells. Endospores are typically more resistant to heat than vegetative cells by a factor of 10^3 or more, while resistance to UV and ionizing radiation may be 100-fold or more. If protected from radiation, spores may survive for very long periods. Striking claims include the isolation of a viable strain of *B. sphaericus* from an extinct bee preserved in 25- to 40-million-year-old amber (Cano and Borucki, 1995), and the recovery of an aerobic endospore former related to *Salibacillus* and *Virgibacillus* from a water droplet trapped in a Permian salt crystal for an estimated 250 million years (Vreeland, Rosenzweig and Powers, 2000); both isolations need to be confirmed by independent laboratories. *Bacillus infernus* was isolated from Triassic shales, lying at depths of around 2.7 km below the land surface, that may have been hydrologically isolated for 140 million years (Boone *et al.*, 1995). Another organism from a deep subsurface environment is *B. subterraneus*, which was isolated from the Great Artesian Basin of Australia (Kanso, Greene and Patel, 2002).

The commonly isolated species, such as *B. subtilis* and *B. cereus*, are very widely distributed worldwide; *B. thuringiensis* has been isolated from all continents, including Antarctica (Forsyth and Logan, 2000). In studies of indoor and outdoor air and dusts, *Bacillus* species commonly dominate the cultivable flora or form a large part of it. The presence of *B. fumarioli* strains showing similar phenotypic behavior and substantial genotypic similarity from Candlemas Island in the South Sandwich archipelago and from volcanoes some 5600 km distant on continental Antarctica is most convincingly explained by their carriage in the air as free spores or spores attached to plant propagules, as no birds are known to visit the latter sites (Logan *et al.*, 2000). Strains indistinguishable from these Antarctic isolates have been cultivated from gelatin production plants in Belgium, France and the USA.

Aerobic endospore formers are often isolated following heat treatment of specimens in order to select for spores, and presence of spores in a particular environment does not necessarily indicate that the organism is metabolically active there; however, it is reasonable to assume that large numbers of endospores in a given environment reflects former or current activity of vegetative cells there. Isolation of organisms showing special adaptations to the environments in which they are found, such as acidophily, alkaliphily, halophily, psychrophily and thermophily, suggests that these organisms must be metabolically active in these niches, but it tells us little about the importances of their roles in the ecosystems, and nothing about their interactions with other members of the flora.

Many species will degrade biopolymers, with versatilities varying according to species, and it is therefore assumed that they have important roles in the biological cycling of carbon and nitrogen; it is further assumed that their activities in food spoilage and biodegradation reflect the contamination of these materials by endospores derived from dusts and other vehicles. Valid though these assumptions may be, the ever-increasing diversity of known species and their apparent primary habitats imply that such generalizations may deserve reconsideration in some cases and that certain species may have quite specialized activities. Although isolates of many of the established species have been derived from soil, or from environments that may

have been contaminated directly or indirectly by soil, the range of isolation sources is very wide.

PATHOGENICITY

Bacillus anthracis

The spore is the primary infectious form of the organism, and infection occurs when endospores enter the body from the environment (Hanna and Ireland, 1999). Spores are rapidly phagocytosed by macrophages, some of which undergo lysis. In cases of inhalational anthrax the inhaled spores are carried, from the lungs (where there is no overt infection; thus pulmonary anthrax is a misnomer), by the surviving macrophages along the lymphatics toward the mediastinal lymph nodes, where the infection progresses. Germination and initial multiplication that begin within the macrophages may occur while in transit to the lymph nodes (Hanna and Ireland, 1999), but phagocytosed spores may not germinate for up to 60 days, and so incubation of the inhalational form of the disease may take between 2 days and 6–8 weeks; this latency does not appear to occur in the cutaneous form of the disease. By analogy with other *Bacillus* species, germination is presumed to be triggered by a specific chemical germinant, but this remains unidentified. The elevated CO₂ level and body temperature of the host cause the organism to transcriptionally activate the capsule and toxin genes. These genes are carried on two plasmids: plasmid pX01 encodes the toxin genes and plasmid pX02 encodes the capsule genes. Loss of either plasmid effectively renders the organism avirulent. The capsule of poly- γ -D-glutamic acid is purported to resist phagocytosis by virtue of its negative charge (Ezzell and Welkos, 1999). The anthrax toxin complex comprises three components: edema factor (EF), protective antigen (PA) and lethal factor (LF), none of which is toxic alone. EF and LF are active in binary combinations with PA and have different activities. PA molecules bind to molecules of a particular host cell membrane protein (anthrax toxin receptor or ATR) (Bradley *et al.*, 2001) and form ring-shaped prepores of heptameric oligomers (aggregates of seven); PA is then cleaved and hence activated by a furin-like protease on the surface of the cell under attack. An active PA heptamer can then bind one or more molecules of EF, LF or both. The complex passes into the cell by receptor-mediated endocytosis and into an acidified endosome; following conformational change of the heptamer in the low-pH environment, the complex escapes directly to the cytosol by insertion of the heptamer into the endosomal membrane. The PA–EF binary toxin interacts with the abundant host protein calmodulin (CaM; the major intracellular calcium receptor) and becomes an active adenylyl cyclase in most cell types; this elevates levels of the secretagogue cAMP and leads to hypovolemic shock. The crystal structure of EF in complex with CaM has been elucidated (Drum *et al.*, 2002). The PA–LF binary toxin is a zinc metalloprotease which cleaves members of the mitogen-activated protein kinase kinase family, thereby affecting certain signaling pathways, and levels of shock-inducing cytokines. This toxin primarily affects macrophages, and removal of macrophages from mice using silica renders them insensitive to the toxin (Hanna, 1999); however, the process which leads to macrophage lysis is unclear (Pannifer *et al.*, 2001). The importance of any interaction between EF and LF awaits clarification. Depending on the host, there is a rapid build up of the bacteria in the blood over the last few hours to terminal levels of 10⁷–10⁹/ml in the most susceptible species. The molecular pathogenesis of infection with *B. anthracis* was reviewed by Little and Ivins (1999).

Bacillus cereus

Bacillus cereus is next in importance to *B. anthracis* as a pathogen of humans (and other animals), causing food-borne illness and opportunistic

infections, and its ubiquity ensures that cases are not uncommon. *Bacillus cereus* causes two distinct food-poisoning syndromes, a diarrheal type and an emetic type. Both syndromes arise as a direct result of the fact that *B. cereus* spores can survive normal cooking procedures. Under improper storage conditions after cooking, the spores germinate and the vegetative cells multiply. In diarrheal illness, the toxin(s) responsible is produced by organisms in the small intestine (infective doses 10⁴–10⁹ cells per gram of food), while the emetic toxin is preformed and ingested in food (about 10⁵–10⁸ cells per gram in order to produce sufficient toxin). Variations in infective dose of the diarrheal illness are reflections of the proportion of ingested cells that are sporulated and so able to survive the acid barrier of the stomach. The capacity of the strain concerned to produce toxin(s) will, of course, influence the infective or intoxicating dose in both types of illness. It is likely that cases showing both diarrheal and emetic symptoms are caused by organisms producing both diarrheal and emetic toxins. Strains of *B. thuringiensis* commonly carry genes for *B. cereus* enterotoxins (Rivera, Granum and Priest, 2000). The safety of using *B. thuringiensis* as a biopesticide on crop plants has been reviewed by Bishop (2002); Bishop, Johnson and Perani (1999) found that the main pesticide strains that they assayed produced low titers of enterotoxin.

Toxins

The toxigenic basis of *B. cereus* food poisoning and other *B. cereus* infections has begun to be elucidated, and a complex picture is emerging (Beecher, 2001; Granum, 2002). *Bacillus cereus* is known to produce six toxins: five enterotoxins and the emetic toxin. The enterotoxins are: (i) hemolysin BL (Hbl), a 3-component proteinaceous toxin which also has dermonecrotic and vascular permeability activities and causes fluid accumulation in ligated rabbit ileal loops; Hbl is produced by about 60% of strains tested (Granum, 2002), and it has been suggested that it is a primary virulence factor in *B. cereus* diarrhea, but the mechanism of its enterotoxic activity is unclear (Granum, 2002); (ii) nonhemolytic enterotoxin (Nhe) is another 3-component proteinaceous toxin which is produced by most strains tested (Granum, 2002) and whose components show some similarities to Hbl; (iii) and (iv) enterotoxin T (BceT) and enterotoxin FM (EntFM) are single-component proteinaceous toxins whose roles and characteristics are not known; (v) enterotoxin K (EntK) is similar to the β -toxin of *Clostridium perfringens* and was associated with a French outbreak of necrotic enteritis in which three people died (Lund, De Buyser and Granum, 2000). The genetics of toxin production are summarized by Granum (2002).

The emetic toxin, cereulide, is a dodecadepsipeptide comprising a ring of four amino- and oxy-acids: [D-*O*-Leu-D-Ala-L-*O*-Val-L-Val] thrice repeated; it is closely related to the potassium ionophore valinomycin (Agata *et al.*, 1994). It is resistant to heat, pH and proteolysis, but it is not antigenic (Kramer and Gilbert, 1989). Cereulide is probably an enzymatically synthesized peptide rather than a direct genetic product; it is produced in larger amounts at lower incubation temperatures. Its production does not appear to be connected with sporulation (Finlay, Logan and Sutherland, 2000), and it is produced in aerobic and microaerobic but not anaerobic conditions (Finlay, Logan and Sutherland, 2002). Its mechanism of action is unknown, but it has been shown to stimulate the vagus afferent through binding to the 5-HT₃ receptor (Agata *et al.*, 1995). The earliest detection system for emetic toxin involved monkey-feeding tests (Logan *et al.*, 1979), but a semi-automated metabolic staining assay has now been developed (Finlay, Logan and Sutherland, 1999).

Molecular studies are giving valuable insights into genetic profiles among the *B. cereus* group (Keim *et al.*, 2000; Turnbull *et al.*, 2002), and the genomes of *B. anthracis* and *B. cereus* have been sequenced (Ivanova *et al.*, 2003; Read *et al.*, 2003).

EPIDEMIOLOGY

Bacillus anthracis

Life Cycle

The natural cycle of infection is as follows: a grazing animal ingests the spores which may then gain access to the lymphatics, and so to the spleen, through abrasions in the alimentary canal. After several days of the organism multiplying and producing toxin in the spleen, the animal suffers a sudden and fatal septicemia and collapses; hemorrhagic exudates escape from the mouth, nose and anus and contaminate the soil, where the vegetative cells sporulate in the air. In an infected herd of herbivores, not all the animals develop clinical disease, and there is serological evidence that mild and symptomless infections occur (Turnbull *et al.*, 1992a). The spores may remain viable in soil for many years and so the persistence of the organism does not depend on animal reservoirs; *B. anthracis* is therefore exceedingly difficult to eradicate from an endemic area. The organism continues to be generally regarded as an obligate pathogen, with its continued existence in the ecosystem appearing to depend on a periodic multiplication phase within an animal host and its environmental presence reflecting contamination from an animal source at some time. Excepting cases of carnivorous scavenging of meat from anthrax carcasses, direct animal-to-animal transmission within a species is very rare; however, such scavengers can show transient carriage of the organism (Lindeque and Turnbull, 1994).

Natural Epidemics

Anthrax is a disease of great antiquity, and descriptions are found in ancient literature such as Virgil's *Georgics* (36–29 BC). Although it is primarily a disease of herbivores, the disease appears to derive its name from the black eschar associated with human cutaneous infections, *anthrax* being the Greek word for coal. Before an effective veterinary vaccine became available in the late 1930s, it was one of the foremost causes of mortality in cattle, sheep, goats and horses worldwide. An outbreak in Iraq in 1945 killed 1 million sheep. The development and application of veterinary and human vaccines together with improvements in factory hygiene and sterilization procedures for imported animal products, and the increased use of artificial alternatives to animal hides or hair, have resulted over the past half century in a marked decline in the incidence of the disease in both animals and humans. Sites where these natural materials were formerly handled, such as disused tanneries, may be sources of infection when they are disturbed during redevelopment. Likewise, anthrax carcasses can remain infectious for many years, even when buried with quicklime. Nonendemic regions must be constantly on the alert for the arrival of *B. anthracis* in imported products of animal origin; the disease continues to be endemic in several countries of Africa, Asia and central and southern Europe, particularly those that lack an efficient vaccination policy.

Human Infection

Apart from artificial attacks, humans almost invariably contract anthrax directly or indirectly from animals. It is a point-source type of disease, and direct human-to-human transmission is exceptionally rare. Indeed, circumstantial evidence shows that humans are moderately resistant to anthrax as compared with obligate herbivores; infectious doses in the human inhalational and intestinal forms are generally very high (LD₅₀ 2500–55 000 spores). Naturally-acquired human anthrax may result from close contact with infected animals or their carcasses after death from the disease or be acquired by those employed in processing wool, hair, hides, bones or other animal products. Most cases (about 99%) are cutaneous infections, but

B. anthracis meningitis and gastrointestinal anthrax are occasionally reported. In industrial settings, inhalation of spore-laden dust used to occur, but cases of clinical disease were rare.

Bioterrorism

Anthrax weapons are normally intended to cause the inhalational form but are likely to cause cutaneous cases as well.

In public consciousness, *B. anthracis* is associated more with warfare and terrorism than with a disease of herbivores, and it is feared accordingly. It has long been considered a potential agent for biological warfare or bioterrorism. Its first use is believed to have been against livestock during World War I (Christopher *et al.*, 1997; Barnaby, 2002). It has been included in various development and offensive programmes in several countries since (Zilinskas, 1997; Mangold and Goldberg, 1999; Miller, Engelberg and Broad, 2001; Barnaby, 2002; Alibek, 2003), and it has also been used in terrorist attacks (Christopher *et al.*, 1997; Lane and Fauci, 2001). There have been a few reports of laboratory-acquired infections, none of them recent (Collins, 1988), but a major outbreak of anthrax occurred in April 1979 in the city of Sverdlovsk (now Yekaterinburg) in the Urals as a result of the accidental release of spores from a military production facility; 77 cases were recorded, and 66 patients died (Meselson *et al.*, 1994).

Bacillus cereus

The diarrheal type of food-borne illness is characterized by abdominal pain with diarrhea 8–16 h after ingestion of the contaminated food and is associated with a diversity of foods from meats and vegetable dishes to pastas, desserts, cakes, sauces and milk. The emetic type of illness, a true food poisoning, is characterized by nausea and vomiting 1–5 h after eating the offending food, predominantly oriental rice dishes, although occasionally other foods such as pasteurized cream, milk pudding, pastas and reconstituted infant-feed formulas have been implicated. One outbreak followed the mere handling of contaminated rice in a children's craft activity (Briley, Teel and Fowler, 2001). Cases may occur at any time of year – as would be expected, as they are caused by improper food handling – and without any particular distribution pattern within a country. Between countries, however, there are differences in the proportions of all outbreaks of food-borne disease that are caused by *B. cereus*, but it is probable cases are underreported.

Other *B. cereus* infections occur mainly, though not exclusively, in persons predisposed by extremes of age, trauma, neoplastic disease, immunosuppression, alcoholism and other drug abuse, or some other underlying condition, and fatalities occasionally result. In the case of posttraumatic endophthalmitis, *Bacillus* species, particularly *B. cereus*, may be the second most commonly isolated organisms after *Staphylococcus epidermidis*. Endophthalmitis may follow penetrating trauma of the eye or hematogenous spread, evolving very rapidly. Loss of both vision and the eye is likely if appropriate treatment is instituted too late (Davey and Tauber, 1987).

Other Species

Opportunistic infections with aerobic endospore formers have been reported since the late nineteenth century. Given the ubiquity of these organisms, infections with them might be commonplace were it not for their low invasiveness and virulence. It is certain that many clinically significant isolates of *Bacillus* were disregarded in the past, and the perceived difficulties of identification may have contributed to this. Although awareness is now better than ever, the problem remains one of recognizing what is a contaminant and what is not. A common feature of case reports, right up to the present, has been emphasis on

the importance of interpreting spore-forming isolates in light of any other species cultured and the clinical context and the danger of dismissing them as mere contaminants. The fact that individual case histories of infections with these organisms continue to warrant published reports indicates that incidents are rare and that authors feel that awareness needs to be improved. The earlier literature was reviewed by Norris *et al.* (1981) and Logan (1988). The factors contributing to the increasing frequency with which opportunistic infections are encountered are well known: host predisposition by suppressed or compromised immunity; malignant disease or metabolic disorder; exposure by accidental trauma and clinical and surgical procedures; drug abuse and advances in bacteriological technique, interpretation and awareness. It seems unlikely that these organisms have changed in virulence over the last century. Although reports of infections with non-*B. cereus* group species are comparatively rare, they are very diverse, and there have been several hospital pseudoepidemics associated with contaminated blood culture systems.

CLINICAL FEATURES

Bacillus anthracis

Cutaneous Infection

The organism is not invasive, and cutaneous infections occur through breaks in the skin; so the lesions generally occur on exposed regions of the body. This may include the eyelids. Before the availability of antibiotics and vaccines, 10–20% of untreated cutaneous cases were fatal, and the rare fatalities seen today are due to obstruction of the airways by the edema that accompanies lesions on the face or neck, and sequelae of secondary cellulitis or meningitis. The incubation period in cutaneous anthrax is generally 2–3 days (with extremes of approximately 12 h to 2 weeks). Results from a study of cutaneous anthrax cases in Turkey indicate that these occur in decreasing order of frequency on hands and fingers, eyelids and face, wrists and arms, feet and legs and neck (Doganay, 1990). A small pimple or papule appears, and over the next 24 h, a ring of vesicles develops around it, and it ulcerates, dries and blackens into the characteristic necrotic eschar (Figure 9.3a). Differential diagnoses include other cutaneous and subcutaneous infections (Hart and Beeching, 2002). The eschar enlarges, becoming thick and adherent to underlying tissues over the ensuing week, and it is surrounded by edema, which may be very extensive (Figure 9.3b). Pus and pain are normally absent; their presence, or the presence of marked lymphangitis and fever, probably indicates secondary bacterial infection. Historical records show mortality rates of approximately 20% in untreated cutaneous cases.

Inhalational Infection

Inhalational (formerly called pulmonary) anthrax cases are more often fatal than cutaneous cases, because they go unrecognized until too late for effective therapy, but undiagnosed, low-grade infections with recovery may occur. Analysis of ten of the cases associated with the bioterrorist events of 2001, in which spores were delivered in mailed letters and packages (Jernigan *et al.*, 2001), revealed a median incubation period of 4 days (range 4–6 days) and a variety of symptoms at initial presentation including fever or chills, sweats, fatigue or malaise, minimal or nonproductive cough, dyspnea and nausea or vomiting. All patients had abnormal chest X-rays with infiltrates, pleural effusion and mediastinal widening. Mediastinal lymphadenopathy was present in seven cases. The number of recorded cases of inhalational anthrax is lower than that might be expected from the high profile given to this condition. In the 20th century there were just 18 reported cases (two of them being laboratory acquired) in the USA, 16 (88.9%) fatal (Brachman and Kaufmann, 1998); figures in the UK

showed a similar picture. In 11 confirmed cases of inhalational anthrax that followed the bioterrorist attack in the USA, early recognition and treatment helped a survival level of 55% to be achieved (Jernigan *et al.*, 2001; Bell, Kozarsky and Stephens, 2002). It is possible that undiagnosed, low-grade inhalational infections with recovery may occur.

Gastrointestinal Infection

Oropharyngeal and gastrointestinal anthrax are not uncommon in endemic regions of the world where socioeconomic conditions are poor, and people eat the meat of animals that have died suddenly; such cases are greatly underreported. They are essentially cutaneous anthrax occurring on the oropharyngeal and gastrointestinal mucosae. Symptoms of gastroenteritis may occur prior to onset of systemic symptoms. Gastrointestinal infections are mainly characterized by gastroenteritis, and asymptomatic infections and symptomatic infections with recovery are not uncommon. The symptoms of oropharyngeal infections are fever, toxemia, inflammatory lesions in the oral cavity and oropharynx, cervical lymph node enlargement and edema, and there is a high case-fatality rate (Sirisanthana and Brown, 2002).

Meningitis

Meningitis can develop from any of the forms of anthrax. The emergence of clinical signs is rapidly followed by unconsciousness, and the prognosis is poor. Outbreaks of primary anthrax meningoencephalitis have been reported from India and elsewhere (George *et al.*, 1994; Kwong *et al.*, 1997).

In fatal cases of any of the human forms of anthrax, the generalized symptoms may be mild (fatigue, malaise, fever and/or gastrointestinal symptoms) and are followed by sudden onset of acute illness with dyspnoea, cyanosis, severe pyrexia and disorientation followed by circulatory failure, shock, coma and death, all within a few hours.

Bacillus cereus

Enteric Disease

The diarrheal, or long incubation, form of *B. cereus* food poisoning has an onset period of 8–16 h, followed by abdominal cramps, profuse watery diarrhea and rectal tenesmus. Occasionally there is fever and vomiting. Thus the symptoms are similar to those of *C. perfringens* food poisoning. Recovery is usually complete in 24 h, although there have been two reports of death (Logan, 1988). Emetic food poisoning due to *B. cereus* is characterized by a shorter onset period of 1–6 h, and the symptoms resemble those of *S. aureus* food poisoning. Nausea, vomiting and malaise, occasionally with diarrhea, characterize the disease. There are rarely complications, and recovery within 24 h is usual, but fulminant liver failure associated with the emetic toxin has been reported (Mahler *et al.*, 1997).

Ocular Disease

Bacillus cereus is one of the most virulent and destructive of ocular pathogens. The most serious of these conditions is panophthalmitis, a rapidly developing infection which may follow penetrating trauma of the eye (commonly by a metal fragment in an environment such as a farm or a garage), intraocular surgery, or hematogenous dissemination of the organism from another site (typically in intravenous drug abusers). Either way, the condition usually evolves so rapidly that irreversible damage occurs before effective treatment can be started; vision is therefore lost, and loss of the eye is normal. *Bacillus cereus* keratitis associated with contact lens wear has also been reported (Pinna *et al.*, 2001).

Figure 9.3 (a) Anthrax infection of the forearms. (Photograph kindly supplied by Professor Mehmet Doganay, Erciyes Universitesi, Kaysari, Turkey.) (b) Anthrax infection of the eye. The characteristic black eschar on the upper lid, particularly, is evident. The eye itself is usually not damaged. Edema of the right side of the face can also be seen. (Photograph kindly supplied by Professor Mehmet Doganay, Erciyes Universitesi, Kaysari, Turkey.)

Other Conditions

Other reported conditions associated with *B. cereus* infection include bacteremia, septicemia, fulminant sepsis with hemolysis, meningitis, brain hemorrhage, ventricular shunt infections, infections associated with central venous catheters, endocarditis (which may be associated with prosthetic valves or intravenous drug abuse), pseudomembranous tracheobronchitis, pneumonia, empyema, pleurisy, lung abscess, brain abscess, osteomyelitis, salpingitis, urinary tract infection and primary cutaneous infections. Wound infections, mostly in otherwise healthy persons, have been reported following surgery, road traffic and other accidents, scalds, burns, plaster fixation, drug injection (including a case associated with contaminated heroin) (Dancer *et al.*, 2002) and close-range gunshot and nail-bomb injuries; some became necrotic and gangrenous. A fatal inflammation was caused by a blank firearm injury; blank cartridge propellants are commonly contaminated with the organism (Rothschild and Leisenfeld, 1996). Neonates also appear to be particularly susceptible to *B. cereus*, especially with umbilical stump infections; respiratory tract infections associated with contaminated ventilation systems have also occurred (Van der Zwet *et al.*, 2000); other infections reported in neonates include intestinal perforation, meningoencephalitis and bacteremia refractory to therapy. There have been reports of wound, burn and ocular infections with *B. thuringiensis* (Damgaard *et al.*, 1997), but there is as yet no evidence of infections associated with the use of this organism as an insecticide. *Bacillus cereus* also causes infections in domestic animals. It is a well-recognized agent of mastitis and abortion in cattle and can cause these conditions in other livestock (Blowey and Edmondson, 1995).

Bacillus thuringiensis is a close relative of *B. cereus* and may produce the *B. cereus* diarrheal toxin, and it has indeed been implicated in cases of gastroenteritis (Damgaard *et al.*, 1997). There have also been reports of wound, burn and ocular infections with *B. thuringiensis* (Damgaard *et al.*, 1997). Cases of illness caused by *B. thuringiensis* may have been diagnosed as caused by *B. cereus*, as the former may not produce its characteristic insecticidal toxin crystals when incubated at 37°C, owing to the loss of the plasmids carrying the toxin genes.

Other Species

In addition to *B. cereus*, a wide range of other aerobic endospore-forming bacteria have been isolated in association with endophthalmitis (Das *et al.*, 2001). *Bacillus licheniformis* has been reported from ventriculitis following the removal of a meningioma, cerebral abscess after penetrating orbital injury (Jones, Hanson and Logan, 1992), septicemia following arteriography, bacteremia associated with indwelling central venous catheters (Blue, Singh and Saubolle, 1995), bacteremia during pregnancy with eclampsia and acute fibrinolysis, peritonitis in a CAPD patient and in a patient with volvulus and small-bowel perforation, ophthalmitis and corneal ulcer after trauma. There have also been reports of L-form organisms, phenotypically similar to *B. licheniformis*, occurring in blood and other body fluids of patients with arthritis, patients with neoplasms, clinically normal persons, and in association with infectious synovitis in birds. Although some authors have claimed a relationship between these organisms and diseases with postulated immunological elements, and higher isolations from the synovial fluids and membranes of arthritic patients have been reported, Bartlett and Bisset (1981) were unable to confirm the latter association. *Bacillus licheniformis* can cause food-borne diarrheal illness and has been associated with an infant fatality (Mikkola *et al.*, 2000). A toxin possibly associated with *B. licheniformis* food poisoning has been identified (Mikkola *et al.*, 2000), but in general, toxins or virulence factors widely accepted as responsible

for symptoms periodically associated with *Bacillus* species other than those in the *B. cereus* group have not been identified. *Bacillus licheniformis* is frequently associated with bovine abortion and has been reproduced by experimental infection of cows, which demonstrated the tropism of the organism for the bovine placenta (Agerholm *et al.*, 1997); this species has also been associated with abortion in water buffalo (Galiero and De Carlo, 1998) and is occasionally associated with bovine mastitis (Blowey and Edmondson, 1995). Many of these types of *B. licheniformis* and *B. cereus* infections are associated with wet and dirty conditions during winter housing, particularly when the animals lie in spilled silage (Blowey and Edmondson, 1995); in one outbreak, a water tank contaminated with *B. licheniformis* was implicated (Parvanta, 2000).

The name *B. subtilis* was often used to mean any aerobic, endospore-forming organism, but since 1970, there have been reports of infection in which identification of this species appears to have been made accurately. Cases associated with neoplastic disease include fatal pneumonia and bacteremia, a septicemia and an infection of a necrotic axillary tumor in breast cancer patients. Breast prosthesis and ventriculoatrial shunt infections, endocarditis in a drug abuser, meningitis following a head injury, cholangitis associated with kidney and liver disease, isolations from dermatolymphangioadenitis associated with filarial lymphedema (Olszewski *et al.*, 1999) and surgical wound drainage sites have also been reported. A probiotic preparation of this species led to a fatal septicemia in an immunocompromised patient (Oggioni *et al.*, 1998). *Bacillus subtilis* has also been implicated in food-borne illness and cases of bovine mastitis and of ovine abortion (Logan, 1988).

Organisms identified as *B. circulans* have been isolated from cases of meningitis, a cerebrospinal fluid shunt infection, endocarditis, endophthalmitis (Tandon *et al.*, 2001), a wound infection in a cancer patient and a bite wound. Roy *et al.* (1997) reported epidemic endophthalmitis associated with isolates identified as *B. circulans* that contaminated a product used during cataract surgery. It must be noted, however, that many isolates previously identified as *B. circulans* might have been misallocated (see comments on this species in *Descriptions of Organisms* above). *Bacillus coagulans* has been isolated from corneal infection, bacteremia and bovine abortion. *Bacillus pumilus* has been found in cases of pustule and rectal fistula infection, and in association with bovine mastitis. *Bacillus sphaericus* has been implicated in a fatal lung pseudotumor and a case of meningitis and has been associated with food-borne illness (Turnbull and Kramer, 1995). Among 18 cancer patients with 24 bacteremic episodes, Banerjee *et al.* (1988) isolated *B. cereus* (eight cases), *B. circulans* (three cases), *B. subtilis* (two cases), *B. coagulans* (one case), *B. licheniformis* (one case), *B. pumilus* (one case), *B. sphaericus* (one case) and six unidentified aerobic endospore formers.

Bacillus brevis has been isolated from corneal infection and has been implicated in several incidents of food poisoning; since these reports, the species was split and transferred to the new genus *Brevibacillus*. Strains of the new species, *B. agri*, have been isolated in association with an outbreak of water-borne illness in Sweden (Logan *et al.*, 2002), and other *Brevibacillus* species have been found in human blood and bronchioalveolar lavage specimens. *Brevibacillus laterosporus* has been reported in association with a severe case of endophthalmitis.

Paenibacillus alvei has been isolated from cases of meningitis, endophthalmitis, a prosthetic hip infection in a patient with sickle cell anemia, a wound infection and, in association with *C. perfringens*, a case of gas gangrene. *Paenibacillus popilliae* has been reported from endocarditis (Wu *et al.*, 1999). *Paenibacillus macerans* has been isolated from a brain abscess following penetrating periorbital injury, a wound infection following removal of a malignant melanoma, catheter-associated infection in a leukemic patient and from bovine abortion, and *P. polymyxa* has been isolated from ovine abortion.

LABORATORY DIAGNOSIS

Safety

Bacillus anthracis

Anthrax is not highly contagious. Cutaneous anthrax is readily treated and is only life threatening in exceptional cases, and the infectious doses in the human inhalational and intestinal forms (also treatable if recognized early) are generally very high. The LD₅₀ is of the order of 10 000 spores, although in the bioterrorist events of 2001 it would appear that at least some of the 11 inhalational cases resulted from exposures to considerably less than this figure. In general, precautions need to be sensible, not extreme. When collecting specimens related to suspected anthrax, disposable gloves, disposable apron or overalls and boots which can be disinfected after use should be worn. For dusty samples that might contain many spores, the use of headgear and dust masks should be considered.

Disposable items should be discarded into suitable containers for autoclaving followed by incineration. Nonautoclavable items should be immersed overnight in 10% formalin (5% formaldehyde solution; 5% glutaraldehyde is also effective). Items that cannot be immersed should be bagged and sent for formaldehyde fumigation. Ethylene oxide and hydrogen peroxide vapor are also effective fumigants, but the latter is inappropriate if organic matter is being treated. The best disinfectant for specimen spillages is again formalin, but where this is considered impractical, 10% hypochlorite solution can be used, but it is rapidly neutralized by organic matter and it corrodes metals. Other strong oxidising agents, such as hydrogen peroxide (5%) and peracetic acid (1%), are also effective but with the same limitations with respect to organic matter. For further discussion, see Turnbull *et al.* (1998). Isolation and presumptive identification of *B. anthracis* can be performed safely in the routine clinical microbiology laboratory, provided that normal good laboratory practice is observed; vaccination is not required for minimal handling of the organism. If aerosols are likely to be generated, the work should be performed in a safety cabinet.

In the case of suspected bioterrorism the laboratory examination of clinical specimens will be as described above for cases of naturally-acquired anthrax, but nonclinical materials may be very hazardous and no attempt to process them should be made without the appropriate instructions from the correct authorities.

Other Species

Clinical specimens for isolation of other aerobic endospore-forming species need no special precautions and can be collected, transported and cultivated in the normal way and handled safely on the open bench.

Specimens and Isolation

Bacillus anthracis

In specimens submitted for isolation of *B. anthracis* from old carcasses, animal products or environmental specimens, the organisms will mostly be present as spores, and these may be selected for by heat treatment (see *Heat treatment* below). There is no effective enrichment method for *B. anthracis* in old animal specimens or environmental samples; isolation from these is best done with polymyxin-lysozyme EDTA-thallos acetate (PLET) agar (Knisely, 1966). Aliquots (250 µl) of the undiluted and 1:10 and 1:100 dilutions of heat-treated suspension of the specimen are spread across PLET plates which are read after incubation for 36–40 h at 37 °C. Colonies of *B. anthracis* are smaller and smoother than on plain heart infusion agar, and *B. cereus* is generally inhibited by the medium. To make the

PLET medium, heart infusion agar (or heart infusion broth with other agar base) is prepared according to the manufacturer's instructions. EDTA (0.3 g/l) and thallos acetate (0.04 g/l) are added before autoclaving. (Note: thallos acetate is poisonous; avoid skin contact and inhalation by wearing gloves and weighing out the powder in a fume cupboard.) After autoclaving at 121 °C for 15 min, the agar is cooled to 50 °C and polymyxin (30 000 units/l) and lysozyme (300 000 units/l) are added in filter-sterilized solutions. It is important that the agar is left at 50 °C for long enough to ensure that this temperature has been reached throughout the medium before the polymyxin and lysozyme are added. After swirling to ensure even suspension of the ingredients, the agar is poured into Petri dishes.

Roughly circular, creamy-white colonies, 1–3 mm diameter, with a ground-glass texture are subcultured (i) on blood agar plates to test for γ phage and penicillin susceptibility, and for hemolysis, and (ii) directly or subsequently in blood (or bicarbonate agar, see subsection *Bacillus anthracis*, under *Diagnosis*, below) to look for capsule production using M'Fadyean's stain or by indirect fluorescent antibody capsule staining. PCR-based methods are being used increasingly for confirming the identity of isolates (see subsection *Bacillus anthracis*, under *Diagnosis*, below).

In all human anthrax cases, specimens from possible sources of the infection (carcass, hides, hair, bones, etc.) should be sought in addition to specimens from the patients themselves. Swabs are appropriate for collecting vesicular fluid from cutaneous cases. Adequate material should be submitted for both culture and a smear for visualizing the capsule. Intestinal anthrax will be suspected only if an adequate history of the patient is known. If the patient is not severely ill, a fecal specimen may be collected, but isolation of *B. anthracis* may not be successful. If the patient is severely ill, blood should also be cultured, although isolation may not be possible after antimicrobial treatment, and such treatment should not await laboratory results. A blood smear may reveal the capsulated bacilli or, if treatment has started, capsule ghosts.

Postmortem blood may be collected by venipuncture, because it is characteristic of anthrax that the blood does not clot at death, and it should be examined by smear (for capsule) and culture. Any hemorrhagic fluid from nose, mouth or anus should be cultured, and if these are positive, no further specimens are required; if they are negative, specimens of peritoneal fluid, spleen and/or mesenteric lymph nodes, aspirated by techniques avoiding spillage of fluids, may be collected.

Inhalational anthrax will only be suspected if the patient's history suggests it. Unless the patient is severely ill, immediate specimen collection is likely to be unfruitful and the person should be treated and simply observed. Paired sera (when first seen and >10 days later) may be collected for subsequent confirmation of diagnosis. In the severely ill patient, blood smear and culture are necessary, but results will depend somewhat on any previous antibiotic treatment. The approach given for intestinal anthrax should be followed for postmortem cases.

Other Species

All the clinically significant isolates reported to date are of species that grow, and often sporulate, on routine laboratory media at 37 °C. It seems unlikely that many clinically important, but more fastidious, strains are being missed for the want of special media or growth conditions.

Enrichment procedures are generally inappropriate for isolations from clinical specimens, but when searching for *B. cereus* in stools ≥ 3 days after a food-poisoning episode, nutrient or tryptic soy broth with polymyxin (100 000 U/l) may be added to the heat-treated specimen.

Several media have been designed for isolation, identification and enumeration of *B. cereus*, and some of these are available commercially. They exploit the organism's egg-yolk reaction positivity and

acid-from-mannitol negativity; pyruvate and polymyxin may be included for selectivity. Three satisfactory formulations are MEYP (mannitol, egg yolk, polymyxin B agar), PEMBA (polymyxin B, egg yolk, mannitol, bromthymol blue Agar) and BCM (*B. cereus* medium) (van Netten and Kramer, 1992). There are no selective media for other bacilli, but spores can be selected for by heat treating part of the specimen, as described below; the vegetative cells of both spore formers and nonsporeformers will be killed, but the heat-resistant spores will not only survive but may be heat-shocked into subsequent germination. The other part of the specimen is cultivated without heat treatment in case spores are very heat sensitive or absent. Heat treatment is not appropriate for fresh clinical specimens, where spores are usually sparse or absent.

Heat Treatment

For specimens with mixed microflora, heating at 62.5 °C for 15 min will both heat-shock the spores and effectively destroy nonspore-forming contaminants [solid samples should first be emulsified in sterile, deionized water, 1:2 (w/v)]. Direct plate cultures are made on blood, nutrient or selective agars, as appropriate, by spreading up to 250 µl volumes from undiluted and tenfold and 100-fold dilutions of the treated sample.

Maintenance

Maintenance is simple if spores can be obtained, but it is a mistake to assume that a primary culture or subculture on blood agar will automatically yield spores if stored on the bench or in the incubator. It is best to grow the organism on nutrient agar or trypticase soy agar containing 5 mg/l of manganese sulphate for a few days and refrigerate when microscopy shows that most cells have sporulated. For most species, sporulated cultures on slants of this medium, sealed after incubation, can survive in a refrigerator for years. Alternatively, cultures (preferably sporulated) can be frozen at -70 °C or lyophilized.

Diagnosis

It is important to appreciate that these organisms do not always stain Gram positive. Although Gram staining is considered to be of limited value in anthrax diagnosis, because it does not reveal the capsule, it was found to be useful during the American bioterrorism attack in 2001. In a well-developed country it is unlikely that large numbers of Gram-positive bacteria in the blood at death are going to be anything but *B. anthracis*, particularly when this is supported by the recent history of events. Before attempting to identify to species level it must be confirmed that the isolate really is an aerobic endospore former and that other inclusions are not being mistaken for spores. A Gram-stained smear showing cells with unstained areas suggestive of spores can be stripped of oil with acetone/alcohol, washed, and then stained for spores. Spores are stained in heat-fixed smears by flooding with 10% aqueous malachite green for up to 45 min (without heating), followed by washing and counterstaining with 0.5% aqueous safranin for 30 s; spores are green within pink or red cells at ×1000 magnification. Phase contrast (at ×1000 magnification) should be used if available, as it is superior to spore staining and more convenient. Spores are larger, more phase-bright and more regular in shape, size and position than other kinds of inclusion such as polyhydroxybutyrate (PHB) granules (Figure 2e), and sporangial appearance is valuable in identification. Details of colonial and sporangial morphologies of the more frequently encountered species are given above (see *Descriptions of Organisms*).

Members of the *B. cereus* group and *B. megaterium* will produce large amounts of storage material when grown on carbohydrate media, but on routine media this vacuolate or foamy appearance is

rarely sufficiently pronounced to cause confusion. Isolates of other organisms have often been submitted to reference laboratories as *Bacillus* species because they were large, aerobic Gram-positive rods, even though sporulation had not been observed, or because PHB granules or other storage inclusions had been mistaken for spores.

The most widely used diagnostic schemes use traditional phenotypic tests (Gordon, Haynes and Pang, 1973) or miniaturized tests in the API 20E and 50CHB Systems (Logan and Berkeley, 1984; Logan, 2002; bioMérieux, Marcy l'Etoile, France). The API 20E/50CHB kits can be used for the presumptive distinction of *B. anthracis* from other members of the *B. cereus* group within 48 h. bioMérieux also offers a *Bacillus* card for the Vitek automated identification system. As many new species have been proposed since these schemes were established, updated API and Vitek databases need to be prepared. Biolog (Biolog Inc., Hayward, CA, USA) also offers a *Bacillus* database. The effectiveness of such kits can vary with the genera and species of aerobic endospore formers concerned, but they are improving with continuing development and increased databases (Logan, 2002). It is stressed that their use should always be preceded by the basic characterization tests described below.

Other approaches include chemotaxonomic fingerprinting by fatty acid methyl ester (FAME) profiling, polyacrylamide gel electrophoresis (PAGE) analysis, pyrolysis mass spectrometry and Fourier-transform infrared spectroscopy. All these approaches have been successfully applied either across the genera or to small groups. As with genotypic profiling methods, large databases of authentic strains are necessary; some of these are commercially available, such as the Microbial Identification System software (Microbial ID, Inc., Newark, DE, USA) database for FAME analysis.

For diagnostic purposes, the aerobic endospore formers comprise two groups, the reactive ones that will give positive results in various routine biochemical tests, and which are therefore easier to identify, and the nonreactive ones which give few if any positive results in such tests. Nonreactive isolates may belong to the genera *Brevibacillus* or *Aneurinibacillus*, or be members of the *B. sphaericus* group or *B.adius*.

Bacillus anthracis

It is generally easy to distinguish virulent *B. anthracis* from other members of the *B. cereus* group. An isolate with the correct colonial morphology, white or grey in colour, nonhemolytic or only weakly hemolytic, nonmotile, susceptible to the diagnostic γ phage and penicillin and able to produce the characteristic capsule (as shown by M'Fadyean staining or indirect fluorescent antibody staining) is *B. anthracis*. (Enquiries about γ phage and indirect fluorescent antibody capsule staining should be addressed to the Diagnostics Systems Division, USAMRIID, Fort Detrick, Frederick, MD 21702-5011, USA.)

An isolate with the characteristic phenotype but unable to produce capsules may be an avirulent form lacking either its capsule or toxin genes or both (Turnbull *et al.*, 1992b) and should be referred to a specialist laboratory; such isolates are generally found in environmental samples, but they may be identified as *B. cereus* and discarded by routine laboratories.

The capsule of virulent *B. anthracis* can be demonstrated on nutrient agar containing 0.7% sodium bicarbonate incubated overnight under 5-7% CO₂ (candle jars perform well). Colonies of the capsulated *B. anthracis* appear mucoid, and the capsule can be visualized by staining smears with M'Fadyean's polychrome methylene blue or India ink (Turnbull *et al.*, 1998) or by indirect fluorescent antibody staining. More simply, 2.5 ml of blood (defibrinated horse blood seems best; horse or fetal calf serum are quite good) can be inoculated with a pinhead quantity of growth from the suspect colony, incubated statically for 6-18 h at 37 °C and M'Fadyean stained. For M'Fadyean staining, make a thin smear from the specimen, and also from a positive control, on a clean slide and allow to dry. Fix by immersion in

95% or absolute alcohol for 30–60 s. Put a large drop (approximately 50 µl) of polychrome methylene blue (M'Fadyean stain) on the smear, and ensure all the smear is covered by spreading the stain with an inoculating loop (flooding the slide is wasteful, unnecessary and ecologically undesirable). Leave for 1 min and wash the stain off with water (into 10% hypochlorite solution). Blot the slide and allow to dry. At ×100–400 magnification, the organisms can be seen as fine short threads; at ×1000 magnification (oil immersion), if virulent *B. anthracis* is present, the capsule should be seen as a clearly demarcated zone around the blue-black, often square-ended rods which lie in short chains of two to a few cells in number. The positive control can be prepared by culturing a virulent strain in defibrinated horse blood as described above. The M'Fadyean stain is preferable to other capsule staining methods, as it is more specific for *B. anthracis* capsules. It dates from 1903 and has proved a remarkably successful rapid diagnostic test since. However, reliable stain and adequate quality control of its performance are becoming hard to guarantee.

Primer sequences are now available for confirming the presence of the toxin and capsule genes (Jackson *et al.*, 1998) and hence the virulence of an isolate. Real-time PCR assays, which use primer and fluorescently-labeled probe systems to allow the rapid and sensitive detection of genes specific for *B. anthracis*, have been developed in several laboratories. Makino and Cheun (2003) described an assay that targeted genes for capsule and PA and allowed a single spore to be detected in 100 l of air in 1 h. Drago *et al.* (2002) outlined an assay targeting fragments of a chromosomal gene (*rpo*) for detecting the organism in clinical samples. Hoffmaster *et al.* (2002) evaluated and validated a three-target assay, with primers for capsule, PA and *rpo*, in order to test suspect isolates and to screen environmental samples during the outbreak that followed the 2001 bioterrorist attack in the USA.

Monoclonal antibody tests based on specific spore cortex or cell wall epitopes, for reliable differentiation of *B. anthracis* from close relatives, are not yet available. King *et al.* (2003) assessed three commercially available immunoassays for the direct detection of *B. anthracis* spores but found that they were limited by their sensitivities, needing at least 10⁵–10⁶ spores per sample. Breakthroughs have recently been made in the long-standing problem of differentiating strains of *B. anthracis* for epidemiological and strategic purposes using amplified fragment length polymorphism (AFLP) analysis (Jackson *et al.*, 1998; Keim *et al.*, 2000).

The three protein components of anthrax toxin [protective antigen (PA), lethal factor (LF) and edema factor (EF)] and antibodies to them can be used in enzyme immunoassay systems. For routine confirmation of anthrax infection, or for monitoring response to anthrax vaccines, antibodies against protective antigen alone appear to be satisfactory; they have proved useful for epidemiological investigations in humans and animals. In human anthrax, however, early treatment sometimes prevents antibody development (Turnbull *et al.*, 1992a).

Schuch, Nelson and Fischetti (2002) found that the PlyG lysin of γ phage may be used to detect *B. anthracis* by luminescence and that the same lysin could kill vegetative cells and germinating spores.

Bacillus cereus

A strain differentiation system for *B. cereus* based on flagellar (H) antigens is available at the Food Hygiene Laboratory, Central Public Health Laboratory, Colindale, London, UK, for investigations of food-poisoning outbreaks or other *B. cereus*-associated clinical problems. *Bacillus thuringiensis* strains are also classified on the basis of their flagellar antigens; 82 serovars have been recognized. This is done at the Pasteur Institute, Paris, France and at Abbott Laboratories, North Chicago, IL, USA.

The enterotoxin complex responsible for the diarrheal type of *B. cereus* food poisoning has been increasingly well characterized (Granum, 2002). Two commercial kits are available for its detection

in foods and feces, the Oxoid BCET-RPLA (Oxoid Ltd, Basingstoke, UK; Product Code TD950) and the TECRA VIA (TECRA Diagnostics, Roseville, NSW, Australia; Product Code BDEVIA48). However, these kits detect different antigens, and there is some controversy about their reliabilities. Other assays, based on tissue culture, have also been developed (Fletcher and Logan, 1999). The emetic toxin of *B. cereus* has been identified, and it may be assayed in food extracts or culture filtrates using HEp-2 cells (Finlay, Logan and Sutherland, 1999). A commercial kit for detecting the emetic toxin is under development. Restriction fragment length polymorphism (RFLP) analysis of *B. cereus* toxin genes or their fragments is of potential value in epidemiological investigations (Schraft *et al.*, 1996; Mäntynen and Lindström, 1998; Ripabelli *et al.*, 2000).

ANTIMICROBIAL SENSITIVITY AND MANAGEMENT OF INFECTION

Bacillus anthracis

Most strains of *B. anthracis* are susceptible to penicillin, and until recently there were few authenticated reports of resistant isolates (Lalitha and Thomas, 1997); consequently this antibiotic was the mainstay of treatment, and there were few studies on the organism's sensitivity to other antibiotics. Mild and uncomplicated cutaneous infections may be treated with oral penicillin V, but the treatment usually recommended is intramuscular procaine penicillin or benzyl penicillin (penicillin G). In severe cases, and gastrointestinal and inhalational infections, the recommended therapy has been penicillin G by slow intravenous injection or infusion until the fever subsides, followed by intramuscular procaine penicillin; the organism is normally susceptible to streptomycin, which may act synergistically with penicillin (Turnbull *et al.*, 1998). The use of an adequate dose of penicillin is important, as Lightfoot, Scott and Turnbull (1990) found that strains of *B. anthracis* in the presence of subinhibitory concentrations of flucloxacillin *in vitro* became resistant to penicillin and amoxicillin. The study of Lightfoot, Scott and Turnbull (1990) on 70 strains and that of Doganay and Aydin (1991) on 22 isolates found that most strains were sensitive to penicillins, with minimal inhibitory concentrations of 0.03 mg/l or less; however, the former authors found that two resistant isolates from a fatal case of inhalational infection had MICs in excess of 0.25 mg/l. *Bacillus anthracis* is resistant to many cephalosporins. Coker, Smith and Hugh-Jones (2002) found that of 25 genetically diverse mainly animal and human isolates from around the world, five strains were resistant to the second generation cephalosporin cefuroxime, and 19 strains showed intermediate susceptibility to this agent; all strains were sensitive to the first generation cephalosporin cephalexin, and to the second generation cefaclor, and three were resistant to penicillin but were negative for β-lactamase production. Mohammed *et al.* (2002) studied 50 historical isolates from humans and animals and 15 clinical isolates from the 2001 bioterrorist attack in the USA; the majority of their strains could be regarded as nonsusceptible to the third generation cephalosporin ceftriaxone, and three strains were resistant to penicillin. Genomic sequence data indicate that *B. anthracis* possesses two β-lactamases: a potential penicillinase (class A) and a cephalosporinase (class B) which is expressed (Bell, Kozarsky and Stephens, 2002). Tetracyclines, chloramphenicol and gentamicin are suitable for the treatment of patients allergic to penicillin; tests in primates showed doxycycline to be effective, a finding confirmed by Coker, Smith and Hugh-Jones (2002) and indicated the suitability of ciprofloxacin (Turnbull *et al.*, 1998). Mohammed *et al.* (2002) found that most of their strains showed only intermediate susceptibility to erythromycin. Esel, Doganay and Sumerkan (2003) found that ciprofloxacin and the newer quinolone gatifloxacin had a good *in vitro* activity against 40 human isolates collected in Turkey but that for another new quinolone, levofloxacin, high MICs were observed for ten strains.

Because human cases tend to be sporadic, clinical experience of alternative treatment strategies was sparse until the bioterrorist attack occurred in the US in late 2001. The potential and actual use of *B. anthracis* as a bioweapon has also emphasized the need for postexposure prophylaxis; recommendations include ciprofloxacin or doxycycline, with amoxicillin as an option for the treatment of children and pregnant or lactating women, given the potential toxicity of quinolones and tetracyclines; however, β -lactams do not penetrate macrophages well, and these are the sites of spore germination (Bell, Kozarsky and Stephens, 2002). Combination therapy, begun early, with a fluoroquinolone such as ciprofloxacin and at least one other antibiotic to which the organism is sensitive, appears to improve survival (Jernigan *et al.*, 2001). Following the 2001 outbreak in the US, the recommendation for initial treatment of inhalational anthrax is ciprofloxacin or doxycycline along with one or more agents to which the organism is normally sensitive; given supportive sensitivity testing, a penicillin may be used to complete treatment. The same approach is recommended for cutaneous infections (Bell, Kozarsky and Stephens, 2002). Doxycycline does not penetrate the central nervous system well and so is not appropriate for the treatment of meningitis.

Bacillus cereus

Despite the well-established importance of *B. cereus* as an opportunistic pathogen, there have been rather few studies of its antibiotic sensitivity, and most information has to be gleaned from the reports of individual cases or outbreaks. *Bacillus cereus* and *B. thuringiensis* produce a broad-spectrum β -lactamase and are thus resistant to penicillin, ampicillin and cephalosporins; they are also resistant to trimethoprim (an Antarctic *B. thuringiensis* isolate was penicillin sensitive, however) (Forsyth and Logan, 2000). An *in vitro* study of 54 isolates from blood cultures by disk diffusion assay found that all strains were susceptible to imipenem and vancomycin and that most were sensitive to chloramphenicol, ciprofloxacin, erythromycin and gentamicin (with 2, 2, 6 and 7% strains, respectively, showing moderate or intermediate sensitivities), while 22 and 37% of strains showed only moderate or intermediate susceptibilities to clindamycin and tetracycline, respectively (Weber *et al.*, 1988); in the same study, microdilution tests showed susceptibility to imipenem, vancomycin, chloramphenicol, gentamicin and ciprofloxacin with MICs of 0.25–4, 0.25–2, 2.0–4.0, 0.25–2 and 0.25–1.0 mg/l, respectively. A plasmid carrying resistance to tetracycline in *B. cereus* has been transferred to a strain of *B. subtilis* and stably maintained (Bernhard, Schrempf and Goebel, 1978).

Although strains are almost always susceptible to clindamycin, erythromycin, chloramphenicol, vancomycin, and the aminoglycosides and are usually sensitive to tetracycline and sulphonamides, there have been several reports of treatment failures with some of these drugs: a fulminant meningitis which did not respond to chloramphenicol (Marshman, Hardwidge and Donaldson, 2000); a fulminant infection in a neonate which was refractory to treatment that included vancomycin, gentamicin, imipenem, clindamycin and ciprofloxacin (Tuladhar *et al.*, 2000); failure of vancomycin to eliminate the organism from cerebrospinal fluid in association with a fluid-shunt infection (Berner *et al.*, 1997); persistent bacteremias with strains showing resistance to vancomycin in two hemodialysis patients (A. von Gottberg and W. van Nierop, personal communication). Oral ciprofloxacin has been used successfully in the treatment of *B. cereus* wound infections. Clindamycin with gentamicin, given early, appears to be the best treatment for ophthalmic infections caused by *B. cereus*, and experiments with rabbits suggest that intravitreal corticosteroids and antibiotics may be effective in such cases (Liu *et al.*, 2000).

Other Species

Information is sparse on treatment of infections with species outside the *B. cereus* group. Gentamicin was effective in treating a case of

B. licheniformis ophthalmitis, and cephalosporin was effective against *B. licheniformis* bacteremia and septicemia. Resistance to macrolides appears to occur naturally in *B. licheniformis* (Docherty *et al.*, 1981). *Bacillus subtilis* endocarditis in a drug abuser was successfully treated with cephalosporin, and gentamicin was successful against a *B. subtilis* septicemia. Penicillin, or its derivatives, or cephalosporins probably form the best first choices for treatment of infections attributed to other *Bacillus* species. In the study by Weber *et al.* (1988), among the isolates of *B. megaterium* (13 strains), *B. pumilus* (four strains), *B. subtilis* (four strains), *B. circulans* (three strains), *B. amyloliquefaciens* (two strains) and *B. licheniformis* (one strain), along with five strains of *B. (now Paenibacillus) polymyxa* and three unidentified strains from blood cultures, over 95% of isolates were susceptible to imipenem, ciprofloxacin and vancomycin, while between 75 and 90% were susceptible to penicillins, cephalosporins and chloramphenicol. Isolates of *B. polymyxa* and *B. circulans* were more likely to be resistant to the penicillins and cephalosporins than strains of the other species – it is possible that some or all of the strains identified as *B. circulans* might now be accommodated in *Paenibacillus*, along with *B. polymyxa*. An infection of a human-bite wound with an organism identified as *B. circulans* did not respond to treatment with amoxicillin and flucloxacillin but was resolved with clindamycin (Goudswaard, Dammer and Hol, 1995). A recurrent septicemia with *B. subtilis* in an immunocompromised patient yielded two isolates, both of which could be recovered from the probiotic preparation that the patient had been taking; one isolate was resistant to penicillin, erythromycin, rifampin and novobiocin, while the other was sensitive to rifampin and novobiocin but resistant to chloramphenicol (Oggioni *et al.*, 1998).

A strain of *B. circulans* showing vancomycin resistance has been isolated from an Italian clinical specimen (Ligozzi, Cascio and Fontana, 1998). Vancomycin resistance was reported for a strain of *B. (now Paenibacillus) popilliae* in 1965, and isolates of this species dating back to 1945 have been shown to carry a *vanA*- and *vanB*-like gene, a gene resembling those responsible for high-level vancomycin resistance in enterococci. Vancomycin resistant enterococci (VRE) were first reported in 1986, and so it has been suggested that the resistance genes in *B. popilliae* and VRE may share a common ancestor, or even that the gene in *B. popilliae* itself may have been the precursor of those in VRE; *B. popilliae* has been used for over 50 years as a biopesticide, and no other potential source of *vanA* and *vanB* has been identified (Rippere *et al.*, 1998). Of two South African vancomycin-resistant clinical isolates, one was identified as *P. thiaminolyticus* and the other was unidentified but considered to be related to *B. lentus* (Forsyth and Logan, unpublished); the latter was isolated from a case of neonatal sepsis and has been shown to have inducible resistance to vancomycin and teicoplanin; this is in contrast to the *B. circulans* and *P. thiaminolyticus* isolates mentioned above, in which expression of resistance was found to be constitutive (A. von Gottberg and W. van Nierop, personal communication).

PREVENTION AND CONTROL

Bacillus anthracis

Cross-infection is not a problem with this organism, as person-to-person transmission is very rare and direct infections from soil are few. Soil is, however, a main reservoir from which animals and so man are infected. In countries free of the disease, disinfection of animal products imported from epizootic areas of the world is necessary to prevent its reintroduction. Hair and wool can effectively be treated with formaldehyde, as can hides and bone meal by heat (Brachman, 1990).

The Sterne attenuated live spore vaccine, based on a toxigenic but noncapsulate strain, was introduced for animal vaccination in the late 1930s, and spores of this strain remain in use as the basis of livestock

vaccines in most parts of the world today. As this vaccine can show some slight virulence for certain animals, it is not considered suitable for human protection in the West, but live spore preparations are used in China and Russia. The former USSR vaccine was developed in the 1930s and 1940s and licensed for administration by injection in 1959. The UK vaccine is an alum-precipitated culture filtrate of the Sterne strain; it was first formulated in 1954, introduced for workers at risk in 1965 and licensed for human use in 1979. The current human vaccine in the USA is an aluminium hydroxide-adsorbed vaccine strain culture filtrate containing a relatively high proportion of PA and relatively low amounts of LF and EF; it was licensed in 1972 (Turnbull, 2000). Concerns about the lack of efficacy and safety data on the long-established UK and US vaccines, especially following the Sverdlovsk incident, and allegations that anthrax vaccination contributed to Gulf War syndrome in military personnel, have led to demands for new vaccines that would necessarily undergo stricter testing than was customary in the past. Favored active ingredients of these next-generation vaccines are whole-length recombinant PA or a mutant (nontoxic) portion of this molecule (Turnbull, 2000).

Bacillus cereus

Diarrheal and vomiting intoxications by this organism are readily preventable by appropriate food-handling procedures. Meat and vegetables should not be held at temperatures between 10 and 45 °C for long periods, and rice held overnight after cooking should be refrigerated and not held at room temperature. Prevention of infection by this organism, and by other *Bacillus* species, in patients following surgery or in those who are immunocompromised or who are otherwise predisposed to infection, depends on good practice.

ACKNOWLEDGEMENTS

We warmly acknowledge the generous assistance given by Dr Peter Turnbull; he kindly gave NAL freedom to use his material on anthrax that had been prepared for another publication for which they were co-authors. We also thank Professor Mehmet Doganay for material reused from the previous edition of this book and Kirsteen Barclay for assistance with the manuscript.

Mycobacterium tuberculosis

Stephen H. Gillespie

Centre for Medical Microbiology, Royal Free and University College Medical School, Hampstead Campus, London, UK

HISTORY

Described by John Bunyan as the Captain of the men of death and by Oliver Wendell Holmes as the White Plague, tuberculosis has been and remains a major threat to human health (Dye, 2000). It is a disease of great antiquity thought to have evolved as a human pathogen during the Neolithic period, and its rise has been associated with the change from a hunter-gatherer lifestyle to pastoralism and farming. Skeletons from the Neolithic period and Egyptian and Peruvian mummies have evidence of tuberculosis (Salo *et al.*, 1994). Chinese records from more than 4000 years ago describe a respiratory disease with cough fever and wasting suggestive of tuberculosis. The disease was recognised by Hippocrates who made an accurate clinical description and probably gave it the name by which it was known for more than 2000 years: phthisis, which recognised the wasting characteristic of the disease. Aristotle and Galen recognised that tuberculosis was transmissible, a point that remained in dispute until the description of the tubercle bacillus by Koch in 1882 and for some years afterwards (Dormandy, 1999).

Tuberculosis has been a major cause of death as evidenced by the seventeenth-century bills of mortality from London which indicate that approximately 20% of deaths were caused by tuberculosis. In Massachusetts during 1768–1773 pulmonary tuberculosis accounted for 18% of all deaths rising to 25% at the turn of the twentieth century (Holmberg, 1990). In Europe the peak of the tuberculosis epidemic was reached at the end of the eighteenth and early nineteenth centuries, whereas in Eastern Europe the peak was delayed several decades and only occurred in Asia in the late nineteenth and early twentieth centuries (Dubos and Dubos, 1952). In industrialised countries it is thought that the impact of social improvement brought about a steady fall in the incidence of tuberculosis but was confounded by a steep rise during and after the two world wars.

Tuberculosis is a disease of overcrowding poverty and poor nutrition. Modern day rates could be correlated with economic indicators such as per capita income and unemployment. More recently, HIV has brought about an enormous growth in the incidence of tuberculosis especially in sub-Saharan Africa (Corbett *et al.*, 2003). In addition, population migration through war and economic factors has resulted in individuals moving from countries of high endemicity to industrialised countries (Maguire *et al.*, 2002). There have been many outbreaks of multiple drug-resistant tuberculosis (MDRTB) in industrialised countries that have resulted in extensive press coverage and public anxiety (Alland *et al.*, 1994; Moss *et al.*, 1997). This has prompted lurid headlines announcing the 'return of the White Plague'. However, it is more accurate to say that for a short time tuberculosis rates in developing countries were falling rapidly and the possibility of

eradication was ahead but for most of the world tuberculosis has remained a common threat with an estimated 8.3 million cases and 1.8 million deaths (Corbett *et al.*, 2003).

DESCRIPTION OF THE ORGANISM

The mycobacteria grouped in the tuberculosis complex are very closely related with >99.9% genetic similarity and identical 16S ribosomal RNA gene sequences. Restricted structural gene polymorphism suggests that the organism has disseminated globally relatively recently (in evolutionary terms) (Sreevatsan *et al.*, 1997b).

The genome of *Mycobacterium tuberculosis* was one of the first to be reported (Cole *et al.*, 1998). The genome size is 4 411 532 bp with 3959 protein coding genes and six pseudogenes. Function has been attributed to 2441 genes, and 912 are conserved hypothetical genes. A total of 606 have unknown function, and 129 genes are absent from *M. bovis* BCG (Cole *et al.*, 1998).

In *M. tuberculosis*, single-gene polymorphisms are rare and main mechanism for genetic plasticity is through the action of insertion sequences leading to gene insertion and deletion (Brosch *et al.*, 2001). Comparative genomics suggests that *M. tuberculosis* is undergoing successive gene deletion, as it adapts to its obligate pathogen lifestyle.

Previous authors had presumed that *M. bovis* was the ancestor of *M. tuberculosis*, but recent deletion analysis studies suggest that either *M. africanum* or *M. canetti* are the ancestral member of the genus with other species emerging from this. With this scheme, *M. canetti* diverged first from the ancestral strain and then successive branches led to the emergence of *M. tuberculosis*, *M. microti* and *M. bovis*, respectively (Brosch *et al.*, 2002). The population genetics of the organism is described below in *Epidemiology*.

PATHOGENESIS

Response to Infection

Classic animal studies suggest that there are four stages of infection (Lurie, 1931; Lurie, 1964). The first stage is contact with macrophage in which some of the organisms are destroyed and some are able to continue to multiply. Pathogenic mycobacteria are able to survive and multiply within macrophages because they inhibit the acidification of the phagolysosome stabilising at pH 6.2–6.3 and are retained within the endosomal recycling pathway, giving the organism access to essential nutrients such as iron (Kaufmann, 2001). Cord factor is thought to play an important role in preventing acidification (Indrigo, Hunter and Actor, 2003). The phagosomes also fail to fuse with lysosomes, although

they do acquire some lysosomal proteins (Russell, 2001). During the second stage, blood monocytes and other immune cells are attracted to the site of infection. The monocytes differentiate into macrophages which are unable to kill the mycobacteria. It is only a few weeks later, the third stage, when the influx of antigen-specific T cells, that mycobacterial multiplication is controlled. This happens because of secretion of IFN- γ which activates the macrophages and releases the block on phagosomal maturation (Russell, 2001). Efficient killing of mycobacteria depends on nitric oxide produced by nitric oxide synthase and by other related radicals (Kaufmann, 2001). This process is enhanced by acidification of the mycobacteria-containing vacuole which can now occur because the block is now lifted. The final stage infection may become dormant or, alternatively, if the immune cells fail to control the multiplication of the bacteria dissemination occurs and active disease develops.

Infected macrophages produce large amounts of proinflammatory mediators such as TNF- α , IFN- γ , IL-6, IL-1 β and IL-12. A range of anti-inflammatory cytokines is produced including IL-4, TGF- β and IL-10 (van Crevel, Ottenhoff and van der Meer, 2002). The balance between proinflammatory and anti-inflammatory cytokines defines the expression of tuberculosis (van Crevel *et al.*, 2001). Uncontrolled cytokine release is responsible for many of the symptoms and signs of tuberculosis such as fever and wasting.

Histopathology

Another way of looking at the pathogenesis of tuberculosis is through histopathology. A complete understanding of the disease requires integration of information from both approaches. There are three main histological lesions described in tuberculosis: exudative, productive and caseous (Canetti, 1955). Although there is some disagreement about the order in which they occur, it is likely that exudative or productive lesions occur first and lead to caseating lesions. The caseous lesions have relatively few organisms present. Following formation of the caseum the lesion may remain solid and evolve toward peripheral tubercle formation and sclerosis. This takes place in all lesions of latent infection as well as in the great majority of active tuberculosis lesions. On the other hand the caseous lesion may soften which, when the lesion communicates with a bronchus, drains leading to the formation of a cavity, a development which has traditionally been associated with the onset of clinical tuberculosis. During the process of cavity formation alveoli are destroyed and neighboring cavities may unite. Cavities are especially difficult to manage because it provides excellent conditions for the multiplication of tubercle bacilli in a site where the immune system and antibiotic therapy may not be effective (see below). Additionally, draining cavities are a source of bacteria that spread to other parts of the lung. Histopathologically the cavity is surrounded by a fibrous capsule inside which there is a zone of intense round-cell infiltration made up of macrophages, CD4⁺ and CD8⁺ cells and no bacteria. Beyond this there is a zone of necrosis in which there are few immune cells and no bacteria beyond which at the air interface of the cavity there is a zone in which bacteria are present in large numbers, in association with macrophages and T cells that are CD4⁺CD8⁻. The bacteria are found within the macrophages and this indicates that, in this outer zone, the lack of T-cell help means that the macrophages are unable to control the growth of bacteria (Kaplan *et al.*, 2003).

EPIDEMIOLOGY

Tuberculosis is spread by the respiratory route. Traditionally patients who are sputum smear positive are considered to be infectious and those who have extrapulmonary disease or who are smear negative are not. Several factors can influence transmission rates, including the infective dose and the energy with which they are expelled into the air. Several epidemiological models have been described to describe this phenomenon (Sultan *et al.*, 1960; Riley *et al.*, 1962; Beggs *et al.*, 2003).

Patients who are heavily infected and those with laryngeal tuberculosis are more likely to transmit infection due to increased coughing (Sultan *et al.*, 1960; Riley *et al.*, 1962; Braden, 1995). Bronchoscopy and autopsy exposure is also more likely to result in infections (Beggs *et al.*, 2003). Transmission is more likely to occur in overcrowded conditions (Kuemmerer and Comstock, 1967; Beggs *et al.*, 2003). Children and individuals who have immunodeficiency, for example HIV infection, are especially vulnerable to infection and outbreaks in schools can be extensive (Hoge *et al.*, 1994). When tuberculosis was introduced into isolated island populations during the nineteenth century, epidemics developed associated with high mortality (Holmberg, 1990).

In immunocompetent individuals infected with *M. tuberculosis*, there is a 5–10% risk of developing active tuberculosis within 2 years of primary disease. Later there is a 5–10% lifetime risk of developing acute disease – reactivation. In countries with high prevalence the disease is found in the young and very young adults (Rieder, 1999). As social and economic conditions improve, clinical tuberculosis is dominated by reactivation disease and is found in increasingly older individuals. Reactivation is associated with failing immunity, but in the absence of HIV or immunosuppressive therapy, it is rare for an identifiable defect to be identified. Individuals who have migrated from high endemicity countries to low endemicity countries appear especially vulnerable to reactivation within the first 2 years (Tocque *et al.*, 1998). Throughout the twentieth century the average age of tuberculosis patients increased and a similar process was occurring in developing countries until the appearance of the HIV epidemic which reversed this trend.

The epidemiology of tuberculosis is quite different from most other infectious diseases. This is due to the relatively long incubation period and the presence of both primary and reactivation forms of disease. Mathematical modeling of the epidemiology suggests that epidemics of tuberculosis are slow to develop peaking between 50 and 200 years after introduction of the disease (Blower *et al.*, 1995). However, the interaction between HIV and tuberculosis serves to facilitate the spread of the disease (Corbett *et al.*, 2003). In many countries the interaction between HIV and tuberculosis has been very severe with co-infection rates greater than 5000/100 000 in Southern Africa. HIV makes the individual more susceptible to infection, and they also have a 10% risk of reactivation disease per year (Glynn, 1998).

A number of molecular techniques have been applied to *M. tuberculosis* including IS6110 RFLP analysis (van Embden *et al.*, 1993; Maguire *et al.*, 2002), gene deletion arrays (Kato-Maeda *et al.*, 2001) and mycobacterial intergenic repeat sequence (MIRU) analysis (see below) (Supply *et al.*, 2000; Supply *et al.*, 2003) which have shed light on the population genetics of this organism. Using these techniques it has been possible to identify groups of related strains that are spreading widely. An example of this is the Beijing lineage which has spread widely in Asia (Bifani *et al.*, 2002). A branch of this lineage described as strain W was responsible for extensive outbreaks in the United States that centered on New York City (Alland *et al.*, 1994; Moss *et al.*, 1997). Recent studies have suggested that ability of this lineage to spread is due to an increased mutation rate caused by alteration in the *mutT* genes; it is suggested that this makes strains of the Beijing lineage more adaptable (Rad *et al.*, 2003). This may also explain the apparent ease with which strain W developed resistance and spread widely.

CLINICAL FEATURES

Pulmonary Disease

Pulmonary disease can be part of primary or post-primary phases of the infection. Many cases are detected through screening radiology, something which played a part in the decline in infection rates in the second half of the twentieth century. Cough is the commonest presenting

symptom (Banner, 1979) and is typically constant and irritating. It is usually productive and can be associated with hemoptysis. Fever and malaise are common but often low grade. Weight loss develops over a number of months and may cause clinical confusion with malignancy. Breathlessness is a late manifestation of disease.

Pulmonary disease can be complicated by extension to local structures resulting in empyema and pericarditis. Severe disease may result in significant loss of lung capacity further complicated by fibrosis.

The chest X-ray has a vital role in diagnosing pulmonary disease. In addition to identifying patients with changes suspicious of tuberculosis, it can demonstrate the presence of cavities, pleural effusions, empyema and pericardial effusions. CT scanning is also gaining a place in diagnosis and evaluation of extent of disease. Where facilities allow endoscopy with a flexible bronchoscope can aid diagnosis by allowing the abnormal area of lung to be visualised and specimens taken.

Tuberculosis Meningitis

Although relatively rare, tuberculosis of the CNS has a serious impact due to the relatively poor prognosis and difficulty in making the diagnosis. Most CNS disease takes the form of meningitis, but cases of localised tuberculosis, tuberculomas, do occur. Spread to the meningitis is usually hematogenous, and coexistent miliary disease is diagnosed in approximately 20% of cases.

Symptoms are typically nonspecific in the early stages of the disease characterised by fever, anorexia and weight loss. Later, headache and neck-stiffness appear, and these may be accompanied by drowsiness which will develop into coma if effective treatment is not instituted. The severity of disease is classified by the Medical Research Council scale: stage I, no disturbance of consciousness or neurological signs and stage II, where there is some clouding of consciousness but coma has not intervened and focal neurological signs may be found. In stage III, patients are comatose or stuporous.

Diagnosis is difficult, as the number of organisms present in cerebrospinal fluid (CSF) is relatively low; so samples are often falsely negative. The application of molecular techniques has improved diagnostic sensitivity. It is the CSF cell count and biochemistry that are most important in making the diagnosis.

Lymph Node Tuberculosis

Tuberculosis lymphadenitis is one of the commonest presentations of extrapulmonary disease, being responsible for over 30% of extrapulmonary disease in some areas (Mehta *et al.*, 1991). In areas where tuberculosis is common the disease usually presents early in life, whereas in low prevalence areas tuberculosis lymphadenitis presents later, usually between 20 and 50 years of age. In many industrialised countries nontuberculosis species are the most common etiological agents of mycobacterial lymphadenitis. The cervical lymph nodes are the commonest site of infection, although mediastinal and abdominal lymphadenitis is found in association with pulmonary and gastrointestinal disease. In some cases the diagnosis of tuberculosis is made by biopsy of mediastinal or abdominal nodes.

Infected lymph nodes may show mild reactive hyperplasia or granulomata with caseation and necrosis. Tuberculous lymphadenitis must be distinguished from lymphoma, metastatic carcinoma, sarcoidosis and other alternative causes of noncaseating granulomata. The diagnosis can be made by fine-needle aspiration or open biopsy followed by bacteriological and molecular examination.

Bone and Joint Tuberculosis

Tuberculosis has a predilection for the spine, and examples of this form of disease have been identified in mummified human remains from Egyptian tombs. Infection in large joints also occurs. Spinal

tuberculosis is characterised by local tenderness usually in the lumbosacral area (>40% of all bony tuberculosis), and this is often associated with the systemic signs of the disease. Collapse of the vertebrae cause kyphosis and may produce a spinal cord compression resulting in the most serious complication. Rupture of pus from the vertebrae may cause the pus to enter the paraspinal space and into the psoas, which may lead to a cold abscess in the groin. Diagnosis is usually made radiologically, and the availability of CT and MRI scanning has made diagnosis much easier in recent years.

Gastrointestinal Disease

Gastrointestinal tuberculosis is now a rare condition in developed countries but remains common in developing countries. Infection can occur in any part of the gastrointestinal tract. Abdominal disease can present acutely (one-third of cases) as an abdominal emergency with pain. More commonly it presents with a slow deterioration characterised by weight loss, fever, malaise and ascites. There are no characteristic diagnostic signs, and the diagnosis is usually made with a combination of clinical suspicion and culture from biopsy or ascites fluid. Radiology using barium examination, CT and ultrasound may be suggestive.

Cutaneous Tuberculosis

Mycobacterium tuberculosis can affect the skin in a number of ways, but cutaneous disease is rare. The organism is capable of causing a primary infection which usually occurs in children or young adults who are inoculated by skin trauma. Typically a nodule develops at the site of the lesion associated with regional lymphadenopathy, the primary cutaneous complex. Lupus vulgaris is chronic form of cutaneous tuberculosis disease where dull red lesions appear on the face, head or extremities. It is usually seen in older patients and often follows a long history before a diagnosis is made. It is a progressive disease that can cause severe facial scarring resulting in considerable deformity. A miliary form of tuberculosis has been described in the very young or in AIDS patients. It is characterised by small purplish papules which can be found over wide areas of the skin.

Tuberculides are fascinating and controversial syndromes that are believed to be cutaneous manifestations of immune responses to tuberculosis. One relatively common example of this is erythema nodosum. Others that may cause considerable diagnostic problems include Bazin's erythema induratum.

Genitourinary Tuberculosis

Renal tuberculosis is one of the less common presentation of tuberculosis. It arises as a consequence of miliary spread of the bacteria in primary infection. Tuberculosis infection is often asymptomatic in the early stages of infection, but later dysuria, hematuria and in advanced cases flank pain may be present. Renal infection can be complicated by fibrosis and renal obstruction which may lead to renal failure. In almost all cases the intravenous pyelogram is abnormal with signs of fibrosis in the ureters.

Endocrine Consequences of Tuberculosis

Mycobacterium tuberculosis has the ability to infect almost all organs of the body. When this involves endocrine tissue the effects can be devastating. Destruction of the adrenal glands produces failure of corticosteroid production and can be rapidly fatal if the diagnosis is not made quickly. This syndrome can be undiagnosed when pulmonary tuberculosis treatment is commenced, but the patient may suffer an adrenal crisis 2–4 weeks into treatment. This phenomenon may be an explanation for some of the cases of sudden death in patients early in their course of tuberculosis.

The pituitary gland may also be affected by *M. tuberculosis* causing failure of endocrine functions. In females this may present as amenorrhea. In men it is corticosteroid axis that is the first presenting system.

LABORATORY DIAGNOSIS

Organisation of Laboratories for the Diagnosis of *M. tuberculosis* and Other Mycobacteria

In industrialised countries the incidence of tuberculosis can vary significantly between areas where the disease is rare to towns and cities where it is common. For some laboratories the number of isolates is low, and this poses difficulties in maintaining the skill required to perform susceptibilities and identifications. To overcome this potential problem most countries in the industrialised world divide adopt a three-level structure. For example, in the UK, smears and cultures are performed in most laboratories sending isolates to regional reference centers for identification and susceptibility testing for first-line agents (Drobniewski *et al.*, 2003). A national reference center acts as a reference for the regional centers and provides a comprehensive susceptibility and identification service. Additionally such national centers should perform research and organise national quality control programs. Technological changes have made the diagnosis of mycobacterial disease considerably easier and the increase in the number of specimens and positives has increased the throughput for most urban laboratories. Additionally, many patients are at risk of MDRTB and are immunocompromised. Such patients may deteriorate rapidly if the diagnosis is not made quickly. This means that there is increasing need for mycobacterial diagnostic facilities to be placed at centers where tuberculosis has re-emerged and in hospital where there are many immunocompromised patients (Davies *et al.*, 1999). Those laboratories that isolate few mycobacteria should refer samples where definitive diagnosis can be made reliably. Such laboratories should aim to provide identification and susceptibility within 21 days of isolation (Association of State and Territorial Public Health Directors and Centers for Disease Control, 1995; Drobniewski *et al.*, 2003).

In developing countries, direct sputum smear examination should be provided at all district hospital laboratories. At least a proportion of all isolates should be sent to reference centers for conformation of identification and susceptibility testing. With the increasing burden of HIV infection and MDRTB, it is desirable that more specimens are cultured and susceptibility testing is performed.

In laboratories that process specimens for the diagnosis of tuberculosis and other mycobacteria, the processing should be performed in a sealable room with negative pressure ventilation, and these laboratories should provide protection against aerosol transmission through an exhaust protective cabinet. The laboratory should have access to an autoclave within or near it. Most industrialised countries have detailed requirements for such containment level 3 or P3 laboratories, the description of which is beyond the scope of this chapter (Collins, Grange and Yates, 1997; Advisory Committee on Dangerous Pathogens, 2001).

Specimens

Almost any tissue or body fluid is suitable for examination for mycobacteria, but the investigation of each disease syndrome requires a different protocol. Specimens should be collected into clean sterile containers and transported to the laboratory with minimal delay. When unusual or precious samples, e.g. biopsy specimens, are taken, the laboratory should be contacted to coordinate specimen transport and processing. Additionally, it is essential that the laboratory provides advice on the correct way of sending potentially infected samples.

When pulmonary tuberculosis is suspected the principal specimen is sputum, but not all patients are capable of producing a satisfactory sample. This may be due to physical weakness or failure to coordinate

the effort required for effective specimen production, and some patients may have a nonproductive cough. Children are very rarely capable of producing an adequate sputum specimen. When sputum is not available, an alternative is an early morning gastric fluid. Fluid aspirated from the stomach contains respiratory secretions coughed up during the night and swallowed. Another moderately invasive method is induced sputum, but this method has been associated with transmission of infection and must be performed in suitable facilities (Breathnach *et al.*, 1998). A more invasive technique is a bronchoalveolar lavage (BAL), and this provides a better specimen when the facilities for this technique are available and the patient is able to tolerate the procedure (Anon., 2000).

Specimens should be considered in two groups, as the protocol for processing them is significantly different. The first group are the specimens which contain a normal flora such as sputum or BAL and these will require decontamination. The second group of specimens are those which come from a normally sterile site including CSF, blood, bone marrow and pleural, pericardial and joint fluid. In addition, aspirated pus and tissue biopsies should be considered in this group.

An accurate white cell count and differential should be performed on CSF and the protein, glucose concentrations should be measured. Tuberculosis meningitis is associated with a high protein and low glucose concentrations. The raised white cell count usually has a lymphocyte predominance, although rarely a neutrophilia may be found.

Specimens of urine are required for the diagnosis of renal tuberculosis. As 24-h collections are likely to become contaminated with other bacteria, three first void samples should be examined. Tissue samples may be obtained in cases of diagnostic difficulty when other less invasive tests have proved negative and the suspicion of tuberculosis or other mycobacterial disease remains. Open liver, lymph node and brain biopsies are commonly taken, but fine-needle aspirates and transbronchial biopsy should be considered to reduce the need for a surgical procedure. When such specimens are contemplated, the laboratory should be contacted so that they can be processed with the minimum of delay. It is particularly important to ensure that specimens are not placed in formalin for histopathological examination before culture can be performed. Additionally, pleural and pericardial fluids can be examined, although a higher diagnostic yield is obtained if biopsy specimens are collected.

Blood should be collected in heparin anticoagulant (not EDTA) or directly inoculated into commercially available mycobacterial liquid culture medium (e.g. MBBacT or BACTEC) (Vetter *et al.*, 2001; von Gottberg *et al.*, 2001). Feces may be examined by microscopy and culture for the presence of *M. avium* intracellulare.

Microscopy

One of the most successful tests for the diagnosis of mycobacterial disease is the direct microscopic examination of specimens for the presence of acid-fast bacteria. Although it requires staff who are experienced in reading smears, it has the advantage of being rapid and inexpensive. For laboratories in developing countries it may be the only diagnostic test that is available. It has a lower limit of detection of approximately 10 000 organisms per milliliter (Hobby *et al.*, 1973). This is 100 times less sensitive than culture, and consequently a negative smear does not preclude the diagnosis of tuberculosis (Cruickshank, 1952; Yeager *et al.*, 1967). Patients who are sputum smear negative are thought to pose a significantly lower risk of transmitting their infection than smear-positive cases. Thus a diagnostic system with limited resources which only uses sputum smear for diagnosis will identify the most important patients: those likely to contribute further new cases.

There are two main staining methods: the Ziehl-Neelsen and related methods and fluorochrome techniques that use auramine or auramine-rhodamine dyes. Smears are semi-quantitative and may provide the clinician an impression of the severity of the infection or progress of a patient on treatment (Anon., 2000). However, the excretion of bacteria into the sputum can be intermittent, and organisms that have been killed

by therapy remain in the sputum for several months (see below). Thus at least three good quality samples of sputum should be examined before the diagnosis is rejected.

Smears can be performed directly from almost all clinical specimens. Exceptions to this rule are urine, and gastric aspirates, which may be contaminated with commensal mycobacteria. This means that there is a significant risk of generating a false-positive result. To assist infection control procedures, laboratories should provide results of sputum examination within 24 h (Association of State and Territorial Public Health Directors and Centers for Disease Control, 1995). This is especially important when patients at risk of MDR-TB are examined or there is the possibility of exposure of immunocompromised individuals to infectious tuberculosis cases.

Decontamination

Mycobacteria grow more slowly than other bacteria and fungi with which the specimen may be contaminated, and thus cultures can be overwhelmed with more rapidly growing species. This can be overcome by decontaminating the specimen or by inoculating it into medium that contains a cocktail of antibiotics that will inhibit faster growing bacteria and fungi.

Decontamination methods have a greater effect on rapidly growing bacteria and fungi, but they do kill mycobacteria too. Thus, it is important that the methods are chosen to be sufficiently stringent to reduce the risk of rapid growing organisms but not so stringent that the mycobacterial recovery rate suffers (Collins, Grange and Yates, 1997). The usual decontamination procedure is to use 2% sodium hydroxide. Because of its effect on mycobacterial viability, the efficacy of decontamination should be monitored closely. Not more than 5% or less than 2% of cultures should fail due to contamination. If the level exceeds 5% then too many cultures will be lost leading to diagnostic delay, whereas if less than 2% are contaminated it suggests that the decontamination is too stringent and mycobacterial viability is being adversely affected with an inevitable reduction in the sensitivity of culture. Similar considerations apply to cultures inoculated into medium containing an antibiotic cocktail (Collins, Grange and Yates, 1997).

Culture of *M. tuberculosis*

Culture of mycobacteria remains the cornerstone of microbiological diagnosis of tuberculosis, as it is still the most sensitive diagnostic techniques available, and the isolation of the organisms allows definitive identification, susceptibility and molecular epidemiological tests to be performed. The slow growth of *M. tuberculosis* is a challenge for the diagnostic laboratory to produce a result in as timely a fashion as possible. There are three main types of isolation media available for primary diagnosis: egg based such as Lowenstein-Jensen, agar based such as Middlebrook 7H10 and finally liquid growth media, e.g. Middlebrook 7H9 reviewed by Collins, Grange and Yates (1997). Growth on liquid media tends to be faster, and automatic systems can be used to monitor growth and identify positive samples rapidly. Many commercial liquid culture systems have been marketed from manual growth detection to continuously monitored systems (Scarparo *et al.*, 2002; Bemer *et al.*, 2004). Almost all of the currently available automated products identify mycobacterial growth by detecting carbon dioxide production. In addition, semi-automated systems are available that provide the advantages of liquid culture without the large capital investment required for a fully automated system (Adjers-Koskela and Katila, 2003). Agar-based solid and liquid media can be used for primary isolation of organisms in specimens from sterile sites, but contaminated samples must be inoculated into liquid medium supplemented with an antibiotic cocktail. Positive specimens inoculated into liquid broth media will usually signal positive within 3 weeks, and samples can usually be discarded after 6 weeks as negative. Egg-based solid medium must be inspected at least weekly, and growth can usually be

seen after 4 weeks. Cultures can be discarded as negative after 8 weeks, although some precious samples, e.g. CSF, may be incubated for a further 4 weeks (Collins, Grange and Yates, 1997).

Cross-Contamination

Care must be taken to ensure that cross-contamination does not take place in the clinical laboratory (Bhattacharya *et al.*, 1998). With careful practices, the rate should be below 1% (Ruddy *et al.*, 2002), but in some circumstances when these methods have broken down, cross-contamination has been much more common (de C. Ramos *et al.*, 1999). Methods of prevention of cross-contamination is reviewed in Bhattacharya *et al.* (1998) and Ruddy *et al.* (2002).

Identification

Identifying mycobacteria can impose a significant delay in the diagnostic process. There are three main approaches, phenotypic tests, DNA hybridisation/amplification and direct sequencing of the 16S ribosomal gene. Phenotypic tests are the longest established methods but require considerable skill and experience to perform (Collins, Grange and Yates, 1997). Once growth has been detected, a ZN film should be examined and the morphology of the bacteria should be determined. *Mycobacterium tuberculosis* exhibits a characteristic cording which is almost diagnostic (Plate 6). The isolate can then be inoculated onto a medium such as para-aminobenzoic acid upon which *M. tuberculosis* will not grow. These two features together with the appearance of the colonies on solid medium make a presumptive identification of *M. tuberculosis* usually within 2 weeks. Definitive identification may be performed using the tests described above.

DNA hybridisation and amplification methods have transformed the speed of mycobacterial identification. These rapid techniques, many of which are produced commercially, use a direct hybridisation method such as Accuprobe which can identify culture isolates within a few hours (Scarparo *et al.*, 2001; Lebrun *et al.*, 2003). The species which are included are *M. tuberculosis*, *M. avium*, *M. intracellulare*, *M. kansasii* and *M. goodii*. Alternatively, a DNA amplification step with or without reverse phase hybridisation to detect specific *M. tuberculosis* genes and several commercial systems such as Probec or INNO-LIPA are available (Lebrun *et al.*, 2003; Wang, Sng and Tay, 2004). When incorporated into the routine workflow of a laboratory, they permit *M. tuberculosis* to be identified in 2–3 days (Davies *et al.*, 1999; Drobniowski *et al.*, 2003). Direct amplification of the 16S ribosomal gene and sequencing enable a definitive identification of any mycobacterial species. This approach is now more widely applied and has resulted in significant time saving to identification and the description of a large number of slow-growing mycobacteria which may be pathogens in humans (Tortoli, 2003). In addition to the 16S gene, the DNA gyrase gene *gyrA* and RNA-dependent polymerase *rpoB* amplicons can be used for speciation (Kim *et al.*, 1999; Dauendorffer *et al.*, 2003).

DNA Amplification Techniques

Increasingly, nucleic acid amplification methods are integrated into routine mycobacterial diagnosis. They are principally approved for the rapid diagnosis of tuberculosis from respiratory samples. Several techniques have now been licensed for use on smear-positive samples, although studies show that these can be useful in examining smear-negative samples (McHugh, personal communication). The application of NAA methods to diagnosis of nonrespiratory samples is more problematical, as biopsy pleural fluid samples often have low numbers of bacteria present making the test less sensitive. However, it is in these difficult cases that the test has the greatest potential to influence diagnosis and alter treatment plans. Great care must be taken in selecting specimens for processing and in reporting the results (Conaty *et al.*, 2005).

Figure 10.1 An integrated conventional and molecular diagnostic service for tuberculosis.

Molecular Susceptibility

The molecular mechanism of resistance is complex for most anti-tuberculosis agents, making reliable molecular susceptibility testing difficult. However, for rifampicin over 90% of resistance mutations are found in a small section of the *rpoB* gene and thus methods that detect point mutations in this region are both sensitive and specific (Telenti *et al.*, 1993; Ramaswamy and Musser, 1998). The most useful methods are direct sequencing from *rpoB* amplicons and commercial kit methods which are available based on a NAA and hybridising stage.

Service Provision

Tuberculosis diagnosis cannot be provided in isolation, and the results obtained should be integrated into the multidisciplinary team discussions required to manage patients with tuberculosis. An overview of the diagnostic process is provided in Figure 10.1.

TREATMENT

The Pre-Antibiotic Era

The association between tuberculosis, poverty and overcrowding led to the theory that the disease could be treated by providing the patient with good food, bed rest and plenty of fresh air. The Sanatorium movement swept Europe and North America in the nineteenth century and provided hope and a cure for many. The isolation imposed on the patients may have helped to reduce the spread of tuberculosis, but there is little evidence that sanatorium treatment significantly contributed to cure (Dormandy, 1999). Before anti-tuberculosis antibiotics became available, surgical treatment proved beneficial with lobectomy and pneumonectomy which removed considerable bacterial load, and in some difficult cases of MDRTB such methods are again used.

The Antibiotic Era

The real revolution in tuberculosis therapy came with the description of streptomycin by Waksman and Schatz (Schatz and Waksman, 1944). They worked on the theory that mycobacteria were soil organisms and that the soil may contain organisms that would produce substances active against them in their competition for the same ecological niche. Attention was focussed on the *Streptomyces*. The drug was rapidly introduced into clinical practice in the United States, but in the United Kingdom, clinical trials were performed to demonstrate its efficacy.

This was the first example of a placebo-controlled comparative clinical trial, and its unexpected result laid the foundation for the modern drug development paradigm. Although streptomycin monotherapy brought about a rapid clinical improvement, the benefit was transitory and later there was no significant difference in outcome (Crofton and Mitchison, 1948). Moreover, many of the infecting strains had developed resistance. Fortunately, help was at hand: *para*-amino salicylic (PAS) acid was developed by Lehman in Denmark and combination therapy prevented the emergence of resistance (Lehman, 1946). The introduction of isoniazid in 1952 provided another highly bactericidal drug (Middlebrook and Cohn, 1953; Middlebrook and Dressler, 1954). A series of clinical trials performed by the United Kingdom Medical Research Council and the United States Public Health Service concluded that the optimum therapy for pulmonary tuberculosis was with these three drugs for 3 months followed by a further 15 of isoniazid and PAS (Fox and Mitchison, 1975). Many other anti-tuberculosis drugs were introduced in the 1950s including ethambutol and second line agents such as thiacetazone and prothionamide. Pyrazinamide was developed but was soon abandoned due to intolerance to the high doses employed. A crucial trial in Madras demonstrated that the results of domiciliary treatment were as good as chemotherapy given in the context of a sanatorium (Fox, Ellard and Mitchison, 1999). The tuberculosis hospitals began to close, and the focus moved to community-based treatment regimens.

The introduction of rifampicin permitted the duration of therapy to be reduced to 9 months (Furesz and Timball, 1963; Canetti *et al.*, 1968), and the delineation of the role of pyrazinamide in chemotherapy permitted a further reduction to 6 months (Fox and Mitchison, 1975). The base regimen consists of an intensive phase of 2 months of rifampicin, isoniazid and parazinamide followed by a consolidation phase of 4 months of rifampicin and isoniazid. Further attempts to shorten the duration of therapy to 5 or 4 months resulted in unacceptably high relapse rates. Further trials demonstrated that intermittent therapy, given two or three times a week, was as effective as daily treatment. The series of clinical trials leading to the current therapeutic regimen are described in Fox, Ellard and Mitchison (1999).

Directly Observed Therapy Short Course

The recognition of the growing tuberculosis epidemic in the 1990s led to the development of new strategies to deliver anti-tuberculosis chemotherapy more effectively. The directly observed therapy short course (DOTS) strategy was devised. This made use of the known efficacy of chemotherapy in a clinical trial setting where all of the doses of the trial agent are observed. In countries where patients are required to pay for their drugs, the poorest member of the community, most likely to suffer tuberculosis, are likely to stop treatment before bacteriological cure can be achieved. As the patient feels well long before bacteriological cure, this is a major problem in tuberculosis therapy. The homeless and those addicted to drugs often lack social structures or self-discipline to complete a 6-month course of therapy. In DOTS each of the doses of treatment is observed. This may be by a health care worker specifically employed by the tuberculosis-control program, a local pharmacist or a responsible family member. By increasing the number of doses taken, the risk of relapse and resistance is reduced. The DOTS idea depends on the development of effective tuberculosis treatment and control program to deliver directly observed therapy. However, DOTS is not a panacea. It can be difficult to organise and in some countries the results of such programs have been disappointing (Walley *et al.*, 2001).

Antibiotic Resistance

The piecemeal introduction of new chemotherapeutic agents highlighted the importance of preventing the development of resistance (Crofton and Mitchison, 1948; Gillespie, 2002). In any prokaryotic genome,

mutations are constantly occurring due to base changes caused by exogenous agents, DNA polymerase errors, deletions, insertions and duplications (David, 1970). For prokaryotes there is a constant rate of spontaneous mutation of 0.0033 mutations/DNA replication that is uniform for a diverse spectrum of organisms (Drake, 1999). The mutation rate for individual genes varies significantly between and within genes, approximately 10–9 for rifampicin and 10–6 for isoniazid (David, 1970; Billington, McHugh and Gillespie, 1999; Gillespie, 2002). The reasons for these variations are uncertain but are thought to be under the influence of local DNA sequence. Thus a patient with tuberculosis with approximately 10^{13} organisms in the body will already have 10 000 rifampicin resistance mutants. To prevent these surviving and coming to dominate the patient's infection the pre-existent mutants are killed by the second or third drug of the combination. It has been assumed that the risk of resistance of an organism developing resistance to two agents is the multiple of the risk of each separately, but the risk of mutants emerging in a patient depends partly on this and the size of bacterial populations with compartments. Therefore, risk of resistance may be more accurately calculated using the formula $P = 1 - (1 - r)^n$, where P is the probability of drug resistance emerging, r is the probability of drug-resistant mutants and n is the number of bacilli in a lesion usually calculated to be 10^8 per lesion (Shimao, 1987). Where patients have developed extensive cavities, or empyema, the bacterial population at one site may be very much higher, increasing the risk of resistance mutants emerging. Also, poor drug penetration into the fibrous cavities or into empyema can significantly reduce the effective dose and produce the situation where there effectively is monotherapy (Lipsitch and Levin, 1998). It is for these reasons that the emergence of drug resistance is associated with poor adherence to an adequately prescribed regimen, and inadequate regimen, with patients who have multiple cavities or empyema (Iseman and Madsen, 1991; Elliott *et al.*, 1995).

Molecular Mechanism of Resistance

Telenti and colleagues were the first to determine the site of mutation that resulted in rifampicin resistance in *M. tuberculosis*. They used the evidence that *E. coli* became resistant to rifampicin through mutation in the β subunit of the *rpoB* gene and sequenced this gene from a series of epidemiologically unrelated strains. They showed that almost all rifampicin-resistant isolates had mutations in a small region of *rpoB*. Subsequently, further clinical studies indicated that mutations are found in this region in up to 95% of resistant isolates (Telenti *et al.*, 1993). For other antibiotics the resistance mechanisms are more heterogeneous. *Mycobacterium tuberculosis* catalase KatG is a peroxynitratase that generates acyl, acylperoxy and pyridyl radicals of isoniazid (Zhang *et al.*, 1992). These inhibit the β -keto-acyl ACP synthase, KasA which interferes with effective cell-wall synthesis (Sreevatsan *et al.*, 1997a). Resistance emerges by modification of catalase by partial or total gene deletions, point mutations or insertions, which lead to the abolition or diminution of its catalase activity (Zhang *et al.*, 1992). This is the most effective mechanism of resistance, as it is found in more than 80% of isoniazid-resistant strains (Ramaswamy and Musser, 1998). Alternatively, low-level resistance can be caused by point mutations in the regulatory region of *inhA* operon resulting in over expression of *inhA* (Wilson, De Lisle and Collins, 1995). Strains with this mutation have normal mycolic acid synthesis but low-level resistance to isoniazid. Point mutations have also been demonstrated in the regulatory region of *ahpC*, which compensate for the effects of absent or reduced catalase (KatG) function and do not directly result in resistance.

The molecular mechanism of resistance has been described for most of the remaining anti-tuberculosis drugs including pyrazinamide (Scorpio and Zhang, 1996), streptomycin (Honore and Cole, 1994; Cooksey *et al.*, 1996), ethambutol (Belanger *et al.*, 1996) and fluoroquinolones (Cambau *et al.*, 1994). For some of the antibiotics, as many as half of the mechanism of resistance is unexplained.

Drug Toxicity

In most instances, tuberculosis treatment is well tolerated, but the main anti-tuberculosis drugs are associated with significant adverse effects. Rifampicin is associated with acute hepatitis most likely to occur in combination with isoniazid. It induces liver enzymes and can significantly affect the metabolism of other drugs. It interferes with the activity of antiretroviral drugs. At higher doses given in intermittent therapy, patients may suffer a flu-like syndrome (Dickinson *et al.*, 1977). Isoniazid is associated with acute hepatitis caused by the hydrazine radical produced *in vivo*. It is for this reason that hepatitis is more common with isoniazid and rifampicin combination than with either of them alone. Pyrazinamide is associated with hepatic damage and up to 5% of patients may not be able to tolerate the drug. Streptomycin has now largely fallen out of use in part because of the risk of renal and vestibular toxicity. In addition, it must be given parenterally, and this may be a problem in resource-poor countries where the sterility of needles cannot be guaranteed. In the context of drug intolerance or resistance, fluoroquinolones such as ciprofloxacin, ofloxacin or moxifloxacin can be used and are well tolerated and are especially useful in patients with pre-existent hepatic disease (Yew *et al.*, 1992; Kennedy *et al.*, 1993).

Management of Drug-Resistant Tuberculosis

MDRTB is defined as infection with an organism resistant to at least isoniazid and rifampicin. This definition is practical because of the critical role these drugs play in successful treatment. Drug-resistant tuberculosis has a much higher mortality between 30 and 60%. There is an increased need for operative intervention to remove infected cavities or perform pneumonectomy. Thus the management of MDRTB differs significantly from susceptible cases where treatment is protocol driven. In the case of MDRTB each patient must be judged as an individual and the regimen must be tailored to the susceptibilities of the infecting organisms and the presence of other complicating features such as drug toxicity or organ failure. There are some basic rules which govern the construction of a therapeutic regimen to treat unexpected or known resistant isolates; they are:

1. *In vitro* susceptibility should be performed on all isolates.
2. In areas where rates of resistance are greater than 5%, all initial treatment regimens should contain four drugs to reduce the risk that further resistance will emerge.
3. Directly observed therapy should be used to ensure that the regimen is taken correctly.
4. The patient should be prescribed a regimen that contains three drug to which the organism is susceptible.
5. New drugs should only be added to the regimen in pairs and ideally only if the strain is known to be susceptible. Piecemeal addition of single agent is likely to result in additional resistance.
6. Drugs used to treat MDRTB often lack the bactericidal and sterilising efficacy of first-line agents, and thus the duration of treatment will need to be longer for up to 2 years.

Treatment of Smear-Negative Pulmonary Tuberculosis

Attempts have been made to utilise treatment regimens shorter than the standard 6 months. A study performed in Hong Kong of daily treatment with isoniazid, rifampicin, pyrazinamide and streptomycin for 2 or 3 months was associated with a relapse rate of 32 or 13%, respectively, during 5 years of follow-up. A later study of 4-month treatment with an initial 4-drug regimen for 2 months followed by a consolidation phase of 2 months of isoniazid and rifampicin was successful. HIV-infected individuals infected with *M. tuberculosis* are often smear negative. Although shorter regimens can be effective, it is probably advisable to

treat all patients with pulmonary tuberculosis with a standard 6-month regimen.

Treatment of Extrapulmonary Tuberculosis

The same basic principles underlie the treatment of extrapulmonary tuberculosis as those discussed above. It should be noted, however, that it may be more difficult for drugs to penetrate into protected sites such as the CSF. There are few controlled clinical trials to inform the duration of treatment, but these suggest that standard therapeutic regimens including the four first-line agents given between 6 and 9 months are adequate. Tuberculous meningitis and tuberculomas provide an exception to this advice, and most authorities suggest treatment durations of between 9 and 12 months. There is considerable trial evidence that corticosteroids have a valuable role to play in the management of tuberculous meningitis and pericarditis. Operative intervention is more often required in extrapulmonary tuberculosis and may be required to drain psoas abscesses, to stabilise the vertebral column in cases of spinal tuberculosis. Emergency surgical intervention may be required to drain tuberculous pus causing pressure on the spinal cord.

TUBERCULOSIS CONTROL

National Infection Control

Early efforts to control tuberculosis were centered on the Sanatorium movement. Segregation of sputum smear-positive patients from the general population may have reduced the risk of transmission. More important was the increasing wealth of the people in industrialised countries providing better nutrition which is thought to increase resistance to infection and the emergence of disease. Improved housing and reduced family size also played its part, as there is evidence that the risk of transmission can be related to average room size and the number of individuals sleeping in the same room.

Bovine tuberculosis remained a threat to public health and was tackled by pasteurisation of the milk. In addition, government-sponsored eradication campaigns in most industrialised countries were instituted with compulsory tuberculin testing of cattle and slaughter of those found to be infected. The advent of anti-tuberculosis chemotherapy meant that smear-positive tuberculosis could be identified and rapidly rendered noninfectious through treatment. National programs such as mass – miniaturised radiography assisted case finding and resulted in a decline of 4% per year. It was not just industrialised countries who with effective case finding and treatment could reduce the incidence of disease. Tanzania, one of the poorest countries in the world, developed an efficient tuberculosis control program that brought about a reduction in the number of cases nationally from 25 000 in 1961 to 12 000 in 1985.

Hospital Infection Control

Institutions such as hospitals and prison are high-risk environments for tuberculosis transmission. Individuals are living close proximity and many may be immunocompromised as a result of immunosuppressive therapy or HIV infection. Patients with sputum smear-positive tuberculosis should be managed as an outpatient if this is possible. If hospital admission is required then they should be boarded in a side room until they have received 2 weeks of therapy. Special precautions are required for patients suspected of being infected with a multiple drug-resistant organism. A list of patients who should be considered at high risk of MDRTB is listed in Table 10.1. Specimens for rapid diagnosis should be obtained, including sputum smear, to determine whether the risk of transmission is high, and sputum should be taken for culture. It is in this circumstance that DNA amplification methods

Table 10.1 Initial assessment of patients with suspected tuberculosis

1. Diagnosis – Does the patient have tuberculosis?	
Suspected	Symptoms and signs} persistent cough, night sweats Suggestive of tuberculosis} weight loss, fever, CXR changes with or without microbiological/histological support (i.e. smear positive/PPD strongly positive)
Confirmed	Culture positive disease
2. Infectiousness – Is the patient with suspected or confirmed tuberculosis likely to be infectious to others?	
Infectious	(a) Sputum smear positive pulmonary disease (b) For suspected pulmonary disease assume infectious until proven otherwise (c) Disease of the airway, e.g. laryngeal tuberculosis (d) The following nonpulmonary lesions; open abscess or lesions in which the concentration of organisms is high and drainage from the lesion extensive
Potentially infectious	(a) Sputum smear negative pulmonary disease in which one or more cultures positive or culture results not yet known
Non-infectious	(a) Sputum smear negative, culture negative pulmonary disease (b) Non-pulmonary disease except those mentioned above
3. Drug resistance or MDRTB – Is the patient with suspected or confirmed tuberculosis likely to have drug-resistant disease?	
Suspected drug resistance	(a) Previous treatment for tuberculosis (b) Contact with a person with known drug-resistant disease (c) Birth, travel or residence in an area with a high prevalence of MDRTB, e.g. countries in Asia, Africa, Latin America, South & East Europe (d) HIV infection (e) Failure to respond clinically to a standard treatment regime, e.g. temperature still elevated after 2 weeks treatment (f) Poor compliance with therapy (g) Prolonged smear or culture positive while on treatment
Confirmed	(a) Resistance to one or more first line anti-tuberculosis drugs confirmed by conventional or molecular techniques

to establish the diagnosis of tuberculosis are of particular importance. Methods that determine the *rpoB* genotype provide a rapid mechanism of determining rifampicin susceptibility with approximately 95% sensitivity (Honore *et al.*, 1993). This can be used as a surrogate marker of multiple drug resistance, and rifampicin monoresistance is rare, being usually accompanied at least by isoniazid resistance. Such patients should be managed in negative-pressure single-side rooms. Health care workers should wear personal protective equipment including impervious gowns and high-efficiency particulate masks. When patients with MDRTB are to undergo procedures likely to generate aerosols, these should be performed in a negative pressure room. A summary of the requirements is found in Table 10.1. Health care workers who are immunosuppressed should not work with smear-positive tuberculosis patients because of their increased susceptibility to infection and disease progression. They should be able to exclude themselves from contact with such patients without prejudice.

Vaccination

The first attempt to make a vaccination against tuberculosis was made by Koch who injected heat-killed bacilli. The intense reaction tuberculin-positive individuals expressed became known as the Koch

reaction. This reaction was not accompanied by effective protection. Calmette and Guérin produced a prototypic vaccine by passaging *M. bovis* 231 times through a medium containing glycerol and ox bile. The bacille Calmette–Guérin (BCG) was found to be safe and gained wide acceptance throughout Europe. Many studies have confirmed the efficacy of BCG against tuberculosis especially against miliary forms of the disease such as meningitis (Brewer, 2000). Despite this, the use of BCG remains controversial. Physicians in the US oppose its use preferring the ability to be able to use the Mantoux reaction to diagnose acute disease. Compilations of the results of clinical trials show a wide variation in the protective efficacy with results ranging from –2 to 70% (Brewer, 2000) with an average effectiveness of approximately 50%. This wide discrepancy may be due to different immune responses to mycobacterial antigens during early life. In a country with high tuberculosis prevalence, exposure to mycobacterial antigens through environmental as well as pathogenic species may mean that BCG cannot provide much additional protection.

The manifest shortcomings of BCG has prompted a widespread search for an alternative vaccine. Research groups are searching the genome for potential new vaccine candidates. Several candidate vaccines are at various stages of clinical development, but all are some years from introduction into routine practice.

Non-Tuberculosis Mycobacteria

Stephen H. Gillespie

Centre for Medical Microbiology, Royal Free and University College Medical School, Hampstead Campus, London, UK

INTRODUCTION

Non-tuberculosis mycobacteria are important human pathogens. They were once classified as atypical or anonymous to distinguish them from *Mycobacterium tuberculosis* which is an obligate pathogen (Runyon 1957). They are, for the most part, environmental organisms – something which is characteristic of the genus as a whole. Thus the term is inaccurate as well as unhelpful, and the name non-tuberculosis mycobacteria (NTM) is preferred.

DESCRIPTION OF THE ORGANISM

Taxonomy

The taxonomy of NTM has been transformed by the use of sequence data from the 16S rRNA gene. This gene is approximately 1500 nucleotides containing conserved and hypervariable regions. The sequence of the two hypervariable regions, A and B can be used to speciate organisms. In mycobacteria, region A is the most useful for this purpose, as some distinct species share a sequence in region B. The linear sequence of 16S rRNA folds to give it a number of helices; variation in the sequence in these helices is typical of different groups of species (Tortoli 2003; Tortoli *et al.* 2001). For example, the addition of a cysteine at position 184 in helix 10 is typical of thermo-tolerant rapid growers. There are more extensive and variable length insertions at position 455 in helix 18 of between 8 and 14 nucleotides, and these are associated with slow growers. Strains without any insertions are, with a few exceptions, rapid growers (Brown-Elliott and Wallace Jr. 2002; Tortoli 2003; Tortoli *et al.* 2001).

Alternative sequencing targets have been proposed for identification of mycobacteria including heat-shock protein *hsp65* and the gyrase genes (Hafner *et al.* 2004). Mycolic acids are β -hydroxy fatty acids with long side chains which make up a large component of the mycobacterial cell wall. They differ in the number of carbon atoms in the chain and the presence of different functional groups. The mycolic acid pattern of a cell wall is usually typical of a species. This difference can be detected by running the lipids on GLC, TLC or HPLC (Hale, Pfyffer and Salfinger 2001; Tortoli 2003).

One consequence of the interest in mycobacteria as a result of the HIV epidemic coupled with the availability of inexpensive sequencing facilities is the proliferation of new mycobacterial species that have been isolated from human specimens. This chapter will focus on those species which are most commonly isolated in a routine clinical laboratory and will confine a description of the other species to Table 11.1 for slow-growing organisms and Table 11.2 for the rapid growers. Those seeking additional details should refer to (Brown-Elliott and Wallace Jr. 2002; Tortoli *et al.* 2001).

Diagnosis of Non-Tuberculosis Mycobacteria

Isolation of obligate pathogens such as *M. tuberculosis* from a specimen is sufficient for a diagnosis, but for NTM this may not be the case. Many of these organisms are found in the body as commensal organisms or can contaminate laboratory reagents or the specimen from the environment. In many clinical circumstances multiple isolates of NTMs are required before a diagnosis can be confirmed (American Thoracic Society 1997; Hale, Pfyffer and Salfinger 2001; Joint Tuberculosis Committee 2000).

Pulmonary Infection

Pulmonary disease caused by NTM may appear subtly different from that of tuberculosis. Cavities are often thin walled, and there is less surrounding infiltrate. Spread is more contiguous with more marked involvement of the pleura (Kerbiriou *et al.* 2003). Occasionally NTM and notably *M. avium-intracellulare* may cause a single pulmonary nodule (Huang *et al.* 1999; Prince *et al.* 1989) Table 11.3.

Before confirming a diagnosis of NTM infection, it is necessary to exclude alternative diagnoses such as tuberculosis and lung malignancy that is often common in the patients suspected of having these infections. *Mycobacterium kansasii*, *M. xenopi*, *M. malmoense* and the rapid growers are part of the normal flora or can be environmental contaminants; so a single isolate is often insufficient for an unequivocal diagnosis. Thus, to establish a diagnosis of NTM infection, multiple isolates of an NTM are required in specimens from contaminated sites. A single specimen that is smear positive or from bronchoalveolar lavage is more likely to be significant (Joint Tuberculosis Committee 2000). In contrast, a single isolate from a biopsy specimen or from a sterile site can be diagnostic, provided it is supported by compatible histology and laboratory contamination is excluded.

For patients with *M. kansasii*, *M. xenopi* and *M. malmoense* infection sputum is usually an adequate sample. For HIV seronegative individuals infected with *M. avium-intracellulare*, sputum is often negative and bronchial lavage samples should be obtained (American Thoracic Society 1997; Hale, Pfyffer and Salfinger 2001; Joint Tuberculosis Committee 2000).

Lymphadenitis

In the industrialised world NTMs are the commonest cause of mycobacterial lymphadenitis (Grange, Yates and Pozniak 1995). It is still important, however, to exclude the possibility of tuberculosis, usually with a DNA amplification technique. The diagnosis of NTM lymphadenitis depends on demonstrating the presence of granulomata histologically in the context of a negative tuberculin test. A single

Table 11.1 Summary of characteristic of rarely isolated mycobacteria

Species name	Environmental source	Description	Pathogenic associations
<i>M. bohemicum</i> <i>M. celatum</i>	Not known Not known	Shares some phenotypic characteristics with MIA complex Shares phenotypic characteristics with <i>M. xenopi</i>	Lymphadenitis in immunocompromised patients Disseminated and pulmonary infection in AIDS patients, rarely pulmonary infection or lymphadenitis in immunocompetent patients
<i>M. conspicuum</i>	Not known	Only grows at 37 °C in liquid media	Disseminated infection in severely immunocompromised patients
<i>M. dorcium</i> <i>M. heckeshornense</i> <i>M. interjectum</i> <i>M. intermedium</i>	Not known	Scotochromogen Phenotypically and genetically related to <i>M. xenopi</i> Yellow scotochromogen, related to <i>M. simiae</i> A photochromogen related to <i>M. simiae</i>	Meningitis not confirmed pathogen Pulmonary cavitation and infiltrates Lymphadenitis and chronic lung infection Chronic pulmonary infection in patient with chronic obstructive pulmonary disease
<i>M. kubicae</i>		Strongly acid fast, rod shaped and often bent – related to <i>M. simiae</i>	Possible respiratory pathogen
<i>M. lentiflavum</i>		A scotochromogen related to <i>M. simiae</i>	Usually non-pathogenic, but lymphadenitis, chronic pulmonary disease, disseminated infection and abscesses described
<i>M. palustre</i> <i>M. branderi</i> <i>M. heidelbergense</i>	River water	Yellow scotochromogen related <i>M. simiae</i> and <i>M. kubicae</i> Non-chromogenic most closely related to <i>M. celatum</i> Phenotypically similar to <i>M. malmoense</i> but genotypically closest to <i>M. simiae</i>	Possible cause of lymphadenitis Ulcerative tenosynovitis and pulmonary infection Lymphadenitis and pulmonary infection described
<i>M. triplex</i>		Related to <i>M. simiae</i>	Disseminated infection in severely immunocompromised patients
<i>M. elephantis</i>		A scotochromogenic rapid grower, unrelated to other rapid growers	Lymphadenitis and possibly pulmonary infection
<i>M. goodie</i>		Rapid grower which shares phenotypic and genotypic similarities with <i>M. smegmatis</i>	Traumatic osteomyelitis and chronic pulmonary infection
<i>M. immunogenum</i>		Rapid grower sharing phenotypic and genotypic similarities with <i>M. abscessus</i> and <i>M. chelonae</i>	Cutaneous infection, keratitis and catheter related infections
<i>M. wolinskyi</i>		Related to <i>M. smegmatis</i>	Surgical infections, traumatic cellulitis and osteomyelitis

Table 11.2 Summary of rapidly growing mycobacteria

Group	Species	Disease associations
<i>Mycobacterium fortuitum</i> group	<i>M. fortuitum</i> <i>M. peregrinum</i> <i>M. mucogenicum</i> <i>M. senegalense</i> <i>M. septicum</i> Third biovariant ^a	Localised wound infections, venous catheter infections and surgical infections notably augmentation mammoplasty. Venous catheter infections, a common problem in immunocompromised patients
<i>M. chelonae-abscessus</i> group	<i>M. chelonae</i> <i>M. abscessus</i> <i>M. immunogenicum</i>	Wound infections, venous catheter infections and post-traumatic or surgical corneal infections Venous catheter infections, chronic lung infection and surgical wound infections Venous catheter infection

^a Several species have been described within this taxon: *Mycobacterium boenickei* sp. nov., *M. houstonense* sp. nov., *M. neworleansense* sp. nov. and *M. brisbanense* sp. nov. and *M. porcinum*.

isolate from a biopsy specimen is sufficient to make the diagnosis, although yields may be less than 50% of cases (American Thoracic Society 1997). This may, in part, be due to the methods employed and the presence of fastidious mycobacterial species such as *M. haemophilum* and *M. genavense*.

Cutaneous Infection

Infection of the skin with rapidly growing mycobacteria often follows colonisation and infection of intravascular devices. Thus the significance of rapidly growing mycobacteria in skin samples must be evaluated carefully. Multiple isolates are required in clinical circumstances that

are compatible with the diagnosis for certainty. Diagnostic uncertainty may be reduced if cases may form part of known outbreaks with contaminated injections or prostheses.

For *M. ulcerans* and *M. marinum*, significance is more easy to ascribe, as these species are likely to be isolated from patients with characteristic cutaneous lesions making diagnosis easier.

MYCOBACTERIUM AVIUM-INTRACELLULARE

This mycobacterium, responsible for infection in birds, was first identified in 1890 and given the name *M. avium*. A related organism was identified as the cause of an outbreak of pulmonary infection in

a State hospital in Georgia and for some time was known as the Battey bacillus (after the Battey State hospital from which it was isolated). This was given the name *M. intracellulare*.

Epidemiology

Organisms of the *M. avium-intracellulare* complex (MAIC) are widely distributed in nature and have a strong association with acid brown water swamps in the southern USA. *Mycobacterium avium-intracellulare* occurs worldwide where conditions are favorable for its growth: warm temperatures, low pH, low dissolved oxygen, high soluble zinc, high humic acid and high fulvic acid. The availability of these environmental conditions may explain, in part, the geographical variation in the incidence of disease. The organism can be isolated from soil, dust, animals and tap water, and any of these may be the source of infection for immunocompromised patients. The mere isolation of this organism in an environment does not explain the epidemiology on its own, as *M. avium-intracellulare* can be isolated from environmental samples in Congo and Kenya but where MAIC infection is uncommon in AIDS patients.

Before the onset of the HIV, epidemic infections with MAIC were not commonly recognised. Infections, when they were recognised, were mainly those of the respiratory tract and associated with concomitant chronic lung disease or deficient cellular immunity. Its prevalence is increasing (Falkinham III 1996). The predisposing conditions include pneumoconiosis and silicosis due to chronic and long-term exposure to dusts as a result of occupations (e.g. coal mining and farming) (Schaefer *et al.* 1969). For example, in one study, 73% of patients had pre-existing pulmonary disease, 38% smoked and 33% reported alcohol abuse. It has been recognised that MAIC can cause a pulmonary infection in elderly patients with no overt evidence of immunocompromise (Kennedy and Weber 1994; Prince *et al.* 1989).

A chronic lymphadenitis, usually in the cervical and facial region, is the most common presentation in children between 1 and 10 years of age, and MAIC is responsible for the majority of mycobacterial

lymphadenitis in the developed world (Grange, Yates and Pozniak 1995).

Disseminated infection may occur in patients without AIDS, usually associated with malignancy and inherited or iatrogenic immunodeficiency. The HIV initially brought a massive increase in the number of cases of MAIC infection until highly active antiretroviral therapy (HAART) became available. In areas of the developed world where this treatment is available, MAIC infections have become uncommon once again. The main portal of entry is thought to be the respiratory and gastrointestinal tracts. Initially the patient may be colonised, but later disseminated disease with bacteraemia may develop. Pulmonary infection or invasion of other organs, including bone marrow, may take place. Dissemination does not usually take place until the CD4 count has fallen well below 100/mm³. Colonisation and infection with *M. avium-intracellulare* are associated with a worse prognosis compared with uninfected patients. The outcome can be improved with effective treatment.

In areas where *M. tuberculosis* is endemic, HIV-infected individuals are rarely infected with MAIC. The reasons for this dichotomy of presentation are not well understood.

Clinical Features

Lymphadenitis

The submandibular, pre-auricular, submaxillary and rarely intraparotid lymph nodes are involved. The infection follows a chronic course with discharge and sinus formation and must be differentiated from other causes of localised lymphadenopathy such as tuberculosis, lymphoma and cat scratch disease.

Respiratory Infection

There are four syndromes recognised: solitary pulmonary nodules, chronic bronchitis or bronchiectasis, a tuberculosis-like syndrome and diffuse pulmonary infiltrates. In patients with bronchitis-bronchiectasis syndrome are usually in the older age group. Diffuse pulmonary infiltrates are usually found in severely immunocompromised individuals in whom a wide range of clinical and radiological features have been described but bacteraemia predominates (Kennedy and Weber 1994; Prince *et al.* 1989).

Disseminated Disease

The usual symptoms are fever and night sweats, diarrhea, abdominal pain and weight loss. On examination, patients are found to be wasted and febrile. Localised disease is less common, but pulmonary nodules, infiltrates or cavitation may be present. Additionally, intra-abdominal abscess, skin infection, osteomyelitis and cervical lymphadenitis may co-exist (Huang *et al.* 1999). At post-mortem many HIV-infected patients have undiagnosed evidence of disseminated MAIC infection.

On clinical examination patients are wasted and have hepatosplenomegaly. They are often anemic with reduced platelets and have elevated alkaline phosphatase enzymes. Intra-abdominal lymphadenopathy can be detected by ultrasound or CT scanning.

Management of *M. avium-intracellulare* disease

HIV Seronegative Patients

Pulmonary disease: Older studies of treatment and the natural history of disease show that patients who are symptomatic have progressive disease which is difficult to treat, whereas many of those who were

asymptomatic at the time of isolation went on to develop invasive disease (Hunter *et al.* 1981). Isolated pulmonary disease in otherwise healthy women is often difficult to treat, as these patients frequently fail therapy (Prince *et al.* 1989; Huang *et al.* 1999).

Treatment with three drugs including rifampicin, isoniazid with ethambutol were previously thought to give the best results (Hunter *et al.* 1981). Five-year follow-up of patients treated with this regimen showed that 15% of patients failed therapy and 14% relapsed (Anon, 2002). The activity of clarithromycin and quinolones suggest that they may have a role to play, and clinical trials are underway to evaluate this (Research Committee, British Thoracic Society 2001). Open trials suggest that sputum conversion rates of greater than 75% can be achieved with regimens that include a macrolide (Wallace Jr. *et al.* 1994a; Griffith *et al.* 1998; Wallace Jr. *et al.* 2003). Thus, although no comparative clinical trials have yet been reported, macrolides should probably be included in regimens used to treat *M. avium-intracellulare* infections in immunocompetent patients. Treatment can also be given intermittently (Griffith *et al.* 2000). Relapse, when it occurs, may be due not only to treatment failure but to infection with a new and different strains from the environment (Wallace Jr. *et al.* 2003). Some authorities suggest that rifabutin should be the rifamycin of choice for treatment of *M. avium-intracellulare* infection because of its greater *in vitro* activity. However, this drug has a different adverse event profile, and only comparative clinical trials can tell whether the additional activity is gained without increase adverse events (Research Committee, British Thoracic Society 2001).

Lymphadenitis: Surgical excision is essential for diagnosis, as the yield from fine needle aspiration is not complete and there is a considerable risk of sinus formation (American Thoracic Society 1997). Optimal treatment of this condition is surgical excision which has a lower re-operation rate than incision and drainage, curettage or aspiration (Flint *et al.* 2000). Relapse and sinus formation are rare occurring in less than 5% of cases (Rahal *et al.* 2001; Danielides *et al.* 2002). Antimicrobial chemotherapy appears to be unnecessary (American Thoracic Society 1997), although there are reports of successful management with clarithromycin monotherapy (Tunkel and Romaneschi 1995).

HIV seropositive patients: Disseminated *M. avium-intracellulare* infection is a late complication of HIV infection, and since the introduction of HAART, it has become much less common in developed countries, occurring in patients who are untreated or who have been unable to tolerate therapy. The optimal regimen has not yet been established in part, because patients with this infection are at very late stage of their HIV disease where the clinical course is complicated by other opportunistic infections and the complications of HIV itself. In the era of HAART, the management of disseminated *M. avium-intracellulare* infection is underwritten by therapeutic efforts to reduce the HIV viral load, increase the CD4 count and bring about reversal of the immune deficit.

Antibiotics have an important role in reducing bacteremia, and the antibiotics which have been shown to be able to do that include macrolides such as clarithromycin and azithromycin, quinolones such as ciprofloxacin and rifamycins such as rifabutin. The macrolides are highly active and are the cornerstones of all regimens. They are capable of reducing the count of bacteria in the blood when given alone (Hoy *et al.* 1990; Dautzenberg *et al.* 1993). Monotherapy results in the rapid emergence of resistance, and thus combination therapy should be chosen. Clinical trials have supported the superiority of clarithromycin, ethambutol and rifabutin over rifampicin, ethambutol, clofazimine and ciprofloxacin (Shafran *et al.* 1996). A recent comparative trial suggested that lower doses of rifabutin together with ethambutol are more effective than a four-drug regimen of rifampicin, ethambutol, clofazimine and ciprofloxacin while still retaining much of the activity of clarithromycin and rifabutin doses (Shafran *et al.* 1996).

Prophylaxis of *M. avium-intracellulare*: Prophylaxis is necessary to prevent infection in patients with late-stage HIV infection with low CD4 count. Macrolides have been shown to be more effective than

rifabutin which also is an effective agent but is associated with a higher rate of intolerance (Havliir *et al.* 1996; Phillips *et al.* 2002). Ultimately the choice of prophylactic agent will depend on the choice of HAART, as rifabutin interacts with protease inhibitors and patients differ considerably in their ability to tolerate drugs (Cohn *et al.* 2002).

MYCOBACTERIUM KANSASII

Mycobacterium kansasii is a photochromogenic organism that can be isolated from environmental sources. It is one of the commonest NTMs isolated in UK laboratories (Evans *et al.* 1996b).

Epidemiology

Mycobacterium kansasii is one of the most common NTMs isolated making up approximately 5% of significant isolates from surveys (Lillo *et al.* 1990; Evans *et al.* 1996b). Infection is acquired from the environment, and person-to-person spread is thought not to occur. *Mycobacterium kansasii* can be isolated from swimming pools, hot and cold water supplies and storage tanks, and this may be the source of infection in the hospital environment (McSwiggen and Collins). Areas of high and low incidence emphasise the importance of environmental sources in the epidemiology of this infection. Unlike other NTM infections the incidence of *M. kansasii* does not appear to be rising (Breathnach *et al.* 1998; Evans *et al.* 1996b).

Infection is typically found in older patients, and there is a strong male preponderance. A history of cigarette smoking is strongly associated with infection. Chronic lung conditions including pneumoconiosis, treated tuberculosis, chronic obstructive pulmonary disease and bronchiectasis all predispose to *M. kansasii* infection (Corbett *et al.* 1999).

Clinical Feature

The characteristic clinical association is with a chronically progressive pulmonary infection which follows a rather indolent course. The presentation frequently resembles tuberculosis and is often mistaken for it. Cough, sputum production, hemoptysis and the constitutional effects of infection are commonly seen. Pulmonary infection usually arises in patients who have a compromised respiratory tract and who are immunocompetent.

Localised infections are reported but are much less common than in other mycobacteriosis. Lymphadenitis and cutaneous and bone infections have all been reported. Cutaneous infection is usually associated with immunosuppression as is disseminated disease. Some cases of disseminated disease are associated with HIV infection (Breathnach *et al.* 1995). Radiographic abnormalities in patients with *M. kansasii* infection were frequently unilateral. Air-space shadowing involving more than one bronchopulmonary segment and pleural effusions is seen less frequently than in tuberculosis. Cavitation is seen in patients with *M. kansasii* infection as frequently as in those with tuberculosis. Hilar lymphadenopathy and pleural effusions are rare (Evans *et al.* 1996a).

Management of *M. kansasii* Infection

Pulmonary Infections

Mortality rates of *M. kansasii* infection are high, but this is often due to the severe underlying conditions that co-exist in these patients (Jenkins *et al.* 1994). There is widespread agreement that rifampicin is an essential component of successful regimens. Almost all patients become culture negative within 4 months. On the other hand, resistance to this agent or its absence in the regimen is associated with treatment failure (Ahn *et al.* 1983; Banks *et al.* 1984; Pezzia

et al. 1981). With regimens that contain rifampicin, relapse rates are typically low with figures of between 2.5 and 9% (Ahn *et al.* 1983; Jenkins *et al.* 1994).

The American Thoracic Society recommend a regimen of isoniazid, rifampicin and ethambutol given daily for 18 months with at least 12 months of negative sputum cultures. In patients who are unable to tolerate one of these three drugs, clarithromycin would seem a reasonable alternative, but its effectiveness has not been established by clinical trials (see below). Pyrazinamide has no role to play as in therapy for *M. kansasii* infections, because all isolates are resistant (American Thoracic Society 1997). A prospective clinical trial performed by the British Thoracic Society (BTS) in 173 patients with two sputum cultures positive with NTM showed that *M. kansasii* pulmonary infection responds well to 9 months of treatment with rifampicin and ethambutol, but patients who contract this disease have a high mortality rate from other causes. Isoniazid did not appear to be a necessary part of the regimen (Jenkins *et al.* 1994). Consequently the BTS recommend that 9 months of rifampicin and ethambutol is adequate treatment for most patients, but when there is evidence of compromising conditions treatment can be extended to 15–24 months (Joint Tuberculosis Committee 2000). The use of intermittent drug regimens or short course is not sufficiently studied for advice to be given.

In patients in whom there is an inadequate response, clarithromycin and fluoroquinolones could be used, as these agents are highly active against *M. kansasii* and are likely to be beneficial (Yew *et al.* 1994; Gillespie, Morrissey and Everett 2001), although there is no clinical trial data available. Alternatives include prothionamide and streptomycin could be added (Joint Tuberculosis Committee 2000) but both are associated with frequent adverse events. When rifampicin resistance is present a regimen which includes clarithromycin and ciprofloxacin is associated with a favorable outcome (Wallace Jr. *et al.* 1994b).

Extrapulmonary Infection

The treatment of extrapulmonary disease should probably be similar to the pulmonary regimens. For lymphadenopathy, excision is recommended, as this is the optimal treatment for *M. avium-intracellulare* infection, the commonest cause (see below) (American Thoracic Society 1997; Joint Tuberculosis Committee 2000).

MYCOBACTERIUM MALMOENSE

Mycobacterium malmoense was first isolated from four patients with pulmonary disease present in Malmo, Sweden (Portaels, Larsson and Jenkins 1995). It is closely related to *M. avium-intracellulare* and is a non-chromogenic strain that grows very slowly. The slow growth rate may be the reason that some infections are not diagnosed.

Epidemiology

Like other NTMs *M. malmoense* has been isolated from the environment but only rarely (Portaels, Larsson and Jenkins 1995). It has been isolated from human and animal sources. Most cases have been reported from northern Europe including the UK, but cases have been reported from the Americas. The number of cases is increasing, and this is thought to be due to a real rise in the number of cases not just an improvement in mycobacterial diagnostic methods. *Mycobacterium malmoense* has an affinity for the respiratory tract, and the majority of infections are pulmonary. Patients are predisposed to pulmonary infection by previous pulmonary disease, notably treated tuberculosis. Other associated conditions include lung carcinoma, chronic obstructive airways disease and pneumoconiosis (Jenkins 1981; Falkinham III 1996). Immunosuppression by leukemia or other malignancy can predispose to infection, but *M. malmoense* is rarely associated with HIV. The commonest extrapulmonary presentation is cervical lymphadenitis

which occurs most often in children. Disseminated infection is found most often in severely immunocompromised individuals including those with HIV or leukemia. Asymptomatic colonisation of the respiratory tract is reported and must be distinguished from invasive disease.

Clinical Features

The prodromal period varies from a few weeks to more than a year. Cough, weight loss and hemoptysis are the most prominent symptoms, and the overall picture closely resembles tuberculosis. Radiological examination reveals the presence of cavitation in the majority of patients.

Management of *M. malmoense* Disease

Pulmonary Disease

Rifampicin and ethambutol containing regimens given for 18–24 months are better than those in whom other regimens or shorter durations of treatment were used (Banks *et al.* 1984). The addition of second- or third-line drugs increased the rate at which adverse events were reported without improving the outcome. Surgery has an important role to play in those who are suitable for operation, and chemotherapy should be continued afterwards for at least 18 months. A clinical trial of chemotherapy in *M. malmoense* infection showed that treatment of *M. malmoense* with rifampicin and ethambutol for 2 years is preferable to a regimen that contains isoniazid, although there was a non-significant reduction in the relapse rate for the three drug regimen. However, there is a higher death rate for the three-drug regimen (Joint Tuberculosis Committee 2000). Macrolides and quinolones are active *in vitro* (Yew *et al.* 1994; Gillespie, Morrissey and Everett 2001), and there are some anecdotal reports of treatment response when these agents are used in the management of patients who are highly susceptible to infection (Scmitt *et al.* 1999).

Extrapulmonary Disease

Lymphadenitis is the commonest form of *M. malmoense* extrapulmonary disease, and this syndrome should be treated with excision. Otherwise, extrapulmonary disease should be treated in the same way as pulmonary disease.

MYCOBACTERIUM XENOPI

Mycobacterium xenopi is a slow-growing, non-chromogenic mycobacterium which is frequently isolated from human specimens as a coloniser or as a pathogen. It was first isolated from a skin granuloma of a toad *Xenopus laevis* kept in the laboratory for pregnancy testing. It is regularly isolated from human respiratory specimens, and its significance must be carefully determined.

Epidemiology

In Western Europe it is one of the most common NTMs isolated but much less common in the United States. It has been isolated from hospital hot water supplies, and nosocomial outbreaks have been reported. Person-to-person transmission is not thought to occur but cannot be excluded when there are nosocomial outbreaks. The reservoir of *M. xenopi* in the environment is uncertain, but the organism is isolated in fresh or seawater. Clustering of cases in coastal areas suggests a link with the sea. Birds are highly susceptible to infection, and seabirds have been proposed as a reservoir of infection.

Infection, when it occurs, is most likely to occur in males over middle age, often with a long history of previous lung problems

including obstructive airways disease emphysema and healed tuberculosis (Jenkins 1981; Falkinham III 1996). *Mycobacterium xenopi* has also been reported in HIV-infected individuals who are severely immunocompromised (Claydon, Coker and Harris 1991; Kerbiriou *et al.* 2003).

Clinical Features

Isolation of *M. xenopi* is not always associated with disease. Retrospective reviews differ in the proportion of case attributable to the organism, but it has been estimated that half of isolates are not clinically significant. A study of HIV-positive individuals with multiple isolated *M. xenopi* showed that almost all of the patients cleared the organism without specific chemotherapy but with HAART (Kerbiriou *et al.* 2003).

The presentation of pulmonary disease is subacute in most instances. It is almost always associated with cough, but fever is not a prominent sign. Hemoptysis and weight loss may be presenting symptoms. Solitary or multiple nodules or cavitation may be found on radiological examination of the chest (Kerbiriou *et al.* 2003). A syndrome indistinguishable from tuberculosis may also develop. Extrapulmonary disease is rare. Disseminated disease has been reported in HIV-infected patients but is much less common than *M. kansasii* and *M. avium-intracellulare*.

Management of *M. xenopi* Disease

Pulmonary Disease

Mycobacterium xenopi poses many diagnostic and therapeutic problems. In some patients *M. xenopi* may act as a coloniser without causing disease (Smith and Citron 1983; Simor, Salit and Vellend 1984; Jiva *et al.* 1997). Thus it will be present in multiple specimens thus passing the test for significance, although in many such cases it is not responsible for clinical symptoms. In addition, infection with *M. xenopi* is normally indolent with disease developing over a number of years (Banks *et al.* 1984). Thus an isolate in an apparently asymptomatic patient cannot be lightly dismissed, especially in HIV-infected individuals. To overcome the diagnostic difficulty it has been proposed that the criteria for diagnosis of *M. xenopi* infection should be two sputum isolations in the absence of other likely causes of symptoms. (Juffermans *et al.* 1998)

Early studies have suggested that regimens should contain rifampicin and isoniazid together with ethambutol or streptomycin (Costrini *et al.* 1981; Banks *et al.* 1984). A clinical trial suggests that rifampicin and ethambutol is the optimum regimen, although there is a trend to a higher cure rate when isoniazid is added but that the complication rate is increased (Research Committee, British Thoracic Society 2001). In view of the higher complication rate with added isoniazid guidelines suggest that this drug is included only if treatment is failing to render sputum culture negative (Research Committee, British Thoracic Society 2001).

Macrolides and quinolones may have an important role in the treatment of *M. xenopi* infections, as they are active *in vitro* and in animal models (Yew *et al.* 1994; Gillespie, Morrissey and Everett 2001; Lounis *et al.* 2001). There are anecdotal reports of the value of these agents (Scmitt *et al.* 1999). Clinical trial data are not yet available to inform therapeutic choice, but these could rationally be added to treatment in patients who were failing to respond.

The results of medical therapy can be poor, with the 5-year mortality up to 57% (although a minority of these deaths were directly attributed to mycobacterial infection) (Research Committee, British Thoracic Society 2001). Pulmonary resection is often necessary as an adjunct to treatment (Parrot and Grosset 1988). Pulmonary resection may be considered in patients whose disease is localised and who are failing on therapy but otherwise have good pulmonary function.

A study has reported that when these criteria are applied sputum conversion is complete in all but the patients who have incomplete resection (Lang-Lazdunski *et al.* 2001).

MYCOBACTERIUM MARINUM

Epidemiology

Mycobacterium marinum was first recognised as a pathogen of fish. Human infection, when it occurs, usually arises as a result of water contact. Initially most cases were associated with poorly maintained contaminated swimming pools – swimming pool granuloma (Falkinham III 1996). This has now almost completely disappeared due to improved construction and water purification. Most cases seen today arise in association with the maintenance of fish tanks, and fish farming is a risk factor of infection.

Clinical Features

Infection with *M. marinum* causes a chronic granulomatous infiltration of the skin with a similar appearance to sporotrichosis (Falkinham III 1996; Casal and Casal 2001). Nodular or pustular lesions are the most common, and erythematous swelling crusting or swelling may occur. The upper limb, especially the hand, is the most common site of infection. The lesions spread locally in the majority of cases after 4–6 weeks.

Mycobacterium marinum infection must be differentiated from other chronic granulomatous skin infections such as tuberculosis, nocardiosis, coccidioidomycosis, histoplasmosis, leishmaniasis, sporotrichosis, leprosy and syphilis.

Management of *M. marinum* Infection

The organisms are often resistant to isoniazid but susceptible to rifampicin, ethambutol and pyrazinamide. Minocycline and other tetracyclines have been used in treatment, but rifampicin and ethambutol appear to be more successful (American Thoracic Society 1997).

MYCOBACTERIUM ULCERANS

Epidemiology

Mycobacterium ulcerans was first isolated from patients in Bairnsdale Australia with necrotising skin ulcers. Buruli ulcer, the lesion caused by this organism, is described in many tropical and subtropical countries in Africa, Central and South America and Southeast Asia (Hayman 1991; Marston *et al.* 1995).

An environmental source for *M. ulcerans* has not been identified, but epidemiological studies indicate that it is to be found near slow-flowing or stagnant water. Infection is most common in individuals under 15 years of age, and males and females are affected equally. The prevalence of infection is highest in villages close to rivers where farming activities occur. Infection appears to occur by direct inoculation into the skin, as wearing protective clothing such as long trousers makes infection less likely (Marston *et al.* 1995). The incidence of infection is rising in some countries of West Africa (van der Werf *et al.* 1999).

Clinical Features

The disease begins as a small subcutaneous swelling increasing in size until the skin is raised. At first it is attached to the skin but not the deep fascia, but as the lesion progresses it extends to involve this

layer. The skin over the lesion is at first darker but then loses its pigmentation before becoming necrotic and ulcerating. Some cases have a small central vesicle. Rarely the disease may present in an edematous form mimicking cellulitis. Occasionally the necrosis spreads through the deep fascia involving muscle and bone (Hayman 1993). Ulcers are typically painless, usually found on the lower limbs but may more rarely occur on the face or trunk especially in children. The disease is accompanied by remarkably few systemic symptoms, but occasionally secondary infections resulting in sepsis or tetanus cause severe systemic disease and death. Buruli ulcer should be differentiated from foreign body granulomata, phycomycosis fibroma or fibrosarcoma. Extensive scarring can lead to contractures of the limbs, blindness and other adverse sequelae, which impose a substantial health and economic burden.

Pathology

The ulcer usually has straight or undermined edge with subcutaneous spread, producing nodules and a gelatinous material which is readily removed. An edematous form of the diseases has also been described. Microscopically necrotic tissue lines the ulcer, and multiple acid-fast bacilli can be seen. The bacteria form tangled masses and globular forms where many bacteria are found within macrophages have been described, but this latter term should be avoided as it may give rise to confusion with leprosy (Hayman 1993).

Caseation is not a characteristic of Buruli ulceration. Necrosis is present in the lesion including fat necrosis due to infection of the arterioles serving the fat lobules. Mycobacteria can be found in lipid lacunae. The necrosis is characterised by calcification especially in chronic lesions, although this feature is rarely described in Australian cases. In studies of cases biopsied sequentially, three stages are described: necrosis and tissue degeneration, an organising stage and a healing stage (Hayman 1993).

Management of *M. ulcerans* Infection

Surgical treatment including excision and local debridement is the mainstay of therapy (van der Werf *et al.* 1999). There are few clinical trials of antimicrobial treatment, and these have been disappointing. Patients have been treated with isoniazid and streptomycin or oxytetracycline and dapsone and a combination of rifampicin, minocycline and cotrimoxazole, and these may be beneficial. A significant number of patients are left with residual disability.

Control

Vaccination with BCG does appear to provide some protection against infection. Wearing long trousers may be beneficial by preventing the initial inoculation injury necessary to establish infection.

RAPID GROWING MYCOBACTERIA

Mycobacterium fortuitum and the *M. chelonae* group are the species most frequently encountered in the clinical laboratory. *Mycobacterium fortuitum* was first isolated from a frog and *M. chelonae* from a turtle. The group of rapidly growing organisms is conveniently divided into three taxonomically related groups. *Mycobacterium fortuitum* has three species: *M. fortuitum*, *M. perigrinum* and an unnamed taxon. Additional species are being considered for inclusion. The *M. chelonae* group includes *M. chelonae* sensu stricto, *M. abscessus* and *M. immunogenum*. The smegmatis group includes *M. smegmatis*, *M. goodii* and *M. wolinskyi* (Table 11.2). The classification of this group is evolving rapidly with the increasing use of 16S sequencing for identification (Brown-Elliott and Wallace Jr. 2002; Tortoli 2003).

Epidemiology

The rapidly growing mycobacteria are environmental saprophytes and commensal organisms. They may be found in human specimens without evidence of disease; so care must be taken with ascribing significance to isolates (see above). Infections with rapidly growing mycobacteria are mainly associated with skin, soft tissue and catheters (Brown-Elliott and Wallace Jr. 2002; Wallace Jr. 1989; McWhinney *et al.* 1992). Surgical wounds can become infected, and infection may follow the use of any prosthesis that is infected with these organisms (Ozluer and De'Ambrosio 2001). Outbreaks have been associated with contaminated breast implants, breast augmentation surgery and infected prosthetic devices and intravenous injections and intraperitoneal canulae (Galil *et al.* 1999). Keratitis, ophthalmitis and lymphadenitis have been described (Griffith, Girard and Wallace Jr. 1993; Marin-Casanova *et al.* 2003). Disseminated infection can develop in immunocompromised patients, especially those undergoing remission induction chemotherapy. Pneumonia and disseminated skin infection can also occur in immunocompromised patients (American Thoracic Society 1997).

Pathology

Infection with rapidly growing mycobacteria is characterised histologically by polymorphonuclear leukocytosis in microabscesses. Necrosis is almost invariably present, and granulomatous change with Langerhan's giant cells is found in 80%. Caseation necrosis is rarely reported. Acid-fast bacilli are scanty and may not be seen in as many as two-thirds of biopsies. When organisms are present they are usually found in clumps extracellularly (Sungkanuparph, Sathapatayavongs and Prachartam 2003a; Sungkanuparph, Sathapatayavongs and Prachartam 2003b).

Clinical Features

A primary source for infection is not always apparent. Non-surgical skin infection is described in children and young adults. It usually takes the form of cellulitis with abscess formation. The infection follows an indolent path with the patient only seeking medical attention after several weeks. The lesions are red and only mildly tender. The organisms are inoculated into the skin as a result of penetrating trauma, foreign body or pre-existing skin disease. Postoperative infections are often associated with implantation of prostheses including cardiac valves and silicon prostheses used in augmentation mammoplasty. A series of sternotomy wound infections has been reported.

Pulmonary infection is associated with underlying pulmonary disease less often than for other NTMs and may follow a progressive course to death. Cough is the universal presenting symptom, and constitutional symptoms are reported along with progressive disease. Upper lobe infiltrates are most common with most patients developing bilateral disease. Cavitation is present in a minority of patients. Specific underlying diseases are infrequent, but they include previously treated mycobacterial disease, coexistent *M. avium* complex infection, cystic fibrosis and gastroesophageal disorders with chronic vomiting (Griffith, Girard and Wallace Jr. 1993).

Different clinical patterns of disseminated disease have been associated with renal transplantation, renal failure and collagen vascular diseases where skin lesions predominate over organ involvement. In patients with malignancy or defects in cell-mediated immunity, disease is more widespread alongside skin involvement. In this latter situation the mortality is high. Lymphadenitis with rapidly growing mycobacteria has been described in children and has been associated with tooth extraction in some cases.

The outcome of infection with rapidly growing mycobacteria is in large part dependent on the nature of the underlying medical condition. Where there is a severe underlying immune deficit which cannot be reversed, the mortality rate is high.

Management of Infection with Rapid Growers

Pulmonary Disease

More than 80% of cases of pulmonary disease are caused by *M. abscessus* which is the naturally most resistant member of the group of organisms (Griffith, Girard and Wallace Jr. 1993). Treatment of *M. abscessus* infections is often disappointing. Treatment can bring about clinical improvement, but cure is rare. When surgery is technically possible it is recommended (Joint Tuberculosis Committee 2000). Susceptibility testing of rapidly growing mycobacteria is thought to give a good guide to treatment, and regimens should be constructed on the basis of susceptibility test results (Wallace Jr. *et al.* 1985). Regimens should probably include rifampicin, ethambutol and clarithromycin. Fluoroquinolones, sulphonamides, amikacin, ceftazidime and penems may have a role to play in treatment (Wallace Jr. *et al.* 1985; Joint Tuberculosis Committee 2000; Tanaka *et al.* 2002).

Extrapulmonary Disease

Many cases of infection by rapid growers occur in the context of an infected prosthetic device, for example intravenous canulae or other implant. Successful therapy of these catheter-related infections involves removal of the catheter and antimicrobial therapy, usually for 2–4 months (McWhinney *et al.* 1992). Although disease due to *M. fortuitum* may resolve if the catheter is removed, reinsertion of another catheter in a similar location without drug therapy usually results in disease recurrence (as in the above case) (McWhinney *et al.* 1992). Adjunctive therapy should be with ciprofloxacin, amikacin and clarithromycin for up to 4 months. When there is a tunneled line that also has a tissue infection then treatment may need to be extended for 6 months (Brown-Elliott and Wallace Jr. 2002). The oxazolidinone linezolid is active against many mycobacteria including the rapid growers, and there have been several reports of its value in multiple drug regimens, especially when resistant *M. abscessus* is being treated.

Postinjection abscesses should be treated by surgical drainage and clarithromycin for 3–6 months. This advice comes as a result of the experience obtained from a series of outbreaks (Villanueva *et al.* 1997; Galil *et al.* 1999).

Wound infections are one of the most common manifestations of infection with rapidly growing mycobacteria. Infections have often been associated with augmentation mammoplasty and other plastic surgery procedures (Bolan *et al.* 1985; Brown-Elliott and Wallace Jr. 2002; Clegg *et al.* 1983). Therapy depends on the removal of any infected foreign material followed by 6 months of chemotherapy (Morris-Jones *et al.* 2001; Ozluer and De'Ambrosio 2001). Clarithromycin is the main choice with other drugs being added to prevent the emergence of resistance (Wallace Jr. *et al.* 1993).

Disseminated cutaneous infection is mainly with *M. abscessus* usually in patients who are compromised by renal failure or corticosteroid therapy (Wallace Jr. 1989). This is one of the most common presentations of non-pulmonary infection with rapidly growing organisms (Brown-Elliott and Wallace Jr. 2002). Treatment includes drainage of any abscesses that are present coupled with clarithromycin for 6 months together with another agent to which the isolate is susceptible during the first 2 months (Wallace Jr. *et al.* 1993).

MYCOBACTERIUM HAEMOPHILUM

Mycobacterium haemophilum is a fastidious member of the genus which grows more slowly than other species and requires iron-supplemented medium and a lower temperature of incubation (Dawson and Jennis 1980). It was first described in a woman with Hodgkin's disease but

has subsequently been described in patients with severe defects in cell-mediated immunity including HIV (Kiehn and White 1994).

Epidemiology

Infection has been described throughout the world. Although almost all of the patients reported had severe immunodeficiency, lymphadenitis has been reported from immunocompetent children. Prior to the HIV pandemic most patients had been treated with immunosuppressive therapy after organ transplantation or were suffering from lymphoma. *Mycobacterium haemophilum* is now a recognised pathogen for HIV-infected individuals. The true extent of infection with *M. haemophilum* is unknown, but the current incidence is probably an underestimate as few laboratories use appropriate media or culture conditions that permit this organism to be isolated. The extent of the underreporting can only be guessed at, but one laboratory found 13 cases in 20 months, equivalent to one third of all cases reported in the world literature up to that point (Straus *et al.* 1994). Little is known of the mode of transmission, but person-to-person transmission is not thought to occur.

Clinical Features

Several syndromes have been associated with *M. haemophilum* including lymphadenitis in immunocompetent children, cutaneous ulceration, bacteremia, infection of bones and joints and infection of lungs in severely immunocompromised individuals.

Cutaneous lesions are the commonest manifestation of *M. haemophilum* infection. The lesions tend to cluster on the extremities often over joints, and this suggests that this distribution is related to the lower temperatures in these areas. Lesions are typically raised violaceous and fluctuant, ranging in size from 0.5 to 2 cm. Later the lesions enlarge and become pustular and may be painful. The appearances must be distinguished from Kaposi's sarcoma which may co-exist in HIV-positive patients. The majority of patients report joint symptoms including tenderness and swelling. Fewer patients have pulmonary infection, but this is associated with a poor outcome even with therapy. Patients also present with septic arthritis or osteomyelitis (Shah *et al.* 2001). Lymphadenitis may arise in the cervical or perihilar region in children, producing a clinical picture similar to infection with *M. avium-intracellulare* (Armstrong *et al.* 1992).

Laboratory Diagnosis

Mycobacterium haemophilum is a fastidious organism that requires an egg-based chocolate agar medium supplemented with ferric ammonium citrate hemoglobin and hemin for optimum growth. The optimum temperature of incubation is 32 °C. As the organism grows slowly, the incubation period should be extended beyond 8 weeks (Dawson and Jennis 1980). There are no standard methods for determining susceptibility, but there are reports that the organism is susceptible to rifabutin, ciprofloxacin, cycloserine and kanamycin. Approximately half are susceptible to rifampicin, but most are resistant to isoniazid and all to pyrazinamide and ethambutol (Saubolle *et al.* 1996).

Management of *M. haemophilum* Infection

There are few clear guidelines for therapy, but the outcome appears to be influenced by the patient's underlying immunosuppression with patient's recover associated with reversal of the immune deficit (Paech *et al.* 2002). The organisms are most susceptible to ciprofloxacin, clarithromycin, rifabutin and rifampin, and regimens that include these drugs have been associated with a successful outcome (Saubolle *et al.* 1996).

OTHER NON-TUBERCULOSIS MYCOBACTERIA

With almost 100 species of mycobacteria described, there is an expanded understanding of the organisms that infect humans. Many of these are isolated in clinical laboratories rarely. Many of these are found in the Tables 11.1 and 11.2. For most there are only anecdotal case reports; so firm recommendations for therapy cannot be given in most instances, but guidance is usually derived by analogy with therapeutic strategies used for the treatment of related species.

Mycobacterium scrofulaceum is closely related to *M. avium* and *M. intracellulare* and shares many biochemical, phenotypic and environmental characteristics. It has been described in children with lymphadenitis in cutaneous infections and as a cause of cavitary lung disease in patients predisposed by pneumoconiosis (Corbett *et al.* 1999; Primm, Lucero and Falkinham III 2004). Despite its similarity to *M. avium*, it is only rarely isolated in patients with advanced HIV disease.

Mycobacterium simiae is a photochromogenic mycobacterium that was first isolated from feral monkeys imported into the United States. *Mycobacterium simiae* shares many similarities with *M. avium* and *M. scrofulaceum* and has been associated with infections in HIV-infected individuals, which resemble *M. avium-intracellulare* disease (Al-Abdely, Revankar and Graybill 2000). Treatment for significant infections should be with a regimen suitable for *M. avium*.

Mycobacterium szulgai is a scotochromogen at 37 °C but a photochromogen at 25 °C. It has been described throughout the world, and the majority of infections are pulmonary or disseminated (Tortoli *et al.* 1998a). In addition to these infections in bursa, tendon sheaths, bones, lymph nodes and skin have been reported (American Thoracic Society 1997). It appears to have an environmental source which has not yet been identified. The main risk factors of infection are cigarette smoking, chronic lung disease and a high alcohol intake. For skin, bursa and bone infection, trauma is the major predisposing condition. Therapy is with isoniazid, rifampicin, streptomycin and ethambutol. Therapy can be amended in light of the results of susceptibility tests. Surgery may be used to complement chemotherapy.

Mycobacterium paratuberculosis is closely related to *M. avium-intracellulare* and mainly causes disease in cattle – Johne's disease. Some authors have linked *M. paratuberculosis* with Crohn's disease, but this link has not been proved (Hermon-Taylor and Bull 2002; Bull *et al.* 2003). The organism is unable to grow in the absence of mycobactin on artificial media.

Mycobacterium genavense is a rarely reported organism found in association with severe immunocompromised including advanced HIV infection. Infections have been reported throughout the world. It grows more slowly than most other mycobacteria and could be discarded if cultures are disposed of in less than 35 days. The source of *M. genavense* infection is unknown (Tortoli *et al.* 1998b).

Aerobic Actinomycetes

Stephen H. Gillespie

Centre for Medical Microbiology, Royal Free and University College Medical School, Hampstead Campus, London, UK

INTRODUCTION

The aerobic actinomycetes form a heterogeneous group of organisms only a few of which are human pathogens. They are classified together on morphological criteria: Gram-positive organisms which grow as branching filamentous cells (Plate 7). Although once thought to be fungi imperfecti, they are prokaryotes and there is nothing to suggest that they are higher bacteria. They are closely related to corynebacteria and mycobacteria. Mycobacteria are acid fast by virtue of long chain mycolic acid present in their cell wall. Some strains of corynebacteria contain mycolic acids with a much shorter chain length and may be acid fast when grown under appropriate conditions. Organisms of the genera *Nocardia*, *Rhodococcus*, *Gordona* and *Tsukamurella* possess mycolic acids of intermediate chain length and consequently express a degree of acid fastness.

NOCARDIA SPP.

Introduction

Edmond Nocard, a veterinarian working on the island of Guadeloupe, described a filamentous organism as the cause of bovine farcy. In the following year the organism was characterized and named *Nocardia farcinica*, although later it was recognised that it was a *Mycobacterium* that is the cause of farcy (Nocard 1898). The organism Nocard had isolated was probably *Mycobacterium farcinogus*. The first case of human nocardiosis was reported 1 year later in a patient with pneumonia and a brain abscess: this organism was classified as *Nocardia asteroides* (Blanchard 1896). *Nocardia transvalensis* was isolated from an African patient with Madura foot (Pijper and Pullinger 1927). More than 25 different species have been described. Nocardiae are regularly but rarely implicated in human infections of immunocompetent patients (Beaman *et al.* 1976). They are increasingly recognised in patients on immunosuppressive therapy and those infected with HIV (Beaman *et al.* 1976; McNeil *et al.* 1990; Miralles 1994; Pintado *et al.* 2003).

DESCRIPTION OF THE ORGANISM

Morphological and Physiological Characteristics

Nocardiae are Gram-positive, aerobic catalase-positive non-motile filamentous bacteria that exhibit branching. The filaments break up into rods, and coccid forms and aerial filaments are always produced. The cell wall contains *meso*-diaminopimelic acid,

arabinose and galactose. It is naturally resistant to lysozyme digestion. The G+C% ranges from 64 to 72 (McNeil *et al.* 1990; Saubolle and Sussland 2003). Like other members of the corynebacteria *Mycobacterium Nocardia* (CMN) group, *Nocardia* spp. contain mycolic acids in the cell wall. The carbon chain length ranges between C₄₄ and C₆₀ and is responsible for the weak acid fastness these organism exhibit when grown on appropriate lipid containing media (Butler, Kilburn and Kubica 1987; Saubolle and Sussland 2003). Peptidoglycan makes up as little of 25% of the cell-wall mass rising to 45% during the stationary phase of growth (Beaman and Moring 1988). As in mycobacterial cell walls the peptidoglycan is attached to the arabinogalactan polymer by way of a phosphodiester link.

Taxonomy

The nocardiae are phylogenetically related to the *Mycobacterium*, *Corynebacterium*, *Gordona* and *Tsukamurella* as defined by 16S sequencing. There are at least 25 established species described which include (Chun and Goodfellow 1995; Ruimy *et al.* 1996; Roth *et al.* 2003; Wallace *et al.* 1991) *N. asteroides*, *N. carea*, *N. brasiliensis*, *N. pseudobrasiliensis*, *N. veterana*, *N. farcinica*, *N. brevicatena*, *N. otidiscaviarum*, *N. nova*, *N. seriolae*, *N. transvalensis*, *N. N. vacinii* and *N. pseudobrasiliensis*. Some authors suggest that *N. asteroides* should be divided into five species on the basis of 16S sequencing (Roth *et al.* 2003), and new proposed species are added regularly. The species previously named *N. amarae* has been transferred to the genus *Gordona* on the basis of chemical, microbiological and 16S sequences (Goodfellow *et al.* 1994).

Pathogenesis

Experiments with T-cell deficient mice and experience of immunocompromised patients indicate an important role for T-cell immunity in *Nocardia* infections.

*Nocardia Antigen*s

During the phases of growth the composition of the nocardial cell wall changes significantly and the virulence of *Nocardia* appears to vary with the growth phase of the organism with logarithmically growing filamentous cells being more virulent than stationary phase cells of the same organisms (Beaman and Sugar 1983; Beaman and Moring 1988). The cell wall also contains a number of antigens which have been associated with pathogenicity in mycobacteria: tuberculostearic acid

and trehalose 6–6' dimycolate (cord factor). The latter substance is thought to play a role in reducing phagosomal–lysosomal fusion (Crowe *et al.* 1994; Spargo *et al.* 1991).

Nocardia possesses a superoxide dismutase which is expressed on the surface of the organism and protects it from the toxic effects of superoxide radicals (Beaman *et al.* 1985). This effect is increased by the action of the organism's catalase. Several studies have reported the presence of toxins including a haemolysin in strains of *N. asteroides*, *N. brasiliensis* and *N. otidiscaviarum*.

Interaction with Phagocytes

Nocardiae are readily phagocytosed by macrophages, and although the majority of organisms are killed, some are able to survive as L-forms where they are able to multiply. This may also explain the reports of relapsing infection after apparently successful therapy. L-forms have also been shown to produce fatal infections in mice.

Virulent *Nocardia asteroides* is able to inhibit phagosomal–lysosomal fusion, and this effect appears to be mediated by cord factor (Spargo *et al.* 1991; Crowe *et al.* 1994). There is also evidence that virulent strains are able to block acidification of the phagosome, whereas avirulent strains are unable to do this. This shows similarity with the behaviour of *Mycobacterium tuberculosis* (see Chapter 10) (Indrigo, Hunter Jr. and Actor 2003). *Nocardia* is also able to use acid phosphatase as a carbon source inhibiting the effect of this toxic macrophage enzyme. *Nocardia* also possess mycolic acids, and these have been implicated in mycobacterial pathogenicity.

EPIDEMIOLOGY

Habitat

The nocardiae are environmental organisms found in soil and vegetation, and they are thought to have a role in the decay of organic plant material. Nocardiae have been isolated from marine environments and freshwater sources including tap water (Beaman and Beaman 1994). *Nocardia asteroides* is more frequently isolated in temperate countries and *N. brasiliensis* in tropical and subtropical regions (Beaman and Beaman 1994). Isolation of *Nocardia* from human specimens may represent colonization, contamination or infection. One study from Australia suggested that as little as 20% of isolates were clinically significant (Georghiou and Blacklock 1992).

Animal Infection

Nocardiae are reported to cause infection in a wide range of animal species including cattle, horses, dogs and pigs. These infections take the form of bovine mastitis which results in reduction in milk production. Equine infections are rarely reported and take the form of bronchopneumonia which may develop into disseminated disease. This syndrome is associated with foals with combined immunodeficiency and adult horses with hyperadrenalism secondary to pituitary tumours. Localized abscesses are also reported rarely.

Human Infection

It is normally assumed that nocardial infections are rare, but a number of studies have suggested that their incidence is underestimated (Beaman *et al.* 1976; Georghiou and Blacklock 1992). With the increasing number of patients who are immunocompromised, the number of cases of *Nocardia* infection is likely to rise. Organisms of the *Nocardia* genus may act as primary pathogens in adults without evidence of immunocompromised or may act as opportunists. Opportunist infections are especially associated with organ transplant-

ation, malignancy, lymphoma sarcoidosis collagen vascular disease or HIV infection (McNeil and Brown 1994).

In immunocompetent patients cutaneous infection is usually caused by *N. asteroides*, *N. brasiliensis* and *N. otidiscaviarum*. There are many cutaneous syndromes described including lymphocutaneous infection, skin abscesses and skin infection associated with dissemination (Georghiou and Blacklock 1992; Sachs 1992; Goodfellow *et al.* 1994). Mycetoma is a chronic granulomatous subcutaneous infection of the foot which occurs in tropical countries and is thought to be associated with walking barefoot, although mycetoma of the hand has also been reported (Beaman and Beaman 1994). The infection can be caused by aerobic actinomycetes including *N. brasiliensis*, *Actinomadura madurae*, *Streptomyces somaliensis* or other nocardiae. Ocular infection is usually secondary to minor corneal trauma or inadequately cleaned contact lenses or ocular surgery. This may lead to keratitis and later to ophthalmitis (Douglas *et al.* 1991). Ocular infection can be seen from a distant site in immunocompromised patients with another infective source.

Colonization of the respiratory tract of immunocompetent patients is not uncommon and may even result in a mild self-limiting infection. *Nocardia asteroides* is implicated in invasive disease which takes the form of a subacute or chronic cavitary pneumonia (Georghiou and Blacklock 1992). Common predisposing conditions include local compromised of pulmonary defences such as chronic obstructive pulmonary disease, pulmonary fibrosis, healed tuberculosis, bronchiectasis or general immunosuppression such as steroid therapy or HIV infection (Georghiou and Blacklock 1992). Rarely pulmonary nocardiasis can take an acute fulminating course (Neu *et al.* 1967).

Disseminated infection can occur in any patient but more usually presents in immunocompromised patients and is associated with a poor prognosis. It can develop as a late complication of infection with any of the *Nocardia* spp. (Esteban *et al.* 1994; Poonwan *et al.* 1995). Dissemination of the infection may result in secondary lesions in the brain and the eyes. Central nervous system infection takes the form of isolated brain abscess, and nocardial meningitis is very rare (Bross and Gordon 1991).

HIV Infection

Nocardiasis is a relatively rare complication of infection with HIV in comparison with other organisms such as *Pneumocystis jiroveci* and *Toxoplasma gondii* (Pintado *et al.* 2003). This may be because non-T-cell mechanisms are more important for defence against this organism (McNeil and Brown 1994). *Nocardia asteroides* is the species most commonly associated with infection in HIV-infected individuals, but case reports with *N. farcinica* and *N. nova* have been made (Jones *et al.* 2000).

CLINICAL FEATURES

Although species of *Nocardia* may occasionally be found in healthy persons, they are not considered to be part of the normal flora.

Pulmonary Disease

The majority of cases of pulmonary nocardiasis are caused by *N. asteroides*. The first case of pulmonary nocardiasis occurring in a patient in the USA was described by Flexner in 1898. The pathological feature of pulmonary nocardiasis is usually a suppurative lesion, for example, lung abscess, but a granulomatous response or a mixture of these two may occur. The clinical and radiological features are very variable and non-specific, making the diagnosis difficult without the use of invasive techniques. In the normal course of infection, one or more lung abscesses may develop and enlarge to form cavities similar to those seen in pulmonary tuberculosis. Pulmonary nocardiasis may mimic pulmonary malignance, actinomycosis and fungal infection (Menendez *et al.* 1997). *Nocardia brasiliensis* possesses considerably

more virulence than *N. asteroides* and may cause primary pulmonary infection in otherwise healthy individuals.

The manifestations within the lungs may vary from a mild, diffuse infiltration to a lobar or multi-lobar consolidation. There may be solitary masses, reticulonodular infiltrates and pleural effusions. In many cases the correct diagnosis is not made until *post mortem* when *Nocardia* can be seen microscopically and grown in culture. From the lung the organisms may spread through the blood stream; there they seem to have a predilection for the brain and the kidneys but can establish infection anywhere in the body. Unlike actinomycosis or tuberculosis, bone destruction is rare.

Cutaneous Nocardiosis

Primary cutaneous nocardiosis usually occurs following traumatic introduction of the organisms (usually *N. brasiliensis*) into the skin (Clark *et al.* 1995). The lesions induce pus formation and may develop into cellulitis or pyoderma. Although the infection usually remains local and self-limiting, it may progress and on occasion can spread via the lymphatics to produce a lymphocutaneous lesions (Sachs 1992). This is more likely to occur in *N. brasiliensis* infection (Seddon, Parr and Ellis-Pegler 1995). As local infection can resemble those caused by *S. aureus*, the diagnosis cannot be confirmed without laboratory evidence. Cutaneous infection has most commonly been reported in the USA or Australia and rarely in Europe.

Infections can result in fungating tumour-like masses, termed mycetomas (Figure 12.1). These are chronic subcutaneous infections in which the abscesses extend by destruction of the soft-tissue, sometimes the bone. The infection finally erupts through the skin. In equatorial Africa the mycetomas are caused by *Actinomadura pelletieri* and *Streptomyces somaliensis*, but in Mexico the majority of infections are caused by *N. brasiliensis* (Seddon, Parr and Ellis-Pegler 1995). Mycetomas are usually found in developing countries and rarely in Europe and North America. It is important to differentiate between actinomycotic and eumycotic mycetoma because the latter requires complete excision to effect cure, but the actinomycotic form may respond to aggressive medical treatment and conservative surgical excision.

Madura foot is a chronic granulomatous infection of bones and soft tissue of the result resulting in mycetoma formation and gross deformity. It occurs in the Sudan, North Africa and the west coast of India, principally among those who walk barefoot and are prone to contamination of foot injuries by soil-derived organisms. One of the causative organisms is *N. madurae*, but it is also caused by other nocardiae and fungi.

Systemic Infection

Nocardial lesions in the lungs or elsewhere in the body frequently erode into blood vessels. In systemic nocardiosis the nocardiae behave as pyogenic bacteria, and infection becomes relentlessly progressive. Infection of the central nervous system occurs frequently, but this is often insidious in onset and difficult to diagnose and treat successfully. It often takes the form of a cerebral abscess which may be confused with a pyogenic or fungal abscess or with cerebral toxoplasmosis (McNeil and Brown 1994).

Figure 12.1 Swollen foot of patient with 'Madura foot'.

Clinical Features of Other Nocardiae

Nocardia farcinica is microbiologically related to but distinct from *N. asteroides* and is noted for its propensity to cause serious systemic infection in both normal and immunocompromised hosts and for its natural resistance to multiple antimicrobial agents. *Nocardia farcinica* may cause a variety of clinical presentations including cerebral abscess, pulmonary and cutaneous infection. The similarity between *N. farcinica* and *N. asteroides* means that care must be taken to distinguish these species (Wallace *et al.* 1991; Schiff *et al.* 1993).

Nocardia transvalensis tends to cause pneumonia or disseminated disease in severely immunocompromised patients. It has also been recorded as a cause of mycetoma (McNeil and Brown 1994).

LABORATORY DIAGNOSIS

Nocardiae are difficult to recognize and identify in the routine diagnostic laboratory, and this is made more difficult by the slow growth on primary isolation from clinical samples.

Collection of Specimens

In pulmonary cases specimens of sputum or bronchoalveolar lavage should be collected. Biopsy and autopsy specimens exudate pus, and scrapings from skin lesions should be collected in tightly stoppered bottles and sent to the laboratory without delay. Specimens held in storage or delayed in transit should be kept at 4°C. Preserving fluids are not necessary, but if the laboratory is at some distance, the specimen should be inoculated onto blood agar locally prior to dispatch.

Direct Examination

A presumptive diagnosis of pulmonary nocardiosis may be made by microscopical examination of sputum or broncho-alveolar lavage. Pus and other exudates should be diluted in sterile water if necessary and examined for the presence of microcolonies. These are best seen in an unstained wet mount between slide and cover slip under greatly reduced light or phase contrast light. In many cases the sputum contains numerous lymphocytes and macrophages, some of which contain pleomorphic Gram-positive and weakly acid-fast bacilli and occasionally extracellular branching filaments. Differential of the microcolonies is difficult and requires specialist attention. Branched hyphal filaments may belong to any number of genera, for example, *Nocardia*, *Actinomadura* and *Streptomyces*.

Nocardiae are Gram positive with a variety of shapes and sizes, but they stain irregularly and their filaments are generally beaded. Acid fastness is variable in *N. asteroides*, *N. brasiliensis* and *N. caviae*, both in clinical specimens and culture. The usual Ziehl-Nielsen procedure may be employed, but the period of decolorization with acid alcohol must not exceed 5–10 s.

Tissue Sections

The microcolonies (granules) show up well in sections stained with haematoxylin and eosin, but this stain often fails to demonstrate other morphological forms of nocardiae. The Grocott-Gomori silver methenamine stains the granules very well, and Gram-Wiegert technique is effective for both granules and filaments.

Culture and Isolation

Nocardiae grow on most standard bacteriological media in 2–30 days. Suitable media include brain heart infusion agar and trypticase soy agar enriched with blood. *Nocardia asteroides* grows well on

Sabouraud's agar incubated at 37°C in a humid environment, producing the typical wrinkled pigmented forms. Colonies are cream, orange or pink coloured, and their surface may develop dry chalky appearances and the colonies adhere firmly to the medium. Colonies with abundant aerial growth have a cotton wool ball appearance that may resemble many *Streptomyces* spp. The colours are due to various carotenoid-like pigments, and their intensity depends on the specific culture conditions used to grow the organisms.

Recovery of *Nocardia* spp. from mixed cultures is facilitated by the use of selective media. Buffered yeast extract (similar to that used for *Legionella*) containing polymyxin anisomycin and vancomycin and Sabouraud's dextrose agar with chloramphenicol has been used for sputum. However, many isolates are susceptible to chloramphenicol. Media using paraffin as the sole carbon source have been shown to be effective as a selective medium for nocardiae. Also as *N. asteroides* grows well at 45°C, initial incubation at temperatures above 37°C may help to separate this species from other bacteria. Cultures should be examined at intervals from 2 days to 2 weeks. *Nocardia* spp. grow well on Lowenstein–Jensen medium, produce moist glabrous colonies and must be differentiated from mycobacteria.

Identification

The only constant morphological feature of nocardiae is a tendency for the aerial or vegetative mycelium to fragment. The consistency and composition of the growth medium can affect the growth and stability of both aerial and substrate hyphae. *Nocardia* spp. are Gram positive, weakly acid-fast, non-motile aerobic, catalase positive and oxidase a number of sugars. They are ONPG positive, reduce nitrate and utilize urea. With few exceptions, all *Nocardia* spp. grow in nutrient broth supplemented with lysozyme, whereas most *Rhodococcus*, *Actinomadura* and *Streptomyces* spp. do not. In general, *N. farcinica* is differentiated from *N. asteroides* by the ability of the former to grow and produce acid from rhamnose, to grow on 2,3-butylene glycol and at 45°C. The Gordon series of tests involving 40 different physiological properties is unable to distinguish between *N. farcinica* and *N. asteroides*. Antibiotic susceptibility tests can assist in speciation as an adjunct to biochemical tests. Differentiation tests are summarized on Table 12.1.

For laboratories that have the facility the most rapid method of species identification is to use 16S rDNA amplification and sequencing (Cloud *et al.* 2004).

Table 12.1 Differentiation of *Nocardia* species

Characteristic	<i>N. asteroides</i>	<i>N. brasiliensis</i>	<i>N. transvalensis</i>	<i>N. farcinica</i>
Decomposition of

Serodiagnostic Tests

There is currently no single serodiagnostic test that is routinely used to identify patients with nocardial infection. Patients infected with nocardiae only develop a minimal antibody response that is non-specific. Infection also occurs in patients who are immunosuppressed, making serology an unattractive method for making a diagnosis.

MANAGEMENT OF INFECTION

There are no specific clinical signs diagnostic for pulmonary nocardiosis, and the presentation of disease may run the full spectrum from acute to chronic pulmonary infection. Thus pulmonary infection caused by *Nocardia* spp. is often misdiagnosed as pyogenic infections, tuberculosis, actinomycosis, mycoses of various aetiologies, benign tumours and various forms of neoplasm. Difficulties in diagnosis are compounded when co-existent disease is taken into account, for example, nocardiosis and tuberculosis occur together in 6–30% of cases. In many cases the correct diagnosis is only made when the organisms are visualized on a tissue section isolated in pure culture.

Nocardia spp. show species-specific drug resistance and good identification, and carefully controlled MICs should point the way for directed and prolonged therapy. Sulphonamides or cotrimoxazole are usually the treatment of choice, but many patients, especially those with HIV, are unable to tolerate them and may also be infected with resistant strains (Jones *et al.* 2000). Thus, alternative agents such as aminocycline, erythromycin, amikacin or imipenem may have to be used. The prognosis is poor particularly if the organisms have metastasised to other organs in the body. The *in vitro* activities of new quinolones and cephamycins look promising as agents for treatment. Linezolid has been shown to be active *in vitro* and in an experimental model (Gomez-Flores *et al.* 2004). In the absence of consensus on the length of therapy, some authors suggest that a synergistic combination of a β -lactam/ β -lactamase inhibitor with ciprofloxacin or amikacin followed by a short course of trimethoprim-sulphamethoxazole may be effective in eradicating nocardial disease and may reduce the need for long-term treatment (Tripodi *et al.* 2001).

PREVENTION AND CONTROL

The widespread distribution of nocardiae in the soil makes control of infection with these organisms impossible. Superficial infections are often the result of local trauma and soil contamination of wounds, and therefore one can suggest that all wounds are adequately cleaned and debrided. The use of prophylactic antibiotics is probably not beneficial, as these organisms are resistant to most of the common oral agents.

Person-to-person transmission is very rare, although there are two reports of nosocomial outbreaks among renal transplant patients.

ACTINOMADURA SPP.

Vincent first isolated an organism which he thought responsible for Madura foot which he named *Streptothrix madurae*. It is now known that many organisms can give rise to this syndrome including other aerobic actinomycetes such as *Nocardia* spp. and fungi. The organism that Vincent described was renamed *Nocardia* and then transferred to *Actinomadura* together with *A. pelletieri* (McNeil and Brown 1994). It has been separated from the other aerobic actinomycetes by 16S rRNA sequencing. The genus is defined on the basis of cell wall chemotype the morphology of its aerial hyphae and the presence of a specific sugar madurose which has been identified as 3-O-methyl-D-galactose. It does not possess mycolic acid in its cell wall and fails to grow in the presence of lysozyme. There are as many as 26 species defined, but only two of these are important in human infections: *A. madurae* and *A. pelletieri*.

Actinomadura is one of the most frequent bacterial causes of Madura foot significantly outnumbering cases caused by *Nocardia*. The peak age of onset is between 16 and 25 years, and it may take up to 10 years for cases to present depending of the species involved (Maiti, Ray and Bandyopadhyay 2002). *Actinomadura* infection has also been associated with infection of long-standing indwelling canulae and wounds, although these are rare. Microscopy of the specimens reveals organisms in the form of branched filaments with short chains of spores. Colonies have a molar tooth appearance after 48 h in culture, and aerial hyphae are sparse and may only be seen after 2 weeks in culture. Speciation is on the basis of biochemical tests and 16S sequencing (McNeil and Brown 1994).

Most isolates of *A. madurae* are susceptible to amikacin and imipenem, and many are resistant to ampicillin. Cephalosporins, trimethoprim sulphamethoxazole and penicillins have limited activity (McNeil *et al.* 1990).

DEMATOPHILUS CONGOLENSIS

Dermatophilus congolensis was first recognized as a cattle disease in the Belgian Congo in 1915 by van Saceghem. It is a chronic dermatitis damaging skin wool and more rarely causing foot rot. Humans acquire infection by close contact with infected animals or their products. The clinical spectrum of the disease includes asymptomatic infection, pustular eruption and a pitted keratolysis (Gillum *et al.* 1988; Towersey *et al.* 1993).

The diagnosis of dermatophilosis depends on visualizing the organism in wet mounts or specimens stained with methylene blue or Geimsa. Gram stain is not an effective staining method, as some of the detail of the organism is obscured. *Dermatophilus congolensis* may be isolated with difficulty in brain heart infusion agar containing horse blood but may require animal passage. Colonies are small grey white they pit the agar and β -haemolysis may be seen. The organism is motile and catalase positive and hydrolyses casein slowly (McNeil and Brown 1994). The organism is susceptible to penicillin, streptomycin, chloramphenicol, tetracycline, erythromycin, and trimethoprim-sulphamethoxazole.

GORDONA SPP.

Gordona spp. are rarely isolated from human subjects but have been associated with primary cutaneous infection, catheter-related sepsis, pulmonary infection that resembles tuberculosis and rarely brain abscess (Drancourt *et al.* 1994; Pham *et al.* 2003). The genus was defined in 1988 on the basis of 16S rRNA sequence and includes species previously included in the genus *Rhodococcus*. The following species are found in the genus: *G. bronchialis*, *G. rubropertinctus*, *G. sputi* and *G. terrae*. *Gordona* spp. have mycolic acid with a shorter chain length than mycobacteria but longer than those of *Rhodococcus*. *Gordona* produces mycobactins under conditions of iron limitation. Wrinkled dry beige colonies grow after 3–7 days of incubation on blood agar. Microscopically, the organisms are small, Gram-positive, weakly acid-fast, beaded bacilli. Species within the genus cannot be fully differentiated on the basis of hydrolysis of amino acids and casein, acid production from sugars or HPLC for mycolic acids (Chun and Goodfellow 1995). Species identification requires the use of molecular methods.

OTHER AEROBIC ACTINOMYCETES

Fewer than 20 cases of serious illness due to *Tsukamurella* have been reported, mostly been ascribed to the species *Tsukamurella paurometabola*. They are frequently misidentified as *Rhodococcus*, or *Corynebacterium* species are most easily identified by 16S rRNA PCR and sequencing. Infection usually occurs in the context of

immunosuppression, typically bone marrow transplantation and indwelling venous or CAPD canulae. Treatment is usually successful if associated with removal of intravascular devices and antibiotic therapy (Schwartz *et al.* 2002). *Oerskovia* sp. exist naturally in soil and water, decaying plant material, brewery sewage, aluminum hydroxide gels and grass cuttings, and as they are found in the environment, care must be taken to distinguish colonization and specimen contamination from infection. Reported clinical infection usually occurs in immunocompromised hosts with implantable devices. Most are due to *O. xanthineolytica* and others due to *O. turbata*. A majority of patients required removal of a foreign body as part of their treatment which is usually successful in most cases (Urbina, Gohh and Fischer 2003).

Rothia dentocariosa is a rare cause of endocarditis occurring most frequently in patients with prior heart conditions. Although the clinical course is typically subacute, complications are common, in particular the reported incidence of mycotic aneurysms is as high as 25% (Boudewijns *et al.* 2003). It can be difficult to identify in the laboratory (Von Graevenitz 2004). Penicillin is the treatment of choice, but additional complications may necessitate prompt surgical intervention.

Section Three

Gram-Negative Organisms

Moraxella catarrhalis and *Kingella kingae*

Alex van Belkum¹ and Cees M. Verduin²

¹Department of Medical Microbiology & Infectious Diseases, Erasmus University Medical Center Rotterdam EMCR, Rotterdam; and ²PAMM, Laboratory of Medical Microbiology, Veldhoven, The Netherlands

INTRODUCTION

Moraxella (*Branhamella*) *catarrhalis*, formerly called *Neisseria catarrhalis* or *Micrococcus catarrhalis*, is a Gram-negative, aerobic diplococcus frequently found as a commensal of the upper respiratory tract (Jawetz, Melnick and Adelberg, 1976; Ninane *et al.*, 1977; Johnson, Drew and Roberts, 1981). Over the last 20–30 years, the species has been recognized as a pathogen of the upper respiratory tract in otherwise healthy children and elderly people (Hager *et al.*, 1987; Catlin, 1990; Murphy, 1996; Karalus and Campagnari, 2000). Moreover, *M. catarrhalis* is an important cause of the infective complications of adult chronic obstructive pulmonary disease (COPD) (Hager *et al.*, 1987; Catlin, 1990; Murphy, 1996). In immunocompromised hosts, the bacterium causes pneumonia, endocarditis, septicaemia and meningitis (Doern, 1986). *Moraxella catarrhalis* hospital outbreaks of respiratory disease have been described (Patterson *et al.*, 1988; Richards *et al.*, 1993), establishing the bacterium as a genuine nosocomial pathogen. Because *M. catarrhalis* had long been considered a harmless commensal (Jawetz, Melnick and Adelberg, 1976; Johnson, Drew and Roberts, 1981), knowledge of its antimicrobial resistance profile, pathogenic characteristics and virulence factors has only been acquired recently. Its potential to cause disease, however, is currently undisputed.

Kingella kingae is a member of the HACEK group of microorganisms identified in 1968 as *Moraxella kingii*, named after Elizabeth O. King (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella kingae*). It was renamed in 1974 (see Davies and Maesen, 1986, for a historical review). The bacteria are coccoid, medium-sized (1 µm wide and 2–3 µm in length) Gram-negative rods which are seen as pairs or short chains with rounded or square termini. The organism may be nutritionally fastidious, requiring increased amounts of serum and CO₂ for optimal growth on blood agar medium (Pickett *et al.*, 1991). Bactec blood culture bottles are considered an excellent growth medium for this species (Yagupsky *et al.*, 1992). *Kingella kingae* may cause pitting in the agar and generates mild β-haemolysis, and the bacterium sometimes produces a brownish pigment. The bacteria do not grow on MacConkey agar and are usually catalase negative and oxidase positive. They may display twitching motility and are usually highly sensitive to penicillin. Some strains produce β-lactamase. This bacterial species may be mistaken for *Neisseria gonorrhoeae*. There are two additional species within the genus: the non-haemolytic *Kingella oralis* and *Kingella denitrificans*. The organism is a frequent inhabitant of the oropharynx and may be encountered in the urethral tract as well and was until recently considered a rare cause of disease in humans. However, improvements in diagnostic techniques (Lejbnkiewicz *et al.*, 1999; Yagupsky, 1999b) and an

increased awareness amongst clinicians have resulted in increased numbers of reports (Odum and Frederiksen, 1981). This chapter focuses on *M. catarrhalis* in particular, since the body of available literature for this organism is at least twice that of *K. kingae*.

DESCRIPTION OF THE ORGANISM

In the past, *M. catarrhalis* was considered a non-pathogenic member of the resident flora of the nasopharynx. It was one of the species belonging to the so-called non-gonococcal, non-meningococcal neisseriae. The bacterium was first described in 1896 (Frosch and Kolle, 1896) as *M. catarrhalis*. In the early 1960s, it was shown that *M. catarrhalis* in fact comprised two distinct species: *Neisseria cinerea* and *Neisseria catarrhalis* (Berger, 1963). These could be separated on the basis of nitrate and nitrite reduction and tributyrin conversion. Because of the phylogenetic separation between *N. catarrhalis* and the so-called true *Neisseria* species, the bacterium was moved to the genus *Branhamella* in honour of Sara E. Branham (Catlin, 1970). In 1984, *Branhamella catarrhalis* was reassigned to the genus *Moraxella* as *Moraxella* (*Branhamella*) *catarrhalis* (Bovre, 1984). Ribosomal DNA sequencing has substantiated the validity of the current taxonomic classification (Enright *et al.*, 1994; Pettersson *et al.*, 1998). Catlin (1991) has proposed the formation of a new family, Branhamaceae, to accommodate the genera *Moraxella* and *Branhamella*. However, comparison of 16S rDNA sequences of *Moraxella* spp. has demonstrated the relatedness of *M. catarrhalis* to *Moraxella lacunata* subsp. *lacunata* and to a 'false' *Neisseria*, *Neisseria ovis* (Enright *et al.*, 1994). Apparently, there is no rationale for a separate *Branhamella* genus. Consequently, at the time of writing, *M. catarrhalis* is the preferred name for this bacterial species.

In 1972, the first paper on the taxon *K. denitrificans* was published (Hollis, Wiggins and Weaver, 1972). The bacterium was called TM-1, because of its recovery on Thayer–Martin medium from throat swabs. Later, the TM-1 group was reported to be similar to saccharolytic *Moraxella* species, now known as *Kingella kingae* (Henriksen and Bøvre, 1976). *Kingella kingae* was previously known as *Moraxella* new species 1, *M. kingii*. In 1976, these species were moved to the new genus *Kingella* (Snell and Lapage, 1976). By the end of the 1980s, the species within the *Kingella* genus were studied for differences in their fatty acid composition. This appeared to be inconclusive for an adequate separation of the species *K. denitrificans* and *K. kingae* (Wallace *et al.*, 1988). Later it was demonstrated that species identification of kingellae could be achieved with biochemical testing. The *Haemophilus–Neisseria* identification panel (American Microscan, Sacramento, CA, USA) was able to distinguish the kingellae from all of the other Gram-negative bacteria tested for (Janda, Bradna and

Ruther, 1989). More definitive identification schemes were those based on DNA–DNA hybridization studies (Tonjum, Bukholm and Bovre, 1989). *Kingella kingae*, *K. denitrificans* and *Kingella indologenes* formed distinct groups, well separated from, for instance, the various *Moraxella* species. However, a little later, *K. indologenes* was moved to the genus *Suttonella* on the basis of its ribosomal RNA sequence (Dewhirst *et al.*, 1990), and the same experimental approach led to the identification of *K. oralis* as a new species in the genus *Kingella* (Dewhirst *et al.*, 1993). The ubiquitous presence of this latter species in the oral cavity was defined shortly thereafter, with 26 of 27 people positive for the organism by culture (Chen, 1996).

In conclusion, both *M. catarrhalis* and *K. kingae* are bacteria belonging to phylum BXII of the proteobacteria (Bergey's Manual Trust website, as per 2000; www.bergeys.org). *Moraxella catarrhalis* is a class III gammaproteobacterium, whereas *K. kingae* belongs to the class II of the betaproteobacteria. *Moraxella catarrhalis* belongs to the Pseudomonales (order VIII), Moraxellaceae (family II) and *Moraxella* (genus I). For *K. kingae*, these are Neisseriales (order IV), Neisseriaceae (family I) and the genus *Kingella* (genus IX).

EPIDEMIOLOGY

Epidemiological studies on *M. catarrhalis* have been difficult to perform, as typing systems have become available only recently and because of the lack of a reliable and simple serological test. Clinical interest in *M. catarrhalis* is only recent, and many laboratories were not used to reporting *M. catarrhalis* as a pathogen. The identification of *M. catarrhalis* from sputa is complicated by the presence of non-pathogenic neisseriae. *Kingella kingae* has been identified as an organism usually present in the oropharyngeal mucosa, and epidemiological studies, defining transmission and assessing the pathogenic potential of these bacteria, are urgently required (Abuamara *et al.*, 2000).

Conventional and Molecular Typing Systems

Several phenotyping strategies have been described for epidemiological typing of *M. catarrhalis*, though none of these has been accepted internationally and no extensive use of this technology has been reported. Serological typing of lipopolysaccharide (LPS) (Vanechoutte *et al.*, 1990), isoelectric focusing of β -lactamase proteins (Nash *et al.*, 1986) and electrophoretic profiling of outer membrane proteins (OMPs) (Bartos and Murphy, 1988) and biotyping (Denamur *et al.*, 1991; Peiris and Heald, 1992) have also been used. More recently, methods based on nucleic acid polymorphism have become available. Comparison of restriction endonuclease analysis (REA) with phenotyping (Christensen, 1999) has indicated that REA of genomic DNA, including pulsed-field gel electrophoresis (PFGE), may be used successfully for delineating disease outbreaks (Patterson *et al.*, 1988; Kawakami *et al.*, 1994; Vu-Thien *et al.*, 1999; Yano *et al.*, 2000). The use of strain-specific DNA probes has also been documented (Beaulieu *et al.*, 1993; Walker *et al.*, 1998). Studies identified amplified fragment length polymorphism (AFLP) analysis and automated ribotyping as useful typing procedures (Bootsma *et al.*, 2000; Verduin *et al.*, 2000). Moreover, using these two strategies, researchers have found complement-resistant strains of *M. catarrhalis* to form a distinct clonal lineage within the species. These observations are in agreement with those of earlier studies identifying *M. catarrhalis* as a genetically heterogeneous species from which successful clones occasionally proliferate (Enright and McKenzie, 1997). Expansion of such successful types has also been documented during distinct periods of time and in particular geographic regions (Martinez *et al.*, 1999). Frequent horizontal gene transfer seems to occur (Bootsma *et al.*, 1999; Luna *et al.*, 2000), and phenotypic characteristics could be acquired through cross-species gene acquisition.

For *K. kingae*, all of the methods listed could be used, but only immunoblotting, PFGE and ribotyping have been explored in detail (Slonim *et al.*, 1998).

Carriage of *M. catarrhalis* and *K. kingae*

The *M. catarrhalis* carriage rate in children is high (up to 75%) (Van Hare *et al.*, 1987; Faden, Harabuchi and Hong, 1994; Varon *et al.*, 2000). In contrast, the carriage rate of *M. catarrhalis* in healthy adults is only about 1–3% (DiGiovanni *et al.*, 1987; Ejlertsen, 1991). This inverse relationship between age and colonization has been known since 1907 (Arkwright, 1907). The age-dependent development of secretory immunoglobulin A (IgA) could explain the phenomenon. Remarkably, IgG antibody levels do not correlate with the state of colonization or with lower respiratory tract infection (LRTI) with *M. catarrhalis* in children (Ejlertsen *et al.*, 1994). Interestingly, nasopharyngeal carriage rates are significantly higher in winter and autumn than in spring and summer (Van Hare *et al.*, 1987). Monthly or bimonthly sampling of the nasopharynx of children ($n=120$) by Faden, Harabuchi and Hong (1994) revealed the presence of *M. catarrhalis* in 77.5% of subjects at least once during the first 2 years of life. Furthermore, these authors showed a clear relationship between the frequency of colonization and the development of otitis media. A small Japanese study revealed that colonization in children attending a daycare centre is highly dynamic (Yano *et al.*, 2000). Although clusters of genotypes seemed to persist for periods of 2–6 weeks, frequent changes in the nature of colonizing strains of *M. catarrhalis* were observed. Other authors have described a relationship between the frequency of colonization and the occurrence of upper respiratory infection (Brorson and Malmvall, 1981; Prellner *et al.*, 1984). Klingman *et al.* (1995) investigated the colonization of the respiratory tract of patients with bronchiectasis. Patients were colonized with the same strain for an average of 2.3 months, as determined by restriction fragment length polymorphism (RFLP) patterns, and colonization with a new strain did not correlate with changes in clinical status.

The first large longitudinal carriage study for *K. kingae* was performed by Yagupsky *et al.* (1993, 1995a) in Israel. Children visiting daycare centres had an average carriage rate of 6.1–34.6%, peaking in December and April, nearly 73% having at least one positive culture. These data are similar to those for *Haemophilus influenzae* carriage among children. Frequent transfer of *K. kingae* strains in daycare attendees has been documented using molecular typing. Authors confirmed this hypothesis in a follow-up study (Slonim *et al.*, 1998). Yagupsky, Peled and Katz (2002) highlighted several important features of *K. kingae* carriage. Carriage appeared to be highest in the 0–3-year age group. The carriage rates were equal for males and females. It is striking to note that infection significantly more often occurred in males, for which, at the time of writing, there is no reasonable explanation. The pathogenicity of *K. kingae*, with its seasonal preponderance, could not be explained on the basis of carriage patterns alone.

MORAXELLA CATARRHALIS-MEDIATED DISEASES IN CHILDHOOD

Moraxella catarrhalis is now considered an important pathogen in respiratory tract infections, both in children and in adults with underlying COPD, occasionally causing systemic disease (Doern, Miller and Winn, 1981; Collazos, de Miguel and Ayarza, 1992). Bacteremia caused by *M. catarrhalis* should be considered in febrile children with an immune dysfunction and an upper respiratory tract infection (Abuhammour *et al.*, 1999). In addition, *M. catarrhalis* may be the sole cause of sinusitis, otitis media, tracheitis, bronchitis or pneumonia and, less commonly, ocular infections in children. In children, nasopharyngeal colonization often precedes the development of *M. catarrhalis*-mediated disease (Faden, Harabuchi and Hong, 1994).

Sinusitis

Sinusitis is a very common infection in early childhood, accounting for about 5–10% of upper respiratory tract infections (Wald, 1992a, 1998a, b). It is often underdiagnosed in children because the symptoms are non-specific. In acute sinusitis (where symptoms are present for 10–30 days) and subacute disease (30–120 days), *Streptococcus pneumoniae*, *H. influenzae* and *M. catarrhalis* are the most frequently isolated bacterial pathogens (Bluestone, 1986; Blumer, 1998; Cappelletty, 1998). *Moraxella catarrhalis* accounts for approximately 20% of cases. Interestingly, in children with asthma, the same distribution of bacterial pathogens is found (Wald, 1992b), although Goldenhersh *et al.* (1990) isolated *M. catarrhalis* as the predominant pathogen in chronic sinusitis (symptoms >30 days) in children with respiratory allergy. This would indicate an even more prominent role for *M. catarrhalis* in the aetiology of these widely distributed and highly prevalent infectious diseases.

Otitis Media

Acute otitis media (AOM) is a frequent infection in children: Before the age of 1 year, around 50% of children would have experienced at least one period of AOM. This figure rises to 70% within 3 years (Kabongo, 1989; Klein, 1994). It is the most serious and frequent infection caused by *M. catarrhalis* in children, and therefore, *M. catarrhalis* causes tremendous morbidity, requiring a widespread use of antibiotics, and vaccine development has been suggested (Faden, Harabuchi and Hong, 1994; Berman, 1995; Cohen, 1997; Faden *et al.*, 1997; Fromm *et al.*, 1997; Klein, 1999). Since 1980, a marked increase has been reported in the isolation of *M. catarrhalis* from middle-ear exudates (Kovatch, Wald and Michaels, 1983; Shurin *et al.*, 1983; Marchant, 1990; Block, 1997). This increase in *M. catarrhalis* isolation to its present isolation frequency of approximately 15–20% (Patel *et al.*, 1995) has been accompanied by the appearance of β -lactamase-producing strains (90–95%). The exact magnitude of this apparent increase is unclear (Marchant, 1990), since tympanocentesis and culture of middle-ear fluid are not performed routinely. The isolation rates for *M. catarrhalis* might be an underestimation, given the relative anaerobic environment of the middle ear during infection (Anonymous, 1994). In a study using polymerase chain reaction (PCR), *M. catarrhalis* DNA was detected in 46.4% of paediatric chronic middle-ear effusion specimens ($n=97$), as compared with 54.6% for *H. influenzae* DNA and 29.9% for *S. pneumoniae* DNA (Post *et al.*, 1995). A large percentage (48%) of specimens were PCR positive and culture negative, whereas all culture-positive specimens were also PCR-positive. It is very unlikely that the PCR-positive, yet culture-negative specimens reflect persistence of DNA from old infections (Aul *et al.*, 1998). The severity of symptoms and numbers of bacteria in middle-ear fluid appear to be less for *M. catarrhalis* than for *S. pneumoniae* or *H. influenzae* (Faden *et al.*, 1992).

Lower Respiratory Tract Infections

LRTIs due to *M. catarrhalis* mostly occur in children under the age of 1 year (Boyle *et al.*, 1991). Korppi *et al.* (1992) have investigated the seroconversion to *M. catarrhalis* in patients hospitalized with middle respiratory tract infection (laryngitis, tracheitis and bronchitis) and LRTI. They found seroconversion in only 4 of 76 children (5%) who had *M. catarrhalis*-positive nasopharyngeal aspirate cultures, as compared with 4 of 373 children (1%) who had negative cultures, *M. catarrhalis* being an unlikely pathogen in children. In contrast, several other studies have implicated *M. catarrhalis* as a cause of LRTI in children. *Moraxella catarrhalis* has been isolated in pure culture from secretions obtained by tracheal aspiration in neonates, infants and children with pneumonia (Haddad *et al.*, 1986; Berg and Bartley, 1987; Berner *et al.*, 1996). In a prospective study combining

microbiological and clinical criteria, *M. catarrhalis* was identified as a significant respiratory pathogen in children (Boyle *et al.*, 1991). Both local and systemic antibody responses to *M. catarrhalis* infection have been documented in several studies (Chapman *et al.*, 1985; Black and Wilson, 1988; Goldblatt *et al.*, 1990; Goldblatt, Turner and Levinsky, 1990; Faden, Hong and Murphy, 1992). Pneumonia in children may be complicated by bacteremia with *M. catarrhalis* (Collazos, de Miguel and Ayarza, 1992; Ioannidis *et al.*, 1995; Thorsson, Haraldsdottir and Kristjansson, 1998). *Moraxella catarrhalis* appears to have a role in the causation of LRTI.

Other Infections in Children

Moraxella catarrhalis has been implicated as a cause of bacterial tracheitis in childhood (Wong and Mason, 1987; Brook, 1997; Bernstein, Brill and Jacobs, 1998), for which preceding viral infection has been considered a significant predisposing factor. Although reports on ocular infections have been rare (Macsai, Hillman and Robin, 1988; Abbott, 1992; Bergren *et al.*, 1993; Weiss, Brinser and Nazar-Stewart, 1993), conjunctivitis and keratitis have also been described.

KINGELLA KINGAE-MEDIATED DISEASES IN CHILDHOOD

Kingella kingae has been identified as one of the emerging causes of childhood infectious disease, with an estimated incidence of more than 25 invasive infections per year per 100 000 children ≤ 24 months old (Yagupsky *et al.*, 1993; Yagupsky and Dagan, 1997). This bacterial species is capable of causing vaginitis, meningitis (Namnyak, Quinn and Ferguson, 1991; Hay *et al.*, 2002), soft-tissue infection (Rolle *et al.*, 2001), stomatitis (Amir and Yagupsky, 1998), LRTIs (Yagupsky and Dagan, 1997) and endophthalmitis (Carden *et al.*, 1991). However, these infections are rare: most being case reports. In contrast, Centers for Disease Control and Prevention (CDC) evaluations have demonstrated that invasive infection in children caused by *K. kingae* are not so rare. A significant proportion of clinical isolates received during surveillance studies were from invasive disease: 58 of 78 isolates from blood, bone, joints or fluids (Graham *et al.*, 1990).

Bone and Joint Infections

Osteomyelitis due to *K. kingae* has been reported regularly, even in geographically remote regions such as Iceland (Birgisson, Steingrimsdottir and Gudnason, 1997). As a species, *K. kingae* most frequently causes osteoarticular infections, most commonly involving the bones and joints of the lower extremities (Dodman, Robson and Pincus, 2000). Owing to the fastidious growth requirements of the organism, these infections have been defined as 'hard to detect and treat' (Wildt and Boas, 2001). In contrast with standard radiography, ^{99m}Tc bone scans are informative (La Scola, Iorgulescu and Bollini, 1998). The investigators found that all affected children suffered from upper respiratory tract infection or eczema in the month before the development of osteomyelitis. An analysis of children suffering from septic arthritis or (sub)acute osteomyelitis found that *K. kingae* has become one of the most frequently isolated bacteria (Lundy and Kehl, 1998), replacing *H. influenzae*, probably because of successful vaccination. The use of improved automated blood culture has improved the yield of *K. kingae*-positive cultures derived from joint fluid and blood (Yagupsky *et al.*, 1992; Costers *et al.*, 2003).

Endocarditis and Bacteremia

Kingella kingae bacteremia in children is well recognized (Amir, 1992; Yagupsky and Dagan, 1994; Krause and Nimri, 1996;

Moylett *et al.*, 2000). Endocarditis may arise as a primary disease or secondary to hair-cartilage hypoplasia (Ferber *et al.*, 1997) or chickenpox (Waghorn and Cheetham, 1997), neurological symptoms being described well (Wells, Rutter and Donald, 2001). *Kingella kingae* has a particular tropism for the osteoarticular and cardiac sites of infection, being observed at both sites in the same patient (Sarda *et al.*, 1998).

MORAXELLA CATARRHALIS INFECTIONS IN ADULTS

Moraxella catarrhalis has been associated with a variety of clinical syndromes in adults, including nosocomial infections with rare cases of endocarditis (Neumayer *et al.*, 1999; Stefanou *et al.*, 2000).

Laryngitis

Moraxella catarrhalis is the most common bacterial species isolated from adult patients with laryngitis. Schalen *et al.* (1980, 1985) found that of 40 adults suffering from this disease, 22 were infected by *M. catarrhalis* (55%). Among 40 healthy adults, *M. catarrhalis* could not be isolated from the larynx. The exact role of *M. catarrhalis*, either as a commensal or as a pathogen in adult laryngitis, is incompletely understood.

Bronchitis and Pneumonia

Moraxella catarrhalis is a common cause of exacerbations in COPD (McLeod *et al.*, 1986; Davies and Maesen, 1988; Cabello *et al.*, 1997; Eller *et al.*, 1998; Miravittles *et al.*, 1999). A study has shown *M. catarrhalis* to be the single most frequently isolated bacterium (Sportel *et al.*, 1995). Sarubbi *et al.* (1990) reviewed all respiratory tract cultures ($n = 16\,627$) over a period of 42 months and identified *M. catarrhalis* in 2.7% ($n = 457$) of these cultures. *Moraxella catarrhalis* was found to be the second most commonly isolated respiratory tract pathogen after non-typeable *H. influenzae*. These and many other authors (Pollard *et al.*, 1986; Wallace *et al.*, 1989; Dabernat, Avril and Boussougant, 1990; Wood, Johnson and McCormack, 1996) demonstrated striking seasonality, with winter and spring being the periods with the greatest incidence of *M. catarrhalis* isolation. Preceding viral respiratory tract infection could be the cause of *M. catarrhalis* infections, although this hypothesis remains untested (Van Hare and Shurin, 1987; DiGiovanni *et al.*, 1987).

Pneumonia caused by *M. catarrhalis* tends to be a relatively mild disease. It differs from bronchitis by the presence of mostly lower-lobe infiltrates on chest X-rays (Nicotra *et al.*, 1986; Wright and Wallace, 1989). High fever, pleuritic pain and toxic states are uncommon, as are empyema and bacteremia (Pollard *et al.*, 1986). Collazos, de Miguel and Ayarza (1992) reviewed cases of pneumonia due to *M. catarrhalis* which were similar in both characteristics and clinical symptoms to those described for patients with bronchitis or pneumonia without bacteremia, with a mortality rate in bacteremic cases of 13.3%. Ioannidis *et al.* (1995) described the clinical spectrum of *M. catarrhalis* bacteremia in 58 patients. Predisposing factors included neutropenia, malignancy or respiratory impairment, either alone or in combination. Mortality was high (29%) among patients with underlying respiratory disease, and the infection was more severe when the patient was co-infected with other respiratory tract pathogens. *Moraxella catarrhalis* pneumonia often occurs in patients with end-stage pulmonary or malignant disease, with short-term mortality in some patient categories as high as 45% (Wright and Wallace, 1989). Most patients are among the elderly having underlying cardiopulmonary disease or COPD (Barreiro *et al.*, 1992). Many patients appear to be malnourished, smokers or (ex-smokers), and men are at a greater risk than women.

Nosocomial Infections

It has been difficult to confirm the spread of *M. catarrhalis* among hospitalized patients, no reliable typing system and low pathogenicity being the main reasons. Patterson *et al.* (1988) used REA to confirm an outbreak in a hospital. During the investigation of another putative outbreak, immunoblotting with normal human serum was combined with REA to type *M. catarrhalis* strains (Richards *et al.*, 1993). Both methods provided adequate discrimination between strains but were not always in complete agreement (Morgan *et al.*, 1992). Clear vehicles of bacterial dissemination have not yet been identified in the clinical setting. However, Ikram *et al.* (1993) found the nosocomial spread of *M. catarrhalis* to be common, especially in respiratory wards. They also showed considerable contamination of the environment with *M. catarrhalis*, implying possible aerosol-mediated dissemination. Person-to-person transmission (Ikram *et al.*, 1993) or spread from environmental sources (Calder *et al.*, 1986) has been implicated in nosocomial transmission. Nursery schools have been suggested as being the prime sites where frequent exchanges of strains may occur (Yano *et al.*, 2000).

KINGELLA KINGAE INFECTIONS IN ADULTS

Although most infections are diagnosed among the (very) young, rare cases of chorioamnionitis (Maccato *et al.*, 1991), septic arthritis (Esteve *et al.*, 2001) and meningitis (Reekmans *et al.*, 2000) due to *Kingella* spp. have been diagnosed in adults. In AIDS patients, some of the *Kingella* species may cause infection (Minamoto and Sordillo, 1992; Urs *et al.*, 1994). However, most reported *K. kingae* infections in adults involve the circulatory system.

Bacteremia and Endocarditis

Kingella kingae bacteremia may occur in immunocompetent people (Roiz, Peralta and Arjona, 1997). In some cases, underlying diseases have been associated with the development of *K. kingae* vegetations on the mitral valve. The combination of a motile vegetation in a patient with systemic lupus erythematosus (SLE) and anti-phospholipid syndrome is an example of such a complex disease pattern (Wolak *et al.*, 2000). In addition, primary endocarditis with secondary infectious foci in other parts of the body has been described as well (Lewis and Bamford, 2000). Native valve endocarditis may occur (Hassan and Hayek, 1993), but also the colonization of prosthetic valves has been described, with *K. denitrificans* rather than *K. kingae* (Chakraborty, Meigh and Kaye, 1999). This shows that endocarditis due to *Kingella* spp. may be highly diverse in its presentation, which with difficulties in isolation and identification make this a potentially difficult disease to manage.

LABORATORY DIAGNOSIS

Isolation of *M. catarrhalis* from clinical specimens, i.e. sputum, may be complicated by the presence of non-pathogenic *Neisseria*. Although selective agar media are not necessary routinely, they have been used to isolate *M. catarrhalis* with some success. As an example, acetazolamide, which reduces the growth of *Neisseria* species when used under aerobic conditions, and the antimicrobial agents vancomycin, trimethoprim and amphotericin B may be included in an agar medium to inhibit the growth of the normal flora (Vaneechoutte *et al.*, 1988; Doern, 1990). Vancomycin may also be used for selective enrichment (Yagupsky *et al.*, 1995b).

The following criteria unambiguously distinguish *M. catarrhalis* from other bacterial species: Gram stain; colony morphology; lack of pigmentation of the colony on blood agar; oxidase production; DNase production; failure to produce acid from glucose, maltose, sucrose,

lactose and fructose; growth at 22 °C on nutrient agar; failure to grow on modified Thayer–Martin (MTM) medium; and, lastly, reduction of nitrate and nitrite (Doern and Morse, 1980; Singh *et al.*, 1997). The Gram stain still plays a crucial role, both in assessing the significance of isolating the bacterium from clinical material (e.g. sputum) and in its subsequent identification. In typical Gram stains, *M. catarrhalis* is a Gram-negative diplococcus, with flattened abutting sides, often de-colouring poorly. Colonies on blood agar are non-haemolytic, round, opaque and convex, with a greyish-white colour. The colony remains intact when pushed across the surface of the agar. The bacteria are oxidase positive and produce DNase. Reduction of nitrate and nitrite and tributyrin hydrolysis are additional differentiating characteristics (Speeleveld *et al.*, 1994). The identity of *M. catarrhalis* is best confirmed by positive reactions in at least three of the criteria.

The kingellae do not produce catalase, and their oxidase reactivity may be feeble, especially when the enzymatic activity is probed with dimethyl-*p*-phenylenediamine instead of the more effective tetramethyl compound (Davies, 1997). When cultured in rich media (e.g. 10–20% ascitic fluid agar), the kingellae all ferment glucose and some may ferment maltose and sucrose. In conventional sugar fermentation tests, however, negative results may be obtained. In comparison with species from the genus *Moraxella*, *Kingella* may be recognized by their ability to reduce nitrite to nitrogen and by their ability to breakdown certain carbohydrates. Both species are able to hydrolyse tributyrin and are able to produce DNA-hydrolysing enzymes. *Kingella kingae* may be misidentified as *Eikenella corrodens*, *Cardiobacterium hominis* and, obviously, *Moraxella* or *Neisseria* spp. Although, in the past, *K. kingae* isolated from eye infections, blood or cerebrospinal fluid (CSF) was often correctly identified (Namnyak, Quinn and Ferguson, 1991; Mollee, Kelly and Tilse, 1992), the correct identification from strains derived from bone and joint infection in both adults and children has been problematic (Chiquita, Elliott and Namnyak, 1991; Meis *et al.*, 1992; Yagupsky *et al.*, 1992). Apparently, the choice of culture media for these specimens is critical. When several specialized blood-culture systems were compared, it was shown that all strains were able to grow in BacT/Alert aerobic and BacT/Alert Pedi-BacT bottles produced by Organon Teknika, USA (Host *et al.*, 2000). However, in BacT/Alert FAN anaerobic and Bactec Plus Aerobic media (Becton Dickinson Microbiology Systems, USA), growth was observed for only 63% and 88%, respectively, of the inoculated strains after 12 days.

PCR tests for *M. catarrhalis* have been designed and used clinically, direct detection of *M. catarrhalis* DNA by PCR being concordant with culture and endotoxin detection. However, DNA assays yield significantly more positive results than culture when, for instance, middle-ear effusions are analysed, which suggests superior sensitivity of the DNA amplification assays (Dingman *et al.*, 1998). The clinical relevance of PCR has been validated extensively in the chinchilla model for otitis media. This animal model was instrumental in demonstrating the quick and effective effusion-mediated clearance of DNA and dead *M. catarrhalis* bacteria from the middle-ear cleft, implying that in this case a positive PCR result was indicative of the presence of viable bacteria (Post *et al.*, 1996a). Moreover, PCR has also been reliably used for detecting mixed infections in the same experimental infection model (Bakaletz *et al.*, 1998), thereby validating the applicability of multiplex PCR approaches for detecting mixed bacterial infections (Post *et al.*, 1995; Hendolin *et al.*, 1997). The sensitivity of the PCR tests corresponds to 6 or 7 genome equivalents, making PCR the most sensitive diagnostic assay (Post *et al.*, 1996b). However, the costs and technical demands of PCR make it not appropriate for routine microbiology laboratory testing for this diagnostic application. PCR diagnostic tests have also been developed for *K. kingae* (Stahelin *et al.*, 1998; Yagupsky, 1999a). However, these tests have thus far only been used to corroborate clinical diagnoses for case studies. Extended use, for instance, in epidemiological studies has not been reported yet, and the precise value of PCR tests for *K. kingae* will have to await further evaluation.

ANTIMICROBIAL SUSCEPTIBILITY

Although possessing universal β -lactamase-mediated resistance to penicillins and inherent resistance to trimethoprim, *M. catarrhalis* remains sensitive to most other antibiotics used for treating respiratory infections (Berk and Kalbfleisch, 1996; Hoogkamp-Korstanje *et al.*, 1997; McGregor *et al.*, 1998; Felmingham and Gruneberg, 2000). Strains producing β -lactamase are expected to be resistant to penicillin, ampicillin, amoxicillin and piperacillin (Jorgensen *et al.*, 1990; Fung *et al.*, 1992; Jensen, Schonheyder and Thomsen, 1994; Livermore, 1995; Berk and Kalbfleisch, 1996; Bootsma *et al.*, 1996; Doern *et al.*, 1996).

Kingella kingae still appears to be universally susceptible to penicillin and ampicillin, with minimal inhibitory concentration (MIC) values ranging between 0.5 mg/l and 0.25 mg/l, respectively. Although this was already reported in the early 1990s (Graham *et al.*, 1990), this situation has not changed significantly over the past decade. All isolates are sensitive to gentamicin (MIC \leq 1 mg/l) but are inherently resistant to clindamycin. General extrapolation of susceptibility patterns for these organisms is difficult as most *Kingella* papers describe only limited numbers of patient isolates. Meta-analysis has revealed that the kingellae are still universally susceptible to β -lactam antibiotics, aminoglycosides, fluoroquinolones, erythromycin and cotrimoxazole. Significant resistance to the older quinolones, clindamycin, trimethoprim and vancomycin may exist, however (Amir and Shockelford, 1991). Meropenem appears to be more potent than imipenem, although the initial studies performed used suboptimal test systems (Clark and Joyce, 1993). The largest study thus far published on the susceptibility of clinical *K. kingae* isolates revealed that all strains were susceptible to erythromycin, gentamicin, chloramphenicol, tetracycline and ciprofloxacin (Yagupsky, Katz and Peled, 2001). Nearly 40% of all strictly local sets of strains were resistant to clindamycin, and a single isolate was resistant to cotrimoxazole. High levels of resistance to tetracycline have also been observed. These are due to the presence of a large plasmid encoding the TetM protein (Knapp *et al.*, 1988).

β -Lactamase Production in *M. catarrhalis* and *K. kingae*

The first β -lactamase-positive strain was isolated in 1976 (Wallace *et al.*, 1989). By 1980, however, 75% of *M. catarrhalis* isolates from the United States produced β -lactamase (Catlin, 1990; Wallace *et al.*, 1990). Recent studies from Australia, Europe and the United States all noted β -lactamase production in over 90% of isolates (Manninen, Huovinen and Nissinen, 1997; Doern *et al.*, 1999; Fluit *et al.*, 1999; Thornsberry *et al.*, 1999; Walker *et al.*, 2000). Walker *et al.* (2000) investigated trends in antibiotic resistance of *M. catarrhalis* isolates in a single hospital over a 10-year period. During this period, β -lactamase production increased from 30% to 96%. The trend towards resistance to penicillin and ceftriaxone was due to an increased frequency of β -lactamase-positive isolates. In *M. catarrhalis*, two types of β -lactamases are found that are phenotypically identical: the BRO-1 and BRO-2 type. Both are membrane associated, differ by a single amino acid, are chromosomally encoded and are relatively easily transferred from cell to cell. Fortunately, both enzymes are readily inactivated by β -lactamase inhibitors, and all isolates are still susceptible to amoxicillin in combination with clavulanic acid (Hoogkamp-Korstanje *et al.*, 1997; McGregor *et al.*, 1998). BRO-1 is the most common enzyme and confers higher MICs than BRO-2, the difference being attributed to the production of more enzymes as a consequence of higher transcriptional activity. Studies have shown that the β -lactamase of *M. catarrhalis* is lipidated, suggesting a Gram-positive origin (Bootsma *et al.*, 1999). The inferred lack of a genetic barrier between Gram-negative and Gram-positive bacterial species is a reason for clinical concern. β -Lactamase from *M. catarrhalis* is also

thought to frustrate penicillin therapy of concomitant infections. This phenomenon is referred to as indirect pathogenicity, and in such circumstances, treatment failures have been reported (Patel *et al.*, 1995). This emphasizes the importance of reporting not only pure but also mixed cultures positive for *M. catarrhalis* (Wardle, 1986). Strains of *K. denitrificans* have been demonstrated, on rare occasions, to produce β -lactamases (Minamoto and Sordillo, 1992; Sordillo *et al.*, 1993).

CELL-WALL STRUCTURES OF *M. CATARRHALIS*

Lipooligosaccharides, Peptidoglycan and Capsule

Moraxella catarrhalis lipooligosaccharide (LOS) is semirough, meaning that it probably contains a single repeating O-antigen (Fomsgaard *et al.*, 1991; Holme *et al.*, 1999). It appears to be antigenically well conserved (Murphy, 1989). This corroborates the observation that it did not serve as a useful basis for a typing system (Doern, 1990). The antigenic specificities of three serotypes that have been identified are caused by differences in terminal sugars of one of the branches. Moreover, a structural overlap was documented with the LPS moieties from species of the *Neisseria* and *Haemophilus* genus. The LOS of serotypes B and C contains oligosaccharide chains of variable length. This could be due to phase-variable expression of the biosynthetic genes, as suggested by the presence of tandem repeats (Peak *et al.*, 1996). Another explanation offered is that variations in the activity of enzymes involved in cell-wall assembly result in a different oligosaccharide. LOS is also present in culture supernatants as subcellular elements called blebs, which may facilitate the distribution of LOS in the host. Whether these structures serve some physiological function is, at the time of writing, unknown. LOS (serotype A), once adequately detoxified, can be used as a vaccine when conjugated to a protein carrier (Hu *et al.*, 2000). Increases in anti-LOS IgG are observed upon immunization. The increased levels of antibodies enhanced clearance of bacteria from the lungs of mice after an aerosol-mediated *M. catarrhalis* infection.

Keller, Gustafson and Keist (1992) suggested that *M. catarrhalis* has a multilayered peptidoglycan architecture. This peptidoglycan layer was shown to be responsible for the extraordinary capacity of the organism to trigger various functional capacities of macrophages. Secretion of tumour necrosis factor and nitrite metabolism plus the cells' tumoricidal activity were clearly enhanced, which could be a partial explanation for the low virulence of *M. catarrhalis*. It seems as if peptidoglycan is involved in some sort of suicidal activity, and further studies of the basic mechanisms of this phenomenon are needed. The presence of a polysaccharide capsule has been previously suggested (Ahmed *et al.*, 1991). Capsules are considered to be an important virulence factor in both Gram-positive and Gram-negative bacteria. Unlike the situation in many other bacterial pathogens, the capsule is not detectable when examining colonies of *M. catarrhalis* on agar plates.

Outer Membrane Proteins

In contrast to other non-enteric Gram-negative bacterial species, different *M. catarrhalis* strains have OMP profiles that show a high degree of similarity. Murphy and co-workers identified eight major proteins, designated OMPs A through H, ranging from 21 kDa to 98 kDa (Bartos and Murphy, 1988; Murphy and Loeb, 1989; Murphy, 1990). OMPs C and D appeared to be two different but stable forms of the same protein, the CD protein. The *CD OMP* gene appeared to be strictly conserved among *M. catarrhalis* strains (Murphy, Kirkham and Lesse, 1993). The CD protein was found to be involved in binding purified human mucin from the nasopharynx and middle ear, but not

to mucin from the saliva and tracheobronchial tract (Bernstein and Reddy, 2000). Antibodies raised in mice enhanced clearance in a pulmonary challenge model (Yang *et al.*, 1997; Murphy *et al.*, 1998). The OMP E antigen appears to be of little immunogenicity, but it does possess universally surface-expressed epitopes when different *M. catarrhalis* strains are studied (Bhushan *et al.*, 1997). It may have a function in the uptake of nutrients (Murphy *et al.*, 2000).

In addition to OMPs A–H, Klingman and Murphy (1994) described a novel OMP, designated high-molecular-weight OMP (HMW-OMP) or ubiquitous surface protein UspA. UspA has been recently shown to be encoded by two different genes, which share the coding potential for a homologous, internal protein domain at more than 90% amino acid sequence homology (Aebi *et al.*, 1997; Lafontaine *et al.*, 2000). Mutation in the *UspA1* gene significantly decreased adherence, and *UspA2* is essential for complement resistance (Aebi *et al.*, 1998; Lafontaine *et al.*, 2000). UspA1 protein binds specifically to fibronectin (McMichael *et al.*, 1998), whereas the UspA2 protein preferentially binds to vitronectin. Both proteins are immunogenic in mice, and immunized animals clear bacteria from their lungs rapidly. Genetic studies have shown that intraspecies variability in the genes may be attributed to variation in regions of repetitive DNA (Cope *et al.*, 1999). Moreover, many related genes have been identified in the genomes of a wide variety of bacterial species, suggesting that the proteins serve essential and universally required functions. Although the UspA1/2 antigens, at the time of writing, are the best-studied *M. catarrhalis* proteins, their vaccine potential still is matter of ongoing investigations (Hays *et al.*, 2003).

Moraxella catarrhalis expresses both transferrin (TbpA and TbpB) and lactoferrin (LbpA and LbpB) receptors on its surface (Bonnah, Yu and Schryvers, 1995). These proteins are partially homologous and provide the cell with the capacity to sequester iron from host carrier proteins (Aebi *et al.*, 1996; Campagnari, Ducey and Rebmann, 1996; Du *et al.*, 1998). The receptors themselves appear to be significant virulence factors, since mutation analysis of the transferrin receptor has demonstrated an impaired growth capacity for the mutated strain. The receptors are also immunogenic and may be interesting vaccine candidates (Chen *et al.*, 1999a; Yu *et al.*, 1999). Molecular knock-out of the *tbpB* gene revealed that in the presence of a TbpB-specific monoclonal antibody and human complement, the mutant resisted killing as opposed to the wild type, which was rapidly killed (Luke *et al.*, 1999).

Pericellular Structures

The attachment of bacteria to mucosal epithelial cells is often mediated by pili or fimbriae. Some studies have provided evidence for the expression of pili by *M. catarrhalis* (Marrs and Weir, 1990), whereas others have been unable to demonstrate their presence (Ahmed *et al.*, 1991). Marrs and Weir (1990) found several characteristics that point to the presence of type 4 pili in *M. catarrhalis*. In addition, electron microscopic data revealed that, besides pili similar to those of type 4, an additional non-type 4 class of pili exists. Pili provide the single pericellular structure for which the kingellae have been well investigated. Initially, type 4 pili were discovered in *K. denitrificans*. N-Terminal amino acid sequencing of the composing proteins, in conjunction with electron microscopy, DNA transformation patterns and immunoblotting, provided experimental proof of the presence of these elements (Weir and Marrs, 1992). The same authors then also characterized the genes encoding for the building blocks of these pili (Weir, Lee and Marrs, 1996). This included the discovery of DNA-uptake sequences in the vicinity of the genes, similar to those described previously for the gonococcus (Weir, Lee and Marrs, 1997). The presence of pili has not yet been documented for the other *Kingella* species, but it is considered not unlikely that similar structures will be identified in the near future.

VIRULENCE

In general, the pathogenicity and virulence of a microorganism are defined by five cardinal requirements:

1. binding to and colonization of mucous surfaces;
2. entry into host tissues;
3. multiplication in the *in vivo* environment;
4. interference with host defence mechanisms;
5. damaging the host.

Relatively little is known about the precise virulence traits of *M. catarrhalis*, and for *K. kingae*, essentially nothing is known.

Adherence

It is noteworthy that only a limited number of studies on the precise interaction between *M. catarrhalis* receptors and human antigens have been undertaken. An elegant study was presented by Reddy *et al.* (1997). Using a purified middle-ear mucin glycoprotein, it was shown that only the CD protein of *M. catarrhalis* was capable of establishing a specific interaction with the sialo version of the human protein. A follow-up study from the same laboratory revealed immense heterogeneity in the interaction between upper respiratory tract pathogens and human mucins (Bernstein and Reddy, 2000). The general mechanism of *M. catarrhalis* adherence to host cell surfaces has been studied by Rikitomi, Ahmed and Nagatake (1997). Another study found no differences between source of isolation (blood or lungs) and haemagglutination (Jordan, Berk and Berk, 1990). Furthermore, these investigators showed that attachment was not primarily determined by lectin-carbohydrate interactions. In contrast to the findings of these investigators, an *in vitro* adherence study employing Hep-2 cell cultures demonstrated that strains derived from infections adhere more efficiently than mere colonizers (Fitzgerald *et al.*, 1999b). In addition, experimental periodate treatment suggested that bacterial adherence appears to be mediated by microbial carbohydrate moieties. Adherence of *M. catarrhalis* appeared to be stimulated by neutrophil defensins, peptides with broad-spectrum antimicrobial activity, released from activated neutrophils during inflammation, suggesting that defensin-mediated adherence contributes to the persistence of infection (Gorter *et al.*, 2000). A study by Ahmed *et al.* (2000) investigated the influence of surface charge on adherence. Although bacteria and epithelial cells are both overall negatively charged, interaction between the negatively charged surface of *M. catarrhalis* cells and positively charged subdomains called microplexa on pharyngeal epithelial cells has been documented.

Animal Models

The low virulence of *M. catarrhalis* lack a good animal model. In a murine model designed to study phagocytic responses and clearance mechanisms after endotracheal challenge with *M. catarrhalis*, a high influx of polymorphonuclear neutrophils into the lungs, with clearance in 24–48 h, was noted (Verghese *et al.*, 1990). A similar model uses transoral inoculation of bacteria into the lungs under anaesthesia and operative exposure of the trachea (Unhanand *et al.*, 1992). This model permits an evaluation of the interaction of bacteria with lower respiratory tract epithelium and the precise assessment of pathologic changes in the lungs (Maciver *et al.*, 1993). Kyd *et al.* (1999) used a model for mucosal immunization involving direct inoculation of killed bacteria into the Peyer's patches, followed by an intratracheal booster with dead *M. catarrhalis*. Enhanced clearance of bacteria from the lungs was observed, correlating with higher levels of specific IgA and IgG in serum and bronchoalveolar lavage fluid. Since *M. catarrhalis* inhabits the upper respiratory tract, inhalation models are preferred to intraperitoneal, endotracheal or transoral inoculation models (Hu *et al.*, 1999).

Purulent otitis media could be induced in Sprague-Dawley rats (Westman *et al.*, 1999). This infection progressed in a relatively mild fashion, and upon immunization, a protection rate of 50% or more was induced. Using the same model, a clear increase in the density of goblet cells in the middle ear up to 60 days after inoculation of bacteria was found, suggesting a highly increased mucosal secretory capacity (Caye-Thomasen *et al.*, 2000). In another rat model, inhalation of heat-killed *M. catarrhalis* cells clearly affected the laryngeal mucosa (Jecker *et al.*, 1999), resulting in a clinical syndrome reminiscent of laryngotracheitis in children.

Inoculation of *M. catarrhalis* into the middle ear of chinchillas and gerbils gave rise to effusion, but no live bacteria could be recovered from the middle ear after 24 h (Doyle, 1989). Later studies, however, revealed the feasibility of studying otitis media in the chinchilla model. Chinchillas are not generally available, and PCR would not have reached its current state of clinical applicability without the studies in these animals (Post *et al.*, 1996a; Aul *et al.*, 1998; Bakaletz *et al.*, 1998).

Complement Resistance

In general, rough strains of Gram-negative bacteria, producing LPS devoid of O-specific side chains, are highly susceptible to complement protein C5b-9-mediated killing, whereas smooth strains that synthesize complete LPS are often complement resistant (Taylor, 1995). Since the LPS of *M. catarrhalis* is of the rough type (Fomsgaard *et al.*, 1991), it presumably does not play a major role in complement resistance. However, Zaleski *et al.* (2000) showed that inactivation of a gene involved in the biosynthesis of the gal α 1–4 gal β 1–4 glc LOS epitope results in enhanced susceptibility to serum-mediated killing. Apparently, deviant LOS structures render strains more susceptible to complement attack. Complement resistance may be considered a virulence factor of *M. catarrhalis*: most strains (89%) isolated from LRTIs are resistant to complement-mediated killing, whereas strains from the upper respiratory tract of children are mostly sensitive (58%) (Hol *et al.*, 1993, 1995). Complement-resistant strains inhibit the terminal pathway of complement, i.e. the formation of the membrane attack complex of complement (Verduin *et al.*, 1994a). The binding of human vitronectin, an inhibitor of the terminal pathway of complement, appears to play a crucial role (Verduin *et al.*, 1994b). Another study suggested that OMP *CopB*/OMP B2 is involved in the resistance of *M. catarrhalis* to killing by normal human serum (Helminen *et al.*, 1993). An isogenic mutant not expressing *CopB* was killed by normal human serum, whereas the wild-type parent strain survived. It has been shown that inactivation of the *CopB* gene inhibits iron acquisition from lactoferrin and transferrin (Aebi *et al.*, 1996). Yet another OMP, OMP E, has also been shown to be involved in complement resistance. A *M. catarrhalis* OMP E knock-out mutant showed a clear increase in serum sensitivity (Murphy *et al.*, 2000). We conclude that complement resistance in *M. catarrhalis* probably is a highly multifactorial process, both from the perspective of both the host and the pathogen.

IMMUNITY

Many aspects of immunity to respiratory tract infections are still unknown, but may include local factors such as mucociliary clearance, aerodynamics, alveolar macrophage activity, complement-mediated killing and surfactant activity. These factors play important roles in host defence against oropharyngeal pathogens (Toews, Hansen and Strieter, 1990). The development of an inflammatory response or the development of specific antibody response may, however, augment these host defence mechanisms. As an example, in COPD patients, local host defence to respiratory pathogens is relatively poor (Ejlertsen, 1991). This points to an important role for local defence

mechanisms in non-specific clearance of various bacterial species. Compared to other species, *M. catarrhalis* was cleared relatively slowly from the lungs, and a more pronounced, 400-fold increase in numbers of polymorphonuclear leukocytes in the lungs was observed (Onofrio *et al.*, 1981).

Antibody Responses to Whole *M. catarrhalis* Bacteria

Several authors have investigated antibody responses to *M. catarrhalis* in different patient cohorts. Chapman *et al.* (1985) showed that 90% of adult patients with LRTI had bactericidal antibodies in their convalescent sera; only 37% had bactericidal antibody present in their acute sera. Black and Wilson (1988) obtained similar results. Most children with AOM due to *M. catarrhalis* showed an increase in serum IgG antibody titres (Leinonen *et al.*, 1981; Faden, Hong and Murphy, 1992). In a study in infants with otitis media, a specific IgG response was detected in 10 of 12 children 8 months of age or older, compared with 1 of 6 in younger children. In addition, immunoblotting revealed four immunodominant OMPs: UspA, CopB, TbpB and a protein of 60 kDa, probably OMP CD (Mathers, Leinonen and Goldblatt, 1999).

Antibodies to *M. catarrhalis* are very low or absent in children below the age of 1 year, and the development of an antibody response in children correlates with a decrease in colonization. Antibodies to OMPs of *M. catarrhalis* appear around the age of 4 years (Goldblatt, Turner and Levinsky, 1990; Christensen, 1999). Furthermore, failure to produce significant levels of IgG3 antibodies against *M. catarrhalis* predisposes to infection with the bacterium (Goldblatt *et al.*, 1994).

Moraxella catarrhalis LOS Immunogenicity

It has been reported that antibody responses to these surface structures constitute a major part of the humoral immune response during infection with *M. catarrhalis*. This antibody response is not serotype specific but is directed to common epitopes of the LOS of different *M. catarrhalis* serotypes (Rahman *et al.*, 1995; Oishi *et al.*, 1996). Hence, *M. catarrhalis* LOS may be of interest for evaluation as a possible vaccine candidate (Gu *et al.*, 1998; Hu *et al.*, 2000).

Immunogenicity of Outer Membrane Proteins

OMPs B1, CopB/OMP B2, LbpB, OMP CD, OMP E, OMP G, TbpB and UspA have all been mentioned as potential vaccine candidates. No antibody response to TbpA or LbpA could be detected in convalescent sera of patients with pulmonary infections, limiting their role as vaccine candidates (Yu *et al.*, 1999). Helminen *et al.* (1994) and Sethi, Surface and Murphy (1997) showed that CopB/OMP B2 is a target for antibodies, increasing pulmonary clearance in the mouse. However, certain regions in the protein show interstrain variability; therefore, if this protein is to be developed into a vaccine, only its conserved regions should be targeted. Sethi, Hill and Murphy (1995) found a predominant antibody response to a minor 84-kDa OMP, designated OMP B1. OMP CD does not appear to be an immunodominant antigen, as indicated by an absence of a new antibody response to this protein after exacerbation of *M. catarrhalis* infection in COPD patients. Helminen *et al.* (1994) also presented evidence that UspA may be a target for protective antibodies in humans. Chen *et al.* (1996) immunized mice with purified UspA, and fewer bacteria were isolated from the lungs of immunized mice than from non-immunized controls. The finding that IgG3 is a major contributing factor in the immune response to *M. catarrhalis* was confirmed by a study by Chen *et al.* (1999b) of the immune response of healthy adults and children to UspA1 and UspA2. In a small cohort of children suffering from otitis media, antibodies specific to UspA1/2

proteins were identified (Samukawa *et al.*, 2000a). The amounts of these specific antibodies varied strongly with age (Samukawa *et al.*, 2000b).

Local Antibody Response

Only few investigators have studied the development of antibody responses in middle-ear fluid of children with otitis media (Faden, Hong and Murphy, 1992; Faden, Harabuchi and Hong, 1994; Takada *et al.*, 1998; Karalus and Campagnari, 2000). IgG and IgA appeared to be produced locally in most patients, but also antibodies derived from serum were detected in middle-ear fluids. Faden, Hong and Murphy (1992) showed that middle-ear fluid IgG, IgM and IgA antibody was produced in 100%, 29% and 71% of children, respectively. Of interest, many children with local antibodies in their middle-ear fluid did not develop a systemic antibody response. Local antibodies may play an important role in the recovery and prevention of AOM (Goldblatt, Turner and Levinsky, 1990). In a study focusing on local IgA antibodies to UspA in the nasopharyngeal secretions of children colonized with *M. catarrhalis*, no response was detected (Samukawa *et al.*, 2000b).

Vaccines

The development of vaccines for the prevention of *M. catarrhalis*-mediated disease is, at the time of writing, a hot topic. The most promising vaccine candidates have been recently reviewed by McMichael (2000). The combination of data that are available in today's literature suggests that the development of a *M. catarrhalis* vaccine is well underway: animal models of infection have been developed and described, and several vaccine candidate molecules have been studied for prevalence and genetic conservation among different isolates. Although new candidate molecules are regularly brought forward (Fitzgerald *et al.*, 1999a), relatively little or nothing is known about the optimal routes for vaccine delivery or whether there is a need for adjuvants. A study using a rat model suggests that the mucosal route of delivery for *M. catarrhalis* is more effective than systemic immunization (Kyd and Cripps, 2000).

ACKNOWLEDGEMENT

The authors express their gratitude to all those who directly or indirectly provided inspiration for this chapter. Mrs. Loes van Damme (Erasmus MC, Department of Medical Microbiology) is thanked for providing insight into the classical microbiology of *K. kingae* and its relatives.

Neisseria meningitidis

Dlawer A. A. Ala'Aldeen and David P. J. Turner

Molecular Bacteriology and Immunology Group, Division of Microbiology, University Hospital of Nottingham, Nottingham, UK

INTRODUCTION

Neisseria meningitidis and *N. gonorrhoeae* are the only two recognized obligate human pathogens of the genus *Neisseria*, family Neisseriaceae. *Neisseria meningitidis* (meningococcus) is the most common overall cause of pyogenic meningitis worldwide and is the only bacterium that is capable of generating epidemic outbreaks of meningitis. Vieusseux was the first to describe an outbreak of an apparently new disease, a cerebrospinal fever, which spread rapidly in and around Geneva in the spring of 1805. Several other outbreaks of similar nature were also recorded over the subsequent decades, but the organism was first discovered in Vienna in 1887 by Anton Weichselbaum. He was able to isolate the causative organism in the meningeal exudate of six cases of cerebrospinal fever and gave it the descriptive name of *Diplococcus intracellular meningitidis*, which was later changed to *Neisseria meningitidis* after the German scientist and clinician, Albert Neisser.

DESCRIPTION OF THE ORGANISM

Cultural Characteristics and Biochemical Reactions

Neisseria meningitidis is a Gram-negative, non-sporing, aflagellate, aerobic diplococcus of approximately 0.8 µm in diameter. On solid media, *N. meningitidis* grows as a transparent, non-haemolytic, non-pigmented (grey) convex colony, approximately 0.5–5 mm in diameter, depending on the length of incubation. The organism is relatively fastidious in its growth requirements, and optimal growth conditions are achieved at 35–37 °C, at pH 7.0–7.4 in a moist environment with 5–10% CO₂. It grows poorly on unenriched media but grows reasonably well on blood, chocolate and Modified New York City agar, and on Mueller Hinton agar without the addition of blood. It can survive and grow slowly at temperatures ranging from 25 to 42 °C. It is best transported on chocolate agar slopes and stored freeze-dried, frozen at –70 °C or in liquid nitrogen.

The organism is oxidase and catalase positive. It is capable of utilizing glucose with no gas formation and, unlike gonococci, it also utilizes maltose, although occasional strains are maltose negative on primary isolation. It does not utilize lactose, sucrose or fructose. Meningococci produce γ-glutamyl aminopeptidase, but not prolyl aminopeptidase or β-galactosidase.

Genome Sequence and Analysis

The genomic sequence of two meningococcal strains (serogroup A and B, respectively) were described in 2000 (Parkhill *et al.*, 2000;

Tettelin *et al.*, 2000). Sequencing of a third (serogroup C) strain has also been completed, but not yet published (http://www.sanger.ac.uk/Projects/N_meningitidis/seroC.shtml). The genome is approximately 2.2 Mb in length and contains just over 2000 predicted coding regions. The overall G+C content is about 52%, but many coding regions possess a significantly lower G+C content, suggesting that the meningococcus has relatively recently acquired DNA from other organisms (horizontal exchange). Indeed, a number of genes were identified which are homologous to known virulence factors in other organisms. Comparison of the meningococcal and gonococcal genomic sequences shows that the two species are more than 90% homologous at the protein-coding level. One of the most notable and unique features of the genome is the abundance and diversity of repetitive DNA elements. These range from the short (10 bp) neisserial uptake sequence, which is involved in the recognition and uptake of DNA from the environment, to large gene duplications and prophage sequences up to 39 kb in length. Over 250 Corraia elements, 156-bp sequences bounded by 26-bp inverted repeats, are present in the meningococcal genome. The function of these sequences, which flank many important virulence-associated genes, is unclear, although a role in genome plasticity has been suggested.

Another key finding derived from the genome sequence data is the presence of more than 60 putative phase-variable (contingency) genes (Snyder, Butcher and Saunders, 2001). The phase-variable nature of these genes is predicted on the basis of the presence of homopolymeric tracts or simple repeat sequences (Henderson, Owen and Nataro, 1999). The length of the homopolymeric tracts or repeat sequences can change frequently as a result of slipped-strand mispairing during replication. This process brings the ATG initiation codon into or out of frame with the remainder of the gene, thus activating or inactivating the gene. Many of the phase-variable genes, for example, the capsule biosynthesis operon, are known to be important virulence determinants. The presence of many phase-variable genes may enhance the ability of the organism to adapt rapidly to new environments within the human host.

Neisseria meningitidis possesses specific DNA sequences that are absent from other *Neisseria* species (Perrin *et al.*, 2002). Regions of DNA that are common to the meningococcus and gonococcus, but not present in the commensal species *N. lactamica*, have also been identified (Perrin, Nassif and Tinsley, 1999). The latter sequences may determine aspects of the life cycle common to the pathogenic *Neisseria* species, such as mucosal colonization and epithelial cell invasion, whereas the former may play a role in the pathogenesis of meningococcal disease – particularly haematogenous dissemination and crossing of the blood-cerebrospinal fluid (B–CSF) barrier. The meningococcal-specific sequences reside in eight chromosomal regions, which range in size from 1.8 to 40 kb (Klee *et al.*, 2000). Five

of these regions were shown to be conserved in a representative set of strains and/or carried genes with homologies to previously described virulence factors in other species. For example, one conserved region contained genes homologous to the filamentous haemagglutinin precursor (FhaB) and its accessory protein (FhaC) of *Bordetella pertussis*.

GENERAL EPIDEMIOLOGY

Compulsory notification of meningococcal disease in the UK, imposed in 1912, helped to demonstrate the rise and fall of epidemics. One large peak in reported cases (a few thousand) occurred during the First World War and an even higher one (exceeding 12 000 cases) coincided with the Second World War. Currently, we are experiencing a world-wide epidemic with a clear increase in the number of cases reported in the past two decades. The occurrence of cases is generally unpredictable, but occasional clustering occurs in various geographical areas, particularly during the periods of increased disease activity. The baseline incidence rate between epidemics in the industrialized countries is between one and three cases per 10^5 population compared to 10–25 per 10^5 in underdeveloped countries. Attack rates are highest in those aged under 5 years, and in winter and springtime, possibly due to the prevalence of viral respiratory infections which are thought to act as predisposing factors. In the UK notification of the disease has more than doubled since the early eighties. Until recently, between 2000 and 2500 cases of invasive meningococcal disease were reported annually in England and Wales. Fifty–sixty per cent of cases occur in children less than 5 years of age, of which around 40% are usually in children aged less than 1 year. The highest incidence of cases occurs in the month of January and the lowest in August and September.

In third-world countries more than 310 000 people are thought to suffer from meningococcal diseases annually, of which 35 000 cases would be fatal (Robbins and Freeman, 1988). Over 300 million people live in countries within the meningitis belt of Savannah Africa, which is a vast area extending from Ethiopia in the east to The Gambia in the west and from the Sahara in the north to the tropical rain forest of Central Africa in the south. This belt has expanded since it was first described in 1963 (Lapeyssonie, 1963), and it now includes 15 countries, namely Ethiopia, Sudan, Central African Republic, Chad, Cameroon, Nigeria, Niger, Benin, Togo, Ghana, Burkina Faso, Mali, Guinea, Senegal and The Gambia (Greenwood, 1987). In 1988 and 1989, 80% of meningococcal isolates in the African continent occurred in these 15 countries, and in 1989 more than half the reported cases were from Ethiopia (Riedo, Plikaytis and Broome, 1995). During epidemics, attack rates in some countries of the meningitis belt reach as high as 1000 cases per 10^5 population which contrasts with 5–25 cases per 10^5 in the industrialized countries (Rey, 1991). In many regions of the meningitis belt, epidemics occur in cycles, with intervals between epidemics in the majority of cases less than 12 years (ranging from 2 to 25 years) (Riedo, Plikaytis and Broome, 1995). Epidemics last for approximately 2–4 years (Lapeyssonie, 1963), but in contrast to other areas, cases occur mainly in the hot dry months, possibly due to the influence of dry air on the integrity of the mucosal membranes of the nasopharynx. Major global outbreaks associated with the Hajj pilgrimage have occurred in recent years. Some northern African countries (like Egypt) also experience fluctuating epidemics. Large-scale epidemics have also occurred in many countries of Asia (e.g., Pakistan, India and China) and Central and South America (e.g., Cuba, Chile and Brazil). In Cuba, the attack rate reached levels of more than 50 cases per 10^5 population (Sierra *et al.*, 1991).

Age and Sex

Age-specific rates for meningococcal infection in England and Wales show a sudden rise in the attack rate among infants at around 3 months of age (coinciding with the decline in maternally acquired antibody), which peaks at the age of 6 months (more than 50 cases per 10^5) and remains relatively high for the first 12–24 months of life (Jones,

1995). The attack rate falls dramatically to 10 cases per 10^5 at the age of 2 years and continues to decline until it reaches the overall adult rate of 0.4 cases per 10^5 , only to produce a second but smaller peak (less than five cases per 10^5) among the 17–18 year olds. Boys are probably at a slightly higher risk of invasive disease in the first few years of life, whereas among the teenagers this is reversed. It is interesting that during epidemics the average age of patients is older than between epidemics.

Carriage

As an obligate human pathogen, the natural habitat of the meningococcus is the human nasopharynx. Although seasonal variation, temperature and humidity seem to have a clear impact on invasive meningococcal disease, they have very little, if any, effect on the prevalence of carriage. It is interesting that the highest attack rate of invasive meningococcal disease in Europe and United States is in the first year of life, whereas the highest carriage rate is found among teenagers and young adults. While it is difficult to estimate the true carriage rate in different groups in any community at any one time, it is known that several factors may influence carriage in the population. These include factors related to the organism, the host and the environment. Some serogroups of *N. meningitidis*, such as 29E, are regarded of low pathogenicity and are isolated from carriers, whereas serogroups A, B and C are responsible for over 90% of the invasive meningococcal infections worldwide. Carriage is more common in the second and third decades of life, and more common among smokers than non-smokers. The body's immune status, changes in the oropharyngeal flora and concurrent viral upper respiratory tract infections are also believed to influence carriage. Viral infections, particularly influenza A infection, are increasingly blamed for predisposing individuals to meningococcal carriage and invasive disease (Cartwright *et al.*, 1991; Makras *et al.*, 2001). Carriage rates are known to be much higher among family members and close contacts of infected patients, and in closed communities with overcrowded conditions, such as military recruits' training camps, prisons and schools. Baseline carriage rates of 5–15% are considered usual; however, these can fluctuate and reach much higher levels in certain communities.

Carriage rate is shown to be low (<3%) in children under the age of 4 years but can increase up to tenfold among teenagers, young adults and enclosed populations such as military recruits (Cartwright *et al.*, 1987; Blackwell *et al.*, 1990; Caugant *et al.*, 1992; Caugant *et al.*, 1994; Tyski *et al.*, 2001). Carriage among adults above the age of 25 years is usually below 10%.

It is difficult to obtain an estimate of the actual duration of meningococcal carriage, but it has been shown to be as short as several days to as long as several months (Ala'Aldeen *et al.*, 2000; Neal *et al.*, 2000). It is important to emphasize that carriage is a dynamic process that is influenced by numerous factors. In the 1997–1998 academic year, a longitudinal study was carried out on the dynamics of meningococcal carriage and acquisition among first-year students at Nottingham University, UK. Pharyngeal swabs were obtained from 2453 first-year students at the start of the academic year (October), later on during the autumn term and again in March. During freshers week (the first week of term), the carriage rate rose rapidly from 6.9% on day 1 to 11.2% on day 2 and 19% on day 3 to 23.1% on day 4 (Ala'Aldeen *et al.*, 2000; Neal *et al.*, 2000). The average carriage rate during the first week was 12.9%, by November it was 31% and in December it had reached 34.2%. In March the rate was 28%. Of the students who arrived at the University as meningococcal carriers, 44.1% were still positive later on in the autumn term and 57.1% of these had remained persistent carriers at 6 months. These carried the same or different strains at different times. The study revealed a high rate of turnover of meningococcal carriage among students. Of the index carriers who lost carriage during the autumn, 16% were recolonized at 6 months. Of the 344 index non-carriers followed up, 22.1% acquired carriage during the autumn term and another 13.7% by March.

Patients with invasive disease may carry the organisms for days or weeks before becoming ill. Carriage of a particular meningococcal strain does not necessarily protect against colonization or invasion with a homologous or heterologous strain. In the Nottingham study, one student developed invasive meningococcal disease after carrying the same organism for over 7 weeks.

THE CELL ENVELOPE: ANATOMY, HETEROGENEITY AND STRAIN CLASSIFICATION

The Cell Envelope

The meningococcal cell is contained within a permeable polysaccharide capsule which overlays a multilayered envelope (Figure 14.1), very similar to that of *N. gonorrhoeae* and other Gram-negative bacteria. This envelope consists of three layers: an outer membrane layer, which contains proteins, lipooligosaccharides (LOSs) and phospholipids; a thin but rigid peptidoglycan layer; an inner cytoplasmic membrane which contains, among other things, enzymatic components of the electron transport chain and oxidative phosphorylation. Pili, long filamentous protein projections, also extend outwards from the cell envelope. The cell envelope has been extensively studied for pathogenesis, classification, immune response and vaccine development purposes. Many of the prominent components of the cell envelope, particularly the outer membrane components, show wide structural and antigenic diversity which has been exploited for epidemiological purposes in classifying clinical isolates.

Classification Systems of Clinical Isolates

For epidemiological purposes, several classification systems have been developed for *N. meningitidis*. The most widely used and well established is the one that divides strains immunologically into serogroups, serotypes, serosubtypes and immunotypes, based on antigenic differences in their capsules, PorB protein, PorA protein and LOSs, respectively. For example, a serogroup B serotype 4, serosubtype 15 and immunotype 10 is written as B:4:P1.15:L10.

Other classification tools have also been used including multilocus enzyme electrophoresis (MLEE) and multilocus sequence typing (MLST). The MLEE typing (electrotyping, ET) scheme is based on the presence and electrophoretic mobility of iso-forms of cytosolic enzymes whose molecular weights vary between different strains of meningococci. MLEE has enabled subdivision of genetically related strains of serogroup A to subgroups and serogroups B and C to lineages and clonal complexes (Achtman, 1994). Using this method, it was possible to trace the movement of a certain clone (clone III-I) of serogroup A meningococci from China to Nepal in 1983, to India and Pakistan in 1985, to Mecca in 1987 and to the meningitis belt of Africa and other parts of the world by 1989 (Caugant *et al.*, 1987; Moore *et al.*, 1992). Furthermore, using MLEE it was possible to establish that meningococcal populations are genetically highly diverse. However, only a few of the clonal complexes appear to be responsible for most meningococcal disease. For example, strains belonging to ET-5 and ET-37 clonal complexes dominated the disease-causing serogroup B and C strains, respectively, in the UK and the rest of Europe. These dominant complexes are, however,

Figure 14.1 Schematic diagram of the meningococcal cell envelope. LOS, lipooligosaccharide; OMP, outer membrane protein.

changing slowly with time, and an increase in the incidence of disease appears to coincide with the introduction of a new clonal complex to a particular community.

With the advent of DNA sequencing it became possible to develop the more precise and less cumbersome MLST scheme (Maiden *et al.*, 1998). In this typing scheme, relatively small DNA fragments from seven meningococcal housekeeping genes are amplified by PCR and sequenced. These genes include *abcZ*, *adk*, *aroE*, *fumC*, *gdh*, *pdhC* and *pgm*. Sequences of these genes from diverse meningococcal strains representing various clonal complexes are then aligned. Alleles of each gene are assigned numbers, and strains with particular combinations of allelic mixes of all the seven genes are then allocated a sequence type (ST). MLST has a greater discriminatory power than MLSE, otherwise the two methods serve the same purpose.

In addition to typing schemes, there are numerous comparative fingerprinting schemes, some of which can be converted to typing schemes too. Pulse-field gel electrophoresis (PFGE), restriction fragment length polymorphism (RFLP), fluorescent-labelled amplified fragment length polymorphism (fAFLP) (Goulding *et al.*, 2003) and other PCR-based methods have all been used.

Capsular Polysaccharides: the Serogroup Antigens

The meningococcus possesses a phase-variable polysaccharide capsule, as do many non-pathogenic species of *Neisseria*. The structural and antigenic heterogeneity of the capsular polysaccharide forms the basis of the classification into at least 13 serogroups, namely A, B, C, D, 29E, H, I, J, K, L, W135, X, Y and Z. The serogroup A capsule is composed of mannosamine phosphate, while that of serogroups B, C, Y and W135 contains sialic acid, which is believed to be important in survival and virulence. The capsular polysaccharides of serogroup B and C meningococci are composed of homopolymers of *N*-acetylneuraminic acid with α -2,8 and α -2,9 linkages, respectively. This minor difference in structure leads to markedly different immunological properties: whereas the latter is immunogenic in humans and generates protective antibodies, the former is poorly immunogenic.

Serogroup A meningococci are now rare in the more developed countries but are the major pathogens in the meningitis belt of Africa and a number of Asian countries, where they are responsible for the epidemics. In the UK, serogroup A was responsible for the epidemics in the first half of the century, whereas in the second half this serogroup became increasingly uncommon and was replaced by serogroup B (up to 70%) and serogroup C (20–30%) with occasional isolates of serogroups A, W135, X, Y and 29E strains. Since the introduction of serogroup C-conjugate vaccine into the childhood immunization programme, this serogroup is now gradually becoming uncommon in the UK. In Europe and the American continent, serogroups B and C are currently responsible for about 85% of the cases, with serogroups Y and W135 accounting for most of the remainder. Serogroups H, I and K have been reported in China. In the United States, until the late 1980s serogroup B meningococci accounted for 50% of the cases and serogroup C for 35%. However, in 1989–1991, the two serogroups were almost equally distributed (46 and 45%, respectively) (Jackson and Wenger, 1993). In Norway in 1975, less than 50% of isolates were serogroup B strains but by 1981 these had reached 89.1%, only to drop again to 71.5% by 1990 (Lystad and Aasen, 1991). Serogroup A strains, however, were responsible for 24% of the cases in Norway in 1975 but by 1990 they had almost disappeared. Serogroup B meningococci also dominate in the current epidemics in Central and South America and in South Australia and New Zealand.

With increased international travel, global dissemination of outbreak-associated strains is common. Typical examples are the international epidemics of serogroup A and W135 meningococcal disease that occurred in association with the Hajj pilgrimage in the late 1980s and 1990s, respectively. The infected pilgrims caused numerous secondary infections in their home countries in different parts of the world, such as

Europe, North America and Asia. Similarly, the intercontinental spread of a particular clone of serogroup B:15:P1.16 (clone ET-5), which was responsible for outbreaks in Norway, Iceland, Denmark, the Netherlands and UK, has also been documented as the cause of outbreaks in South Africa and South America (Caugant *et al.*, 1987).

Until recently, non-groupable strains were considered non-pathogenic. It is now clear that expression of the capsular is phase variable (Snyder, Butcher and Saunders, 2001). This means that all capsulated strains are capable of switching the capsule on and off, unless they lose some of the essential genetic components of the capsule biosynthesis pathways. Temporary loss of capsular expression may allow better affinity between bacterial and host surface molecules and facilitate colonization. Capsule expression appears to be an essential requirement for bacterial survival following invasion of various body compartments, e.g. blood and CSF, and may also be required for detachment and transmission from one host to another.

The PorB and PorA Outer Membrane Proteins: the Serotype and Serosubtype Antigens

The meningococcal outer membrane contains a number of major outer membrane proteins (OMPs). PorB (previously named class 2/3 protein) and PorA (class 1 protein) function as porins, allowing entry of nutrients. Like most surface-exposed meningococcal antigens, they exhibit a large degree of antigenic diversity between different strains, hence their use for the serotype and serosubtype classification of meningococci. Strains of *N. meningitidis* are subdivided into over 20 different serotypes and subtypes, designated by numbers. However, many isolates cannot be typed or subtyped with the available monoclonal antibodies, and these are designated non-typable and non-subtypable, respectively.

The antigenic structure of serotype and serosubtype antigens changes rapidly *in vivo* in an individual person and over time in the community. The surface-exposed variable loops of both porins can change antigenicity by insertion or deletion of amino acids or by horizontal transfer of subfragments of their respective genes. These mechanisms will make these genes elusive targets for vaccine development.

Lipooligosaccharide (Endotoxin)

Meningococcal LOS (also called endotoxin) consists of an outer membrane-bound glycolipid which differs from the lipopolysaccharides (LPS) of the *Enterobacteriaceae* by lacking the repetitive O-side-chains and thus resembles the rough form of LPS (Griffiss *et al.*, 1988). It consists of three main components, namely an oligosaccharide core, a hydrophobic lipid A (the toxic component) and a variable oligosaccharide side-chain (the immunogenic component). Nine glycosyltransferase (*lgt*) genes, located at three chromosomal loci, are responsible for the biosynthesis of the oligosaccharide side-chains. The structural and immunogenic heterogeneity of the oligosaccharide side-chains, partly due to the phase-variable expression of four of the glycosyltransferases (*lgtA*, *lgtC*, *lgtD* and *lgtG*), has been used to classify strains into 12 immunotypes using monoclonal antibodies. Immunotypes L1-L8 are predominantly associated with meningococcal serogroups B and C, whereas immunotypes L9-L12 are associated with serogroup A strains. Two of the three meningococcal *lgt* loci (in contrast to the stable gonococcal *lgt* loci) are hypervariable genomic regions. Horizontal gene transfer from commensal *Neisseria* contributes to the genetic diversity of the *lgt* loci (Zhu *et al.*, 2002).

Meningococcal LOS side-chain variation may be important in meningococcal virulence: commensal nasopharyngeal isolates typically possess a short side-chain, whereas invading isolates from blood and CSF display long side-chains. The longer LOS forms terminate in a galactose residue, which can be modified by sialyltransferase, located in the outer membrane of the cell, using either endogenous or host-derived 5'cytidinemonophospho-*N*-acetylneuraminic acid (CMP-NANA) as

a sialyl donor. LOS sialylation decreases the susceptibility of the organism to antibody- and complement-mediated killing, conferring a survival advantage after invasion of the bloodstream. Conversely, adhesion to nasopharyngeal epithelial cells is suppressed by LOS sialylation, probably as a result of steric hindrance of the interaction of OMPs (such as Opa and Opc) with host-cell ligands. LOS is itself known to be cytotoxic to various host cells and may interact synergistically with pili to cause cell damage. A viable LOS-deficient meningococcal mutant has been generated *in vitro* (Steeghs *et al.*, 1998), which will assist in future studies of LOS–host interactions.

PATHOGENESIS

The pathogenesis of meningococcal disease begins with the transmission of the organism from the nasopharynx of one individual to another, which is believed to occur either by direct physical contact or respiratory droplets. The latter probably only transmit the bacteria to persons in close proximity (about 1 m away), thus explaining the association of meningococcal carriage (and disease) with overcrowding (Nelson, 1996). Close contact with a case of invasive meningococcal disease greatly increases the risk of developing invasive disease (usually within a few days) with the same strain. A small number of pathogenic (sometimes referred to as hypervirulent) meningococcal clones such as ET-5 (ST-32) and ET-37 (ST-11) are responsible for most cases of disease; 90% of strains isolated from carriers are never associated with disease and are considered non-pathogenic (Bevanger *et al.*, 1998). In the overwhelming majority of cases, therefore, the acquisition of a new meningococcal strain results in the asymptomatic colonization of the nasopharyngeal mucosa rather than disease. Even the acquisition of a pathogenic clone causes disease in only 1% of individuals (Caugant *et al.*, 1994). There is thus a strong argument to regard the bacterium as a common respiratory commensal, which rarely causes any deleterious effects to its host. The detection of meningococci in subepithelial layers in the nasopharynx of healthy carriers (Sim *et al.*, 2000) suggests that cellular invasion leading to an intracellular habitat may represent a successful survival mechanism for the organism. Disease may therefore be regarded as an occasional ‘accident’ resulting from this strategy; the nasopharyngeal transmissibility and colonization/invasion fitness of pathogenic clones having the side-effect of invasive disease (a dead-end event in the biology of the organism) in susceptible persons (Taha *et al.*, 2002). Transient invasion of the bloodstream, which is a hostile environment for bacteria, is probably quite common but goes unrecognized in most cases as the host’s immune system clears low-level bacteraemia. Rarely, if the bacteria survive and multiply in the bloodstream, resulting in an unchecked bacteraemia, they may induce septicaemia or proceed to invade meningothelial cells, resulting in meningitis. The predilection of meningococci to invade the meninges is poorly understood but probably involves the same mechanisms utilized to attach to and invade nasopharyngeal and submucosal cells. Metastatic infections at other sites are comparatively rare. The factors that contribute to both fitness and pathogenicity include the polysaccharide capsule, the type IV pilus, OMPs such as Opa and OpcA and secreted proteins such as immunoglobulin A1 (IgA1) protease. Screening of the meningococcal genome sequence has identified several other previously unrecognized proteins, which may also contribute to fitness and pathogenicity.

Polysaccharide Capsule

The ability to express a polysaccharide capsule (analogous to other bacteria that commonly colonize the nasopharynx such as *Haemophilus influenzae* and *Streptococcus pneumoniae*) is believed to be important for the transmission of the meningococcus, protecting the organism from desiccation and enabling aerosol transmission; the absence of a capsule in *N. gonorrhoeae* makes the organism highly susceptible to drying. In the nasopharynx, phase-variants lacking

capsule expression are common, as are strains lacking the capsule biosynthesis operon, indicating that capsule expression is not a prerequisite for colonization (Claus *et al.*, 2002). Indeed, intimate adherence (and subsequent transmigration across the epithelial cell barrier) is enhanced in the absence of the capsule. The transcriptional regulatory protein, CrgA, has been shown to downregulate capsule expression and promote adhesion to epithelial cells (Deghmane *et al.*, 2002). Following invasion, the capsule is an essential virulence factor which protects the organism against phagocytosis and complement-mediated killing (Klein *et al.*, 1996).

Type IV Pili

Analogous to many Gram-negative bacteria, meningococci produce phase- and antigenically variable type IV pili, which act as long-range attachment organelles. Type IV pili are filamentous structures, 6 nm in diameter, which protrude from the cell surface. At least 22 proteins are required for pilus biogenesis and function. The pilus fibre is composed of repeating units of the 18–22-kDa PilE protein, which may be post-translationally glycosylated. A 110-kDa polypeptide, PilC, located at the tip of the pilus, is believed to act as an adhesin. PilC is upregulated by initial interactions with host cells and is essential for obtaining a fully adhesive phenotype. The pilus receptor is thought to be CD46 (Kallstrom *et al.*, 1997).

In addition to adhesion, type IV pili are important for other phenotypes including bacterial aggregation, twitching motility and DNA transformation. Pili may also enhance LOS-mediated host-cell cytotoxicity and lead to cortical plaque formation. A role in modulating host-cell signal transduction pathways is postulated, as pili produce transient increases in cytosolic free calcium (Kallstrom *et al.*, 1998).

Opa and OpcA

After the initial pilus-mediated adhesion, further interactions of meningococci with epithelial cells are mediated by opacity OMPs, such as Opa and OpcA. Downregulation of capsule expression and removal of sialic acid from LOS are required for Opa and OpcA to interact with host-cell molecules. Opa are a family of phase-variable basic proteins with a molecular weight of about 28 kDa, each encoded by a distinct *opa* gene. Meningococci usually possess four or five Opa loci. They are surface-exposed and, apart from two hypervariable regions, are fairly constant in sequence. Opa variants bind members of the large CEACAM (formerly CD66) family including CEACAM 1, 3, 5 and 6, which are differentially expressed on host cells. The binding of CEACAM molecules mediates adhesion to and invasion of epithelial cells (Virji *et al.*, 1996). Opa binding of CEACAMs on polymorphonuclear cells leads to phagocytosis.

The OpcA proteins (formerly known as Opc) are another group of OMPs, which, although superficially similar to the Opa proteins in terms of their size and physicochemical properties, share only 22% homology with these proteins (Olyhoek *et al.*, 1991). Transcriptional (phase-variable) regulation leads to zero, intermediate or high-level expression. OpcA promotes adherence of non-piliated meningococci to epithelial cells via cell-surface heparan sulphate proteoglycans (de Vries *et al.*, 1998). OpcA also facilitates adhesion to and invasion of endothelial cells through the binding of vitronectin. The OpcA–vitronectin interaction allows the meningococcus to attach to the integrin $\alpha_v\beta_3$ on the apical surface of the endothelial cells (Virji, Makepeace and Moxon, 1994).

IgA1 Protease and Other Autotransporter Proteins

Meningococci secrete a protease via the autotransporter pathway (type V secretion) that was demonstrated to cleave IgA1 (but not IgA2) at the hinge region, thus generating functionally useless antigen-binding Fab fragments. The functional significance of this cleavage is uncertain,

but surface-bound Fab fragments may enhance the resistance of the bacterium to the bactericidal activity of IgG and IgM antibodies. Lamp1, the major integral membrane glycoprotein of lysosomes, is also cleaved by IgA1 protease. Pilus-induced elevation of cytosolic free calcium has been shown to trigger lysosomal exocytosis, which in turn increases the surface levels of Lamp1. Once on the surface, Lamp1 is accessible to cleavage by IgA1 protease secreted by the adherent bacteria (Lin *et al.*, 1997). Reducing the lysosomal levels of Lamp1 enhances the intracellular survival of the organism. Furthermore, enhanced IgA1 protease activity is a feature of pathogenic meningococcal clones (Vitovski, Read and Sayers, 1999).

In addition to IgA1 protease, several other meningococcal proteins are translocated to the outer membrane or secreted via the autotransporter pathway. These include NhhA and App, which show homology to adhesins in *H. influenzae*, and AspA, a subtilisin-like serine protease which shows homology to a virulence determinant in *Bordetella pertussis* (Peak *et al.*, 2000; Abdel-Hadi *et al.*, 2001; Turner, Wooldridge and Ala'Aldeen, 2002). The role of these autotransporter proteins in relation to meningococcal fitness and pathogenesis has yet to be determined.

PATHOPHYSIOLOGY

During meningococcal septicaemia, there are signs and symptoms of circulatory failure, multi-organ dysfunction and coagulopathy. There is increased vascular permeability and vasodilatation that results in capillary leak syndrome with peripheral oedema. Loss of intravascular fluid and plasma proteins results in hypovolaemia and reduced venous return, and hence reduced cardiac output, hypotension and reduced perfusion of vital organs. Systemic hypoxia, acidosis and gross electrolyte and metabolic impairment eventually culminate in multiorgan dysfunction. On the molecular level, the underlying pathophysiology of meningococcal sepsis is complex and involves numerous interactive cascades, including cytokine, chemokine, host-cell receptors and coagulation and complement components. Figure 14.2 summarizes some of these interactive events.

The Role of Endotoxin

The lipid A moiety of the endotoxin is thought to be primarily responsible for septic shock, extensive tissue damage and multi-organ dysfunction through stimulating the release of inflammatory mediators including tumour necrosis factor- α (TNF- α) and a series of interleukins and other cytokines. In addition, meningococcal endotoxin

seems to trigger a number of major intravascular cascade systems, including coagulation, fibrinolysis, complement and kallikrein-kinin (van Deuren, Brandtzaeg and van der Meer, 2000). Although endotoxin is largely membrane-associated, it is shed from live organisms in large quantities via the outer membrane vesicles (blebs), which also contain OMPs. This bleb shedding is known to occur *in vitro* (in broth cultures) and *in vivo*. Increasing levels of circulating endotoxin are associated with increasing seriousness of disease, and very high levels (>700 ng/l) are associated with fulminant septic shock, disseminated intravascular coagulation (DIC) and a high fatality rate (Brandtzaeg, 1995). Endotoxin seems to trigger, directly or indirectly, the release of extremely high levels of monocyte tissue factor activity, as detected in severely septicaemic patients, suggesting that monocytes are responsible for the overwhelming DIC (Osterud and Flaegstad, 1983).

Coagulopathy

Coagulopathy is a common feature of meningococcal septicaemia and is indicated by the presence of: prolonged kaolin partial thromboplastin time, prothrombin time and thrombin time; reduced platelet count, plasma fibrinogen, plasminogen and α -2-antiplasmin; increased fibrin degradation products, fibrinopeptide A and plasminogen activator inhibitor-I; reduced functional levels of coagulation factor V, antithrombin III, protein C, protein S and extrinsic pathway inhibitor (Brandtzaeg, 1995; van Deuren, Brandtzaeg and van der Meer, 2000). Severity of disease is also predicted from markedly increased levels of immunoreactive plasminogen activator inhibitor-I, and figures exceeding 1850 μ g/l almost always reflect a fatal outcome (Brandtzaeg, 1995). The fibrinolytic cascade seems to be activated early in the disease, which is then downregulated by increasing levels of plasminogen activator inhibitor-I, resulting in the formation of microthrombi in various body organs, including the skin and the adrenal glands. The uncontrolled and excessive consumption of coagulation factors then results in a haemorrhagic diathesis with disseminated tissue haemorrhages.

Activated Complement Cascades

It has long been established that late complement components are vital for complete protection against invasive meningococcal disease. Both the classical and alternative pathways are important for protection. Those with complement deficiencies, including C2, C3, C4b, C5-9 and properdin, are at high risk of developing meningococcal disease and may suffer more severe disease. Those with late complement component deficiencies are particularly at much greater risk of acquiring meningococcal disease and developing second episodes of disease. It is interesting that these patients suffer from disease at an older age with lower mortality rate, and with serogroup Y being the most frequently isolated serogroup. Whereas men suffering from the X-linked properdin deficiency are at much greater risk of developing severe disseminated meningococcal disease with a very high mortality rate (Densen *et al.*, 1987). This highlights the importance of the early complement components and the initiation of complement activation and, by inference, the role of the alternative pathway in meningococcal lysis.

The complement cascade is triggered during meningococcal infection, probably by the effect of endotoxin alone. In cases of severe septic shock, the alternative pathway seems to dominate over the classical pathway. Although complement-mediated bacteriolysis is an effective protective antibacterial mechanism, it is believed to have some indirect detrimental effect via the release of the C3a, C4a and C5a anaphylatoxins and/or the release of membrane-bound endotoxin which may follow the attack of the membrane-attack complex (Frank, Joiner and Hammer, 1987). Increased levels of C3 activation products and terminal complement complexes are thought to reflect the severity of disease (Brandtzaeg, 1995).

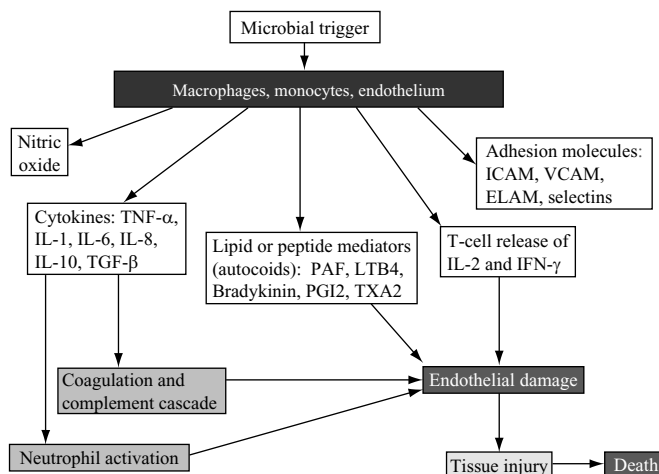

Figure 14.2 Summary of molecular events during meningococcal sepsis.

The Source of Pro-Inflammatory Cytokines

Meningococcal disease is associated with elevated levels of pro-inflammatory cytokines. During septic shock, increased levels of endotoxin, TNF- α , IL-1 β , IL-6 and IL-8 are detected in the peripheral blood and reflect disease severity. During meningococcal meningitis without septicaemia, there may be a compartmentalized CSF rise in endotoxin levels associated in about half of the cases with a CSF rise in TNF- α and IL-1 β , which all reflect the severity of the meningitis (Brandtzaeg *et al.*, 1992a; Brandtzaeg, Ovstebo and Kierulf, 1992b). The rise in IL-6 and IL-8 does not seem to be compartmentalized. Epithelial cells of the meninges upregulate the genes for TNF- α , IL-6 and IL-8 in response to exposure to meningococcal cells (Wells *et al.*, 2001). IL-1 β , on the other hand, appears to be produced by meningeal macrophages (Garabedian, Lemaigre-Dubreuil and Mariani, 2000).

Host Factors that Affect the Risk and Severity of Meningococcal Disease

In addition to the complement component deficiencies described above, other host factors are known to affect the risk and/or severity of meningococcal disease. Deficiencies in serum mannose-binding lectin, which binds to meningococci and activates complement, predisposes to invasive meningococcal disease, especially in children (Hibberd *et al.*, 1999; Jack *et al.*, 2001). Genetic differences in the ability to express certain cytokines may also impinge on the outcome of infection. For example, persons who are homozygous for an IL-1 β gene variant, which results in low-level expression of IL-1 β , are prone to more severe disease (Sparling, 2002). Similarly, a polymorphism in the neutrophil receptor for IgG₂ (CD32) has recently been shown to be associated with more severe bacteraemia and sepsis, although it does not predispose to infection *per se*, nor does it increase the severity of meningitis (Domingo *et al.*, 2002). The coagulation system plays an important role in the outcome of meningococcal disease. Deficiency of either protein C or its cofactor protein S is associated with an increased risk of purpura fulminans (Esmon *et al.*, 1997). Patients with severe meningococcal disease have been shown to have decreased endothelial expression of the two receptors, thrombomodulin and protein C receptor, which are essential for the activation of protein C.

Consequences of the Bacterial Insults

General

The uncontrolled and complicated cascades of organism- or endotoxin-induced events, including inflammatory mediators and coagulopathies, eventually lead to capillary leakage syndrome, circulatory collapse, myocarditis, renal failure, adult respiratory distress syndrome, adrenal haemorrhage, haemorrhagic skin and serosal surface lesions, muscular infarction and other organ dysfunctions. Of these, circulatory failure is the most prominent cause of death in overwhelming meningococcal disease. Myocardial dysfunction is probably due to a combination of many effects, including a direct effect of the bacterium and its endotoxin, inflammatory mediators, impaired coronary artery perfusion, hypoxia, acidosis, hypocalcaemia, hypokalaemia, hypomagnesaemia and hypophosphataemia.

Outcome of disease can be predicted from the initial renal function (e.g. serum creatinine level), and those who develop uraemia or anuria early in the disease will have much poorer prognosis than those who develop only a mild degree of renal impairment. Adrenal haemorrhages, the so-called Waterhouse-Fredrichsen syndrome, which is observed in a large percentage of fatal cases, is not unique to fulminant meningococcal septicaemia, as it occurs in other overwhelming Gram-negative endotoxaemia with DIC. The resulting adrenal insufficiency is an additional factor contributing to the circulatory collapse.

Haemorrhagic skin lesions (petechiae and ecchymoses), which vary in size and severity, reflect the meningococcal predilection for the dermal blood vessels and reflect the severity of DIC and state of septicaemia. There is vascular damage (with or without vasculitis) with endothelial cell injury or death with meningococci identifiable and/or cultivable from lesion biopsies.

The central nervous system

Bacterial endotoxin and peptidoglycan are believed to be mainly responsible, directly or indirectly through inflammatory mediators, for the meningeal inflammation, blood-brain barrier dysfunction and the changes in CSF. These include cellular, biochemical and hydrodynamic changes of the CSF. The combination of increased CSF secretion, impaired CSF absorption and blood-brain barrier dysfunction can lead to the accumulation of CSF, raised intracranial pressure and reduced cerebral blood flow. Increased CSF lactate indicates brain tissue hypoxia. In patients with meningococcal septicaemia and meningitis, the brain tissue hypoxia, which is worsened by the shock-induced underperfusion, vasculitis and DIC, may result in neuronal injury and varying degrees of brain tissue damage.

CLINICAL MANIFESTATIONS

Meningococci are capable of causing a wide range of different clinical syndromes, which can vary in severity from a transient mild sore throat to meningitis or acute meningococcal septicaemia, which can cause death within hours of the appearance of symptoms. Bacteraemia with or without sepsis, meningococcal septicaemia with or without meningitis, meningoencephalitis, chronic meningococcaemia, pneumonia, septic arthritis, pericarditis, myocarditis, endocarditis, conjunctivitis, panophthalmitis, genitourinary tract infection, pelvic infection, peritonitis and proctitis are all among the diseases caused by meningococci. Meningitis and/or septicaemia are by far the most common presentations of disease. It is important to remember that the clinical picture can progress from one end of the spectrum to the other during the course of disease.

Transient Meningococcaemia

Relatively mild culture-positive flu-like illness can present with non-specific symptoms such as raised temperature and joint pain with or without rash and can persist for days or weeks. Such mild bacteraemia may resolve completely without treatment or progress to acute severe disease or persist as chronic meningococcaemia.

Acute Meningococcal Septicaemia With or Without Meningitis

Acute meningococcal disease may present initially with a series of non-specific manifestations which combined may provide indicative diagnostic clues. This may include signs of septicaemia, meningitis or both. Presentation with severe meningococcal septicaemia is less common but deadlier than meningitis.

The majority of cases occur in young children and present with rapid onset of raised temperature with or without vomiting, photophobia, convulsions, skin rash, lethargy, irritability, drowsiness, reluctance to feed, diarrhoea and other more localized signs and symptoms. In older children and adults, headache, restlessness, generalized muscular pain and arthralgia are also noted. Rarely, acute abdominal pain may be the predominant feature. The onset may be preceded by prodromal symptoms mimicking viral upper respiratory tract infections. On examination, the patient is often distressed with temperature ranging from normal to 41 °C.

Meningococcal septicaemia is most often associated with the characteristic meningococcal rash (Plate 8). These lesions, when present,

can be macular, maculopapular, petechial, purpuric, ecchymotic or necrotic in nature and can appear anywhere on the body, including the trunk, extremities, pressure sites, palm, sole, face, palate and conjunctivae. Adjacent lesions can coalesce and form confluent purpurae, petechiae, haemorrhagic bullae or even gangrenous necrotic skin and subcutaneous lesions. In severe cases, DIC with intense peripheral vasoconstriction may cause peripheral gangrene, which can involve fingers, toes or even entire limbs.

In severe cases, patients present in septic shock (hypotension which is refractory to fluid resuscitation) with tachycardia, progressively impaired peripheral perfusion, increased respiratory rate, hypoxia, cyanosis, acidosis, electrolyte imbalance, elevated plasma lactate levels, progressive circulatory failure with oliguria or even anuria. Progressive impairment of central perfusion leads to a decline in the level of consciousness and may lead to coma. Poor prognostic signs include extensive and rapidly progressing necrotic skin lesions, shock, multi-organ failure, decreasing level of consciousness and DIC.

Varying degrees of respiratory failure and acute respiratory distress syndrome are found in most patients with meningococcal septic shock. These are caused by various factors, including pulmonary oedema due to capillary leak syndrome, pulmonary vascular occlusion due to DIC and elastase release from neutrophils (Donnelly *et al.*, 1995). Reversible oliguria or renal failure occur in severe cases due to hypovolaemia and impaired organ perfusion. In cases of prolonged shock, tubular and cortical necrosis can cause irreversible renal failure. Myoglobinuria, due to muscle necrosis, may further contribute to renal failure (van Deuren *et al.*, 1998).

Meningitis

Signs and symptoms of meningococcal meningitis include general (non-specific) and localized (specific) ones. Patients often remain alert, but signs of cerebral involvement, such as convulsions, declining level of consciousness and coma may be present. Depending on the previous immune status, localized signs may appear early or late in the course. In the young and previously healthy, localized signs of meningeal irritation may occur early in the disease. Unless accompanied by the characteristic rash (present in more than half of the cases), none of these are characteristic to meningococcal meningitis. Most, but not all, patients present with clear signs of meningeal irritation. Of these, neck stiffness is by the far the most important; however, it is present in less than half of the patients (Carpenter and Petersdorf, 1962). In infants and young children, neck stiffness is difficult to detect, but when the child is left to assume the most comfortable position, extension of the neck may be observed. Additional signs include a bulging fontanelle due to increased intracranial pressure, irritability and lying on one side facing away from the source of light (photophobia). A positive Kernig's sign, the inability to extend the knee when the hip is flexed in supine position, is another important and pathognomonic sign of meningeal irritation. An attempt to flex the neck in a sudden movement with the patient in a sitting position with the legs outstretched will induce a reflex flexion of both hips and knees (Brudzinski's sign).

Other Manifestations

Acute or chronic meningococcal septic arthritis is relatively common and may complicate any of the acute meningococcal diseases. It usually affects one or more joints and manifests at any stage of disease (Schaad, 1980). Occasionally, arthritis is the only presenting complaint, which most often involves a single large joint such as the knee or the hip. Meningococci may be seen in Gram stains and isolated from cultures of joint aspirates. An immunoreactive arthritis (or pericarditis) may also occur typically 3–5 days into the illness.

Upper and lower respiratory tract infection, such as otitis media, pharyngitis, bronchitis and pneumonia, can occur as part of disseminated

meningococcal disease or as primary infections. Primary pneumonia is typically caused by serogroup Y meningococci (Koppes, Ellenbogen and Gebhart, 1977), especially in the elderly, and has a good prognosis. Blood or sputum cultures can yield the organism; culture-positive nasopharyngeal swabs can be misleading and are not therefore recommended. Respiratory infections due to meningococci, which respond well to conventional antibiotics, are probably underdiagnosed, as cultures are not routinely obtained in many patients unless empirical treatment fails. Furthermore, meningococci isolated from sputum can easily be dismissed as respiratory *Neisseriae* and not considered as significant.

Similarly, other organs may be attacked by meningococci as part of meningococcal septicaemia or as a primary organ infection. These include pericarditis, myocarditis and endocarditis. Myocarditis is thought to be present in most cases of overwhelming septicaemia. Also, meningococcal urethritis and endocervicitis in sexually active women and proctitis in homosexuals can occur (Faur, Weisburd and Wilson, 1975). Meningococci seem to be responsible for 2% of all bacterial conjunctivitis, and this may proceed to systemic meningococcal disease in nearly one-third of cases (Barquet *et al.*, 1990).

Chronic Meningococcal Disease

Finally, chronic meningococcal disease (chronic meningococcaemia) is a rare but long recognized clinical entity which presents as chronic intermittent high temperature, joint pain and headache with or without skin lesions affecting adults more than children (Benoit, 1963). The condition can last for months and cause a variety of complications. The organism may be isolated from the blood in the first few weeks of the illness.

Morbidity and Mortality

A significant number of the patients who recover end up with permanent neurological sequelae, including mental retardation, cerebellar ataxia, cranial nerve deficits, deafness (due to auditory nerve damage), persistent headache, hydrocephalus, dementia, convulsions, peripheral nerve lesions, subdural empyema and psychoneurological complications.

Mortality rate from meningococcal disease varies between 5 and 70% depending on a number of factors, including the severity of disease, the speed by which it develops, the organs involved, the age and immune status of the patient, the socioeconomic status, the standard of health care and the speed by which the disease is diagnosed and antibiotics administered. An analysis of case fatality rates between 1963 and 1998 in Oxford, UK, showed a rate of 11%, which had not fallen during this period (Goldacre, Roberts and Yeates, 2003). In those patients who present with signs of severe septicaemia, particularly in underdeveloped countries, the mortality rate can reach up to 70% (deMorais *et al.*, 1974). In developed countries, 15–30% of septicaemic patients die, despite treatment in advanced intensive care units. The mortality rate for patients with septicaemic shock remains very high (20–50%), despite state-of-the-art intensive care facilities.

The overall mortality from meningococcal meningitis in Europe and North America is 5–15%, despite the sensitivity of the organism to many antibiotics and the high standard of health care in these two continents (Jones, 1995). Children seem to have a better chance of recovery from meningococcal meningitis than adults. The mortality rate for children under the age of 5 is around 5% compared to 10–15% in adults.

A combination of improvements in initial management of patients, use of a mobile intensive care service and centralization of care in a specialist unit were shown to reduce the overall case-fatality rate (from 23% in 1992/93 to 2% in 1997) in a paediatric population, despite disease severity remaining largely unchanged (Booy *et al.*, 2001). Most deaths occur in the first 2 or 3 days of admission to hospital. Very rapid development of septicaemia and septic shock is a

poor prognostic sign; some patients succumb within a few hours of the appearance of the first symptoms.

LABORATORY DIAGNOSIS

Specimens

Cerebrospinal Fluid

Any signs and symptoms suggestive of meningitis should prompt the clinician to consider performing a lumbar puncture without delay. However, this procedure is not an absolute must in all cases of meningococcal disease, and its risks must be weighed against its benefits. In the presence of raised intracranial pressure (ICP), lumbar puncture is associated with fatal cerebral herniation and therefore should not be performed (Mellor, 1992). A mild increase in intracranial pressure is present in virtually all patients with meningococcal meningitis and is not a contraindication for lumbar puncture. However, when clinically evident, it is considered severe enough to prevent lumbar puncture attempts. Even in the presence of markedly increased intracranial pressure, papilloedema may appear late in the process (24–48 h); therefore, more acute signs of raised ICP and incipient cerebral herniation should be looked for: these include severe deterioration in the level of consciousness, bradycardia, abnormal blood pressure, respiratory abnormalities, cranial nerve paralyses (especially 3rd and 6th nerves) and changes in muscle tone or other neurological abnormalities. The role of computerized tomography (CT) scanning to exclude raised ICP prior to lumbar puncture is controversial (Oliver, Shope and Kuhns, 2003). Cerebral herniation is uncommon and may occur without any CT abnormalities; careful clinical examination may be more sensitive in detecting significantly raised ICP. Lumbar puncture should also be avoided in the presence of septicaemic shock, as this may aggravate the circulatory collapse, and it is important to remember that, in cases of meningococcal septicaemia without signs of meningitis, the CSF examination may not reveal any cellular or biochemical abnormality.

In meningitis, depending on white cell counts and bacterial load, the CSF may remain clear or become very cloudy. Two hundred white cells per mm³ (0.2×10^9 cells/l) can make the CSF look turbid. The leucocyte count (predominantly polymorphonuclear cells) can reach as high as 10 000 per mm³, as can the bacterial cell count (not measured routinely). Protein content is raised and may even reach levels as high as 10 g/l, and glucose levels fall below 40% of plasma glucose levels or may even be undetectable. Raised lactate dehydrogenase and neuraminidase levels can also be detected in the CSF of patients with meningococcal meningitis.

Direct microscopy of the CSF deposit often provides the first positive diagnostic clue that can guide the choice of antibiotic. The Gram stain may reveal Gram-negative diplococci in more than two-thirds of the cases presenting with meningitis, provided the patient has not received antibiotics prior to lumbar puncture. Diplococci are seen both inside and outside the pus cells. The serogroup of the causative organism, knowledge of which assists in the management of contacts of the index case, can be obtained without delay by probing the CSF deposit with capsular polysaccharide-specific antibodies conjugated to latex or fluorescein isothiocyanate.

Recovery of the organism from the CSF remains the ultimate diagnostic goal. The organism is often isolated in cases with septicaemia without signs of meningitis; CSF parameters may otherwise be normal. Following the recent awareness campaigns in the UK and the increased awareness of General Practitioners (GPs) of meningococcal disease, many patients will have received antibiotics before they arrive in the hospital. This dramatically reduces the chances of recovering *N. meningitidis* from the CSF.

Blood

Blood cultures may yield the organism in up to 60% of cases if taken before antibiotics are administered. This rate is markedly reduced after the first dose of penicillin. *Neisseria meningitidis* may grow in the conventional (simple) broth culture systems without producing visible turbidity; therefore, in all patients with suspected meningococcal disease, blind subculture (usually after 12–18 h) of the broths onto solid media is strongly recommended. If negative, the procedure may be repeated after 48 h of incubation.

Throat and Nasopharynx

Throat and nasopharyngeal culture may also reveal the organism in more than half of the cases, which can support but not necessarily confirm the diagnosis. With the increasing use of antibiotics prior to admission, these specimens may be the only source where isolates can be obtained. Therefore, it is very important that throat swabs are taken by the GP or the hospital doctor as soon as the disease is suspected irrespective of whether the first dose of penicillin is administered. Swabs must be transported to the laboratory as soon as possible in order to maximize the chances of recovery of the organism.

Skin Lesions

Skin lesions may also yield the causative organism. Petechial lesions can be injected with a small volume of sterile saline and aspirated with a hypodermic needle and inoculated into a broth medium. Alternatively, skin biopsies can be Gram stained and processed for culture immediately. In patients with meningococcal septicaemia, the organisms can be recovered from skin biopsies even after the start of antibiotics (van Deuren *et al.*, 1993).

Isolation of *N. meningitidis*

No effort should be spared to isolate the causative organism and, where possible, all the relevant culture specimens should be taken before antibiotics are administered. Recovery and identification of the organism is important for clinical and epidemiological reasons. Isolation of the organisms will confirm the diagnosis, influence the choice of antibiotics, provide useful epidemiological information and boost the confidence of the clinicians in managing meningococcal disease. Meningococci can be isolated from a number of possible sources, including the CSF, blood, throat or nasopharyngeal swabs, skin lesions, joint aspirates, eye swabs, or any other body fluid or tissue specimens.

Identification

Isolates must be identified to species level in the local laboratory and further classified in a reference laboratory. Meningococci must be differentiated from other oxidase-positive, Gram-negative diplococci using biochemical and immunological tests (Barrow and Feltham, 1993). The rapid carbohydrate utilization test, although largely superseded by more convenient tests in many countries, provides fast and reliable means of identification. In this test a heavy bacterial inoculum is suspended in broth containing individual sugars; meningococci will ferment glucose and maltose (but not lactose and sucrose) within an hour or so. γ -Glutamyl aminopeptidase activity can be detected in rapid tests, such as Gonocheck-II (EY Laboratories, Inc., San Mateo, California, USA) where adding meningococcal colonies to the rehydrated substrates will produce a yellow reaction. Isolates from the nasopharynx, throat, conjunctivae, rectum or other sites where gonococci and respiratory *Neisseriae* can also be carried, must be precisely

identified. Co-agglutination tests (e.g., Phadebact Monoclonal GC Test, Launch Diagnostics Ltd, Kent, England), using specific anti-gonococcal antibodies conjugated to protein A of non-viable staphylococci, will identify or exclude gonococci but not meningococci.

The serogroup of the organism is identified by detecting the capsular polysaccharide antigen using immunological tests including latex agglutination, coagglutination and counter-immunoelectrophoresis.

It is important to remember that there is always a potential risk of acquiring meningococcal infection through handling live organisms while performing biochemical or antibiotic sensitivity tests. Therefore, any work with live cultures of *N. meningitidis* should be performed in a class 1 safety cabinet.

Detection of Meningococcal Antigens, Antibodies and DNA

In culture-negative CSF, presumptive diagnosis can be obtained by detecting very low levels of meningococcal antigens using various immunological and biochemical techniques. Using specific antibodies, the capsular polysaccharide antigens of serogroups A, C, W135 and Y can be reliably identified in the CSF of more than three quarters of cases. This test is not reliable for serogroup B due to the capsule's poor immunogenicity and its cross-reaction with the capsule of *E. coli* serotype K1, which is another common cause of meningitis in young infants.

High titres of specific anti-meningococcal antibodies in a single specimen of serum, or rising titres in paired sera, can also provide laboratory confirmation of suspected cases when other methodologies prove negative (Clarke *et al.*, 2002). Antibodies are detected by enzyme-linked immunosorbent assay with crude preparations of outer membrane vesicles as antigens (Jones and Kaczmarek, 1995).

Meningococcal DNA can be detected in the CSF and whole blood (collected in bottles with EDTA) during the acute stage of the disease, even after the start of antibiotic therapy. Diagnostic polymerase chain reaction (PCR) tests are now widely used in reference laboratories in most developed countries. In UK, quantitative PCR has demonstrated a direct correlation between bacterial load on admission and disease severity (Hackett *et al.*, 2002a; Hackett *et al.*, 2002b). An increasing proportion of meningococcal cases are now confirmed on the basis of a positive PCR test alone. In the absence of an isolate, PCR can also be used to determine the capsular group, PorB type and PorA subtype of the infecting organism.

Other Investigations

Peripheral white cell count varies from subnormal levels to over 45×10^9 cells/l. In patients presenting with skin rash and septicaemia, clotting parameters must be monitored. In these cases, prothrombin and activated partial thromboplastin time are usually prolonged. Diminished plasma fibrinogen and increased fibrinogen degradation product titre are detected.

Poor prognostic peripheral blood parameters include low white blood cell count ($<10 \times 10^9$ cells/l), thrombocytopenia, grossly abnormal coagulation indices (Algren *et al.*, 1993) and raised serum creatinine.

MANAGEMENT

In the pre-antibiotic era, particularly following the great success of the use of anti-diphtheria antiserum in treating cases of diphtheria, therapeutic administration of immune sera became fashionable for a number of infectious diseases, including meningococcal meningitis. Good results were obtained with anti-meningococcal antisera administered intrathecally, intracisternally or intravenously with clear reduction in mortality rates (Flexner, 1913). The first use of anti-

biotics was in the latter part of 1935, following the discovery of the sulphonamides, which were then replaced by penicillin in the following decade. For the past six decades, penicillin has remained the mainstay of specific anti-meningococcal treatment.

Chemotherapy

The choice of antibiotic treatment varies depending on a number of interrelated factors including those relating to the patient, organism, pharmacokinetics of the antibiotics (CSF penetration), circumstances, epidemiological data, affordability and hospital facilities. The standard approach, particularly in meningitis, is to empirically cover for most of the possible causative organisms using relatively broad-spectrum antibiotics until the diagnosis is confirmed and then switch to penicillin.

The Start of Chemotherapy

Treatment should commence as soon as the disease is first suspected. Parenteral penicillin given by the GP before referral to hospital, or by hospital doctors on arrival, has been shown to reduce the mortality rate (Cartwright *et al.*, 1992; Strang and Pugh, 1992). GPs are recommended to give benzylpenicillin (1.2 g for adult; 600 mg for a child) intramuscularly or intravenously. It is wise, however, to place an intravenous cannula as soon as possible and obtain a throat or nasopharyngeal swab and two sets of blood cultures, one from each arm, before antibiotics are commenced. Initial antibiotic therapy should not be delayed, pending other investigations such as lumbar puncture or CT scanning.

Empirical Therapy

It is widely recommended now that until positive laboratory identification of the organism is made, the patient must be treated empirically with a broad-spectrum bactericidal antibiotic that is effective against most other possible causes of pyogenic meningitis. Recently, third generation cephalosporins, such as cefotaxime (200 mg/kg/day) or ceftriaxone (100 mg/kg/day), have replaced the conventional penicillin and chloramphenicol combination in the more developed countries (Peltola, Anttila and Renkonen, 1989). Although these cephalosporins do not necessarily improve on morbidity or mortality, they offer the advantage of using a single, relatively non-toxic therapeutic agent which penetrates the CSF extremely well. They are effective against *N. meningitidis*, *S. pneumoniae*, *H. influenzae*, *E. coli* and *Streptococcus agalactiae* (serogroup B streptococci), but not against *Listeria monocytogenes*. Furthermore, chloramphenicol-resistant *H. influenzae* are now widespread, and strains of meningococci with reduced sensitivity to penicillin [minimum inhibitory concentration (MIC) ≥ 0.12 mg/l] have emerged in many countries. The mechanism of resistance does not seem to involve β -lactamase production, rather it is believed to be due to the reduced affinity of penicillin for penicillin-binding protein 2, as a result of changes in the nucleotide sequence of its gene, *penA* (Zhang *et al.*, 1990; Saez-Nieto *et al.*, 1992). Until the mid 1980s no such strains were known, and by the end of the decade nearly half of the strains in Spain showed some degree of insensitivity to penicillin, while remaining fully sensitive to the third generation cephalosporins. The clinical significance of meningococci with reduced sensitivity to penicillin is unclear; few treatment failures have been described, and there is no association with a fatal outcome (Trotter *et al.*, 2002). Nevertheless, the increasing frequency of strains less susceptible to penicillin highlights the need for ongoing surveillance.

Cefuroxime, a second generation cephalosporin, and ceftazidime, another third generation cephalosporin, are also effective in treating meningococcal meningitis. However, these two agents are not

recommended for empirical treatment, especially knowing that ceftazidime is not very effective against *S. pneumoniae*. The major shortcoming of the cephalosporins is that they are not effective against *L. monocytogenes*, although a relatively uncommon cause of meningitis, and they are comparatively expensive. In many underdeveloped countries, where cephalosporins are not affordable, the combination of penicillin and chloramphenicol is still used.

Specific Antibiotic Treatment

Penicillin remains the drug of first choice and is highly effective for penicillin-sensitive strains. The drug's penetration into the CSF is poor in the absence of an inflamed blood-CSF barrier; however, when high and frequent (meningitic) doses of penicillin are given, good therapeutic levels are achieved. Premature infants and neonates are given up to 100 mg/kg daily in two divided doses, infants (1–4 weeks) 150 mg/kg daily in three divided doses, children (1 month to 12 years) 180–300 mg/kg daily in 4–6 divided doses and adults 2.4 g every 4 h. The temptation to reduce the dose upon clinical improvement must be avoided because the CSF penetration of penicillin reduces, as the inflamed blood-CSF barrier recovers.

Meningococci are usually highly sensitive to benzylpenicillin (MIC 0.003–0.06 mg/l). Strains with MIC between 0.12 and 1.0 mg/l are considered of reduced sensitivity, although many of these still respond to therapeutic doses of intravenous penicillin. Meningococci are also highly sensitive to many, but not all, other penicillin derivatives such as ampicillin, amoxycillin and antipseudomonal penicillins (MICs <0.06 mg/l). Phenoxymethylpenicillin (Penicillin V) is not very effective (MIC of 0.25 mg/l), and meningococci are highly resistant to the penicillinase-resistant penicillins, such as methicillin (MIC of ≥ 6.0 mg/l).

All meningococcal strains isolated in 1994 in England and Wales were susceptible to therapeutic doses of penicillin, with 93% of strains showing an MIC of <0.1 mg/l and with the remainder having an MIC of 0.16–0.64 mg/l (Jones and Kaczmarek, 1995). In countries where penicillin-resistant meningococcal strains have not been isolated, the cephalosporins can be replaced with high-dose parenteral benzylpenicillin as soon as the diagnosis is confirmed. However, irrespective of the country and the prevalence of resistant strains, it is safe practice to test for sensitivity of the organism to penicillin before the antibiotics are switched.

In cases of penicillin allergy or organism's penicillin insensitivity, the cephalosporins should be continued, unless history suggests anaphylaxis. Chloramphenicol, which is bactericidal to meningococci and achieves a high concentration in the CSF, is a good alternative to penicillin in the poorer countries. It is given at doses of 100 mg/kg/day (maximum of 4 g/day) or as single long-acting chloramphenicol injections in oil. The latter is as effective as a 5-day parenteral penicillin course for treating meningococcal meningitis. Single injection of chloramphenicol in oil is not as effective against pneumococcal meningitis and, therefore, should not be used for empirical treatment of pyogenic meningitis.

Antibiotic treatment should be given for a total of 7 days (Radetsky, 1990). Five-day courses have also been successful; however, in the presence of acute complications, treatment is usually extended to 10–14 days. It is interesting that it has been clearly demonstrated that, following antibiotic administration, the increased levels of circulating free endotoxin and endotoxin-activated inflammatory mediator systems decline very rapidly (Brandtzaeg, 1995).

Management of Septic Shock

Management of meningococcal septicaemia is a medical emergency and requires intensive care facilities for the first 48 h until the patient is clinically and physiologically stable. Clinical and laboratory signs of septic shock must be recognized immediately, and those with

rapidly progressing disease, rapidly spreading skin rash, increasing tachycardia and tachypnoea, oliguria, low peripheral white blood cell count and signs of DIC require urgent intervention. Hypotension, which may develop late, is not always present on admission, particularly in children, and therefore could be a misleading parameter for impending septic shock (Nadel, Levin and Habibi, 1995). An increasing gap between core and peripheral temperature is a poor prognostic sign suggesting worsening underperfusion.

Hypovolaemia and electrolyte imbalance should be monitored and corrected with fresh frozen plasma or colloid, electrolyte supplements and inotropes as soon as possible. Hypokalaemia, despite acidosis, hypocalcaemia and hypoglycaemia are seen in the early phase of disease and ought to be corrected with care. Dialysis may be necessary, especially if severe oliguria or renal failure is present. It is very important to ensure that a high concentration of oxygen is given in all cases. A child's ventilation can deteriorate very rapidly, and pulmonary oedema and/or respiratory distress syndrome may develop soon after admission. Therefore, all children must be electively ventilated even if no signs of underventilation or respiratory failure are evident (Nadel, Levin and Habibi, 1995). Furthermore, children requiring colloid support of 40–80 ml/kg, or those who are obtunded, should also be electively ventilated. Low doses of heparin are also often given, although this remains controversial. Recent data have supported the use of protein C (or activated protein C) concentrate in patients with septic shock/DIC (Alberio, Lammler and Esmon, 2001). The optimum use and degree of benefit from this therapy remains unclear at present.

Management of Raised Intracranial Pressure

Attempts to correct raised intracranial pressure, if present, are made only after systemic shock is brought under control. In severe meningitis, extensive measures may be needed to reduce intracranial pressure. Electrolyte imbalance, hypovolaemia and cardiac output must be corrected. While colloids are administered to correct the hypovolaemia, subsequent crystalloids are restricted. Other measures such as hyperventilation (maintaining pCO₂ between 3.5 and 4.5 kPa) and careful use of mannitol are also important. Patients must be managed in an intensive care unit and nursed in a quiet room with the head slightly raised above the rest of the body.

The Use of Corticosteroids in Meningitis

Dexamethasone reduces the severity of neurological complications in bacterial meningitis (regardless of the aetiological agent) and is now recommended for both adults and children with suspected meningitis (van de Beek *et al.*, 2003). Treatment should commence with, or a few minutes before, the initiation of antibiotic therapy. Recommended regimens are 10 mg 6-hourly for 4 days (de Gans and van de Beek, 2002) in adults and 0.4 mg/kg 12-hourly for 2 days in children (El Bashir, Laundry and Booy, 2003).

Other Measures

Supportive measures are required to correct any other organ dysfunction and/or other complications. Monitoring cardiac output using echocardiogram is useful. There are a number of potentially therapeutic agents under investigation that may be useful in correcting the pathophysiology of the disease. One of the most promising of these is recombinant amino-terminal fragment of bactericidal/permeability protein (rBPI21). This naturally occurring antimicrobial protein, which is found in neutrophil granules, binds to and neutralizes the effects of endotoxin. In a phase III trial, rBPI21 reduced the incidence of complications from meningococcal disease (Levin *et al.*, 2000).

PREVENTION AND CONTROL

Control of meningococcal outbreaks consists of a number of interrelated measures which include management of individual cases, notification of known and suspected cases, chemoprophylaxis to close contacts, good clinical surveillance, small- or large-scale vaccination and information dissemination. Concerted efforts are required among the hospital physician, the microbiologist, the public health specialist and the GP to prevent secondary cases and control fear and anxiety among case contacts.

In all cases of suspected meningococcal diseases, attempts should be made to obtain positive culture from CSF, blood, throat swab or any other appropriate specimens while the patient is in the hospital, or retrospectively by sending paired sera or other clinical materials for the detection of antigen, antibody or DNA to a reference laboratory. All meningococcal isolates should be sent to such a reference laboratory for a full identification of individual strains. While in the hospital, patients should be isolated for the first 24 h following antibiotic administration. The risk of acquiring disease from patients is minimal in the ward but is greater in the laboratory, particularly for those who handle live cultures (see section on Laboratory Diagnosis).

Notification of all strongly suspected and proven cases of meningococcal disease to the appropriate public health authorities at the earliest opportunity is essential so that close contacts of the index case are identified. Detailed information is needed on full clinical and epidemiological aspects of these cases. In many countries the disease is notifiable by law, and as soon as an outbreak is recognized, an active surveillance must follow. Outbreaks are identified when two or more meningococcal cases are associated in time, place and identity of the meningococcal isolates. Outbreaks can occur within individual families, communities or institutions.

Contacts of the index case are approximately a 1000 times more at risk of developing disease than the rest of the community and are therefore given prophylactic antibiotics to eradicate possible carriage. Close contacts include household and kissing contacts that have been exposed to the index case over the previous 10 days (incubation period is 2–10 days) and also include infants and young children in play groups and nurseries. Nasopharyngeal culture of close contacts is unnecessary, delays antibiotic administration and may have undesirable social implications. It is important to adequately inform close contacts about the disease and the need for compliance with prophylaxis. They must receive clear instructions to seek medical advice immediately, should they develop any signs or symptoms of meningococcal disease. It is interesting that nearly one-third of immediate family contacts of patients carry an organism, which in 90% of cases has the same identity as that of the index strain.

Chemoprophylaxis

Between the 1940s and the 1960s, sulphonamides were the mainstay of treatment and eradication of carriage. However, sulphonamide-resistant strains (MICs ≥ 10 mg/l) are now prevalent worldwide. Whereas resistance to rifampicin (MIC ≥ 5 mg/l) is much less common and resistance to ciprofloxacin (MIC < 0.02 mg/l) is extremely rare. A 2-day course of 12-hourly oral rifampicin (600 mg in adults, 10 mg/kg in children and 5 mg/kg in infants) is highly effective in up to 95% of cases. However, failure due to lack of compliance, drug resistance or recurrence is known. Rifampicin should not be used during pregnancy and in patients suffering from liver diseases. Also, the drug is expensive, causes discolouration of body fluids and soft contact lenses and interferes with the function of the oral contraceptive pill. Alternatives are single doses of ciprofloxacin (500 mg orally; not in young children) and ceftriaxone (250–500 mg intramuscularly, 125 mg in children under the age of 12 years). The latter, which has been shown to be more effective than rifampicin (Schwartz *et al.*, 1988), offers the additional advantage of being licensed for use in pregnancy and young children. Minocycline (100 mg orally twice daily for 3 days) is also effective; however, it

should not be given to children and pregnant women because of its vestibular toxicity and its ability to discolour the growing teeth.

Prophylactic antibiotics are given simultaneously to all the identified close contacts as soon as the index case is diagnosed. The throat of the index case is also cleared of organisms by giving these antibiotics before discharge from hospital. Random administration of antibiotics to school contacts, which should be coordinated by the department of public health medicine, is only advised in nursery and play-group settings, but not for older children, unless they are close contacts. Except in exceptional circumstances, infants under the age of 3 months are not given prophylaxis. Finally, close contacts of cases caused by serogroup A or C (or rarely W135 or Y) meningococci may be offered the currently available capsular polysaccharide (or serogroup C conjugate) vaccines. A vaccine against serogroup B is not yet available (see section on Vaccines).

Natural Immunity

Protection has been correlated with the presence of bactericidal antibodies (Frasch, 1983), and various lines of evidence highlight the importance of humoral bactericidal activity in host defence against *N. meningitidis*. For example, the peak incidence of the disease occurs in children under 1 year of age, who, as a group, have few or no bactericidal antibodies. Meningococcal disease is up to 10 000 times more common in terminal complement component-deficient individuals than in normal healthy individuals, with a much higher frequency of second episodes of the illness (Andreoni, Kayhty and Densen, 1993). Passive immunization with antibodies (serum therapy) and active immunization with some capsular polysaccharides (which stimulates antibody response but not T-helper cell response) have been successful in the treatment and prevention of the disease. Further evidence emerged following a study reported by Goldschneider, Gotschlich and Arstenstein (1969) where preimmune sera were obtained from new recruits of the American Armed Forces and examined for susceptibility using serum bactericidal activity and immunofluorescence. Unlike the control group, the majority of those who lacked bactericidal activity against prevalent strains acquired meningococci. Thus, bactericidal assays have become established as the best available test to determine the protective ability of specific antisera raised against polysaccharide vaccine candidates. However, it is not certain to what extent the *in vitro* experimental conditions reflect events occurring *in vivo*, nor whether the above data apply to infections with all serogroups. The data linking bactericidal antibodies with protection relate primarily to the serogroup A and C polysaccharides but have been extended to include bactericidal antibodies against OMPs.

While the great majority of the studies have focused on the role of serum bactericidal activity in the host defence against meningococcal disease, much less attention has been given to the killing of bacteria by phagocytosis, and therefore little is known about the relative importance of phagocyte-mediated killing of meningococci as compared to serum bactericidal activity. Finally, for most antigens, an efficient humoral immune response resulting in the production of antibodies and the generation of memory response requires help from T lymphocytes. However, T cells respond to peptide antigens associated with molecules of the major histocompatibility complex (HLA in humans) and so will not be stimulated by polysaccharide vaccines. This may explain why the protective efficacy of these vaccines is short lived and ineffective in young children. A way to overcome this problem is to conjugate the polysaccharide containing B-cell epitopes to carrier proteins containing epitopes for recognition by T cells. This may be achieved by using proteins containing T-cell epitopes as carriers in conjugate vaccines.

Ideal Vaccines

An ideal meningococcal vaccine should be safe, offer long-lasting immunity to all age groups, cross-protect against all meningococcal serogroups and serotypes, be given orally or nasally and be easily

incorporated into the World Health Organization's Expanded Programme on Immunization. So far no such vaccine has been developed. Nevertheless, there are vaccines available against four out of 13 serogroups of meningococci. These are based on the native capsular polysaccharide of serogroups A, C, Y and W135. However, these unconjugated polysaccharide vaccines offer only a relatively short-lived immunity against their homologous serogroups, and they do not affect carriage rates or interrupt transmission of infection within a community. Furthermore, they offer little protection to children under the age of 2 years, the most vulnerable age group, and hence they are not suitable for including in paediatric immunization programmes. No polysaccharide vaccine yet exists against serogroup B meningococcal disease, and this is seen as a major obstacle to the wider use of meningococcal vaccines in Europe and American continents.

Serogroup A and C Capsular Polysaccharide

The first successful vaccines produced were against serogroup A and C *N. meningitidis* using high-molecular-weight (>100kDa) capsular polysaccharide from these strains (Gotschlich, Liu and Artenstein, 1969). A series of large-scale field trials were conducted in the 1970s among different age groups in different parts of the world, including Europe, Africa and South America, which showed that the capsular polysaccharide vaccine is effective in controlling epidemics of serogroup A disease in almost all age groups. It soon became clear that antibody responses among infants to the serogroup A and C capsular polysaccharide vaccines depended on a number of factors including the age of the infant, the molecular weight of the antigen, the number of doses of antigen and the prior experience of the infant with naturally occurring antigens cross-reactive with the meningococcal capsular polysaccharide. It became evident that children under the age of 2 years do respond, particularly to serogroup A capsular polysaccharide, with small increases in specific antibodies. The strength of the response and its duration increased with age, and in adults 100% seroconversion was achieved which lasted longer than it would be in children. For example, Reingold *et al.* showed that the serogroup A capsular polysaccharide vaccine efficacy in children vaccinated at less than 4 years of age almost disappeared over the following 3 years, whereas those who were 4 years of age or older when vaccinated showed evidence of vaccine-induced clinical protection for 3 years after vaccination (Reingold *et al.*, 1985).

The serogroup C capsular polysaccharide vaccine, when administered routinely among recruits of the United States army to prevent severe outbreaks, has virtually eradicated the serogroup C meningococcal disease in this population. Subsequent trials and antibody response studies among children confirmed this success among age groups above 2 years but not among children less than 2 years of age. It is interesting from more recent data to show that although anticapsular antibodies and bactericidal activity in adults decline substantially by 2 years following vaccination, both persist at a level significantly above prevaccination levels for up to 10 years (Zangwill *et al.*, 1994).

On the basis of these results, serogroup C capsular polysaccharide vaccines were, until recently, recommended for general use in epidemics except for children under the age of 18 months. In contrast, serogroup A capsular polysaccharide vaccines were recommended to be given during epidemics in all age groups including infants with a booster dose given to those under the age of 18 months. These vaccines were also offered to those who are at increased risk of meningococcal disease, including those with late complement component deficiencies and those with functional or anatomical asplenia. Military recruits in the UK and USA and all would-be Hajj pilgrims were also offered the vaccines. Following recent Hajj-related outbreaks of serogroup W135 meningococci, a certificate of vaccination against serogroups A, C, Y and W135 meningococci is a visa requirement for all pilgrims travelling on the Hajj. It is important that, due to significant shortcomings, these capsular polysaccharide vaccines were not useful for routine immunization of infants.

Glycoconjugate Serogroup A and C Vaccines

The success of linking Hib capsular polysaccharide to a protein carrier which results in a vaccine which induces a thymus-dependent (T-cell dependent) IgG response in young children, and thus immunological memory, encouraged the development of capsular polysaccharide-protein conjugate vaccines for serogroups A and C meningococci. Purified capsular polysaccharides have been conjugated to either tetanus toxoid or to non-toxic cross-reacting mutant of diphtheria toxin (CRM197) and shown to be safe and immunogenic (inducing a memory response) in clinical trials.

The UK was the first country to use meningococcal serogroup C conjugate (MCC) vaccines which were licensed on the basis of immunogenicity and safety data but without a formal efficacy study. It is now increasingly clear that the vaccine is protective in all age groups, including children under the age of 2 years. Meningococcal serogroup C conjugate vaccines were introduced into the UK childhood vaccination programme in late 1999 and scheduled for all under the age of 18 years (Miller, Salisbury and Ramsay, 2001). In 2002, these vaccines were also made available to those aged 20–24 years. Preliminary estimates of efficacy suggest that the vaccine is 88–96% effective against invasive serogroup C meningococcal disease. Occasional, unexplained vaccine failures have been documented in all age groups. More recently, a multicentre collaborative study showed that the MCC vaccine protects against carriage of Group C meningococci (Maiden, Stuart and the UK Meningococcal Carriage Group, 2002).

The success of the MCC vaccines, and the imminent development of similar conjugate vaccines against serogroup A, W135 and Y meningococcal disease, heralds the prospect of effective vaccine prevention of virtually all non-serogroup B invasive meningococcal disease.

Vaccines Against Serogroup B Disease

Serogroup B Capsular Polysaccharide

Serogroup B meningococcal capsular polysaccharide consists of repeated residues of α -(2–8)-linked oligomers of sialic acid which serves as an important virulence factor and protective cell component for the organism. Candidate vaccines based on the native serogroup B polysaccharide induce a transient antibody response of predominantly IgM isotype. This poor immunogenicity of the serogroup B capsular polysaccharide could be due to sensitivity to neuraminidases or immunotolerance of the host due to its similarity to sialic acid moieties in human brain tissues (Finne *et al.*, 1987), which has caused considerable concern regarding the possible induction in humans of adverse autoimmune consequences by administration of serogroup B capsular polysaccharide-based vaccines. Nevertheless, attempts are on going to produce a capsular polysaccharide-based serogroup B vaccine. Attempts have been made to generate anticapsular bactericidal antibodies using mimotopes or using a modified B polysaccharide in which the *N*-acetyl groups at position C-5 of the sialic acid residues are replaced with *N*-propionyl groups. The latter has been conjugated to either tetanus toxoid or to recombinant meningococcal PorB and subjected to extensive preclinical trials (Fusco *et al.*, 1998).

OMPs

In view of the problem associated with the poor immunogenicity of serogroup B capsular polysaccharide, much of the attention has focused on non-capsular antigens, including constitutively expressed and iron-regulated OMPs. It is important to know that recurrence of meningococcal disease is extremely rare in the absence of immunodeficiencies, irrespective of the serogroup of the infecting strain. This indicates that non-capsular antigens can generate long-lasting cross-protective immunity.

Outer Membrane Vesicles

In the past decade, a number of serogroup B meningococcal vaccines based on outer membrane vesicles (some enriched with PorA and PorB) were developed and tested in clinical trials (Bjune *et al.*, 1991; Sierra *et al.*, 1991; Zollinger *et al.*, 1991). Following large-scale placebo-controlled, randomized double-blind trials, only the vaccines produced in Norway and Cuba showed significant protective efficacy. The Norwegian vaccine consisted of OMPs from the Norwegian epidemic strain of *N. meningitidis* (B:15:P1.7.16) and was given to children aged 14–16 years. It produced a point estimate of protective efficacy of 57% after a 30-month follow-up and therefore was considered insufficiently effective for general use (Bjune *et al.*, 1991). The Cuban vaccine consisted of serogroup C capsular polysaccharide mixed with OMPs from a Cuban epidemic strain (B:4:P1.15). When given to children aged 10–16 years, it offered an estimated point efficacy of 83% after 16 months of follow-up (Sierra *et al.*, 1991), and as a result, the vaccine is now incorporated into the routine childhood vaccination programme in Cuba. Although the Cuban trial did not directly address efficacy in children aged less than 10 years, follow-up studies of the mass vaccination have suggested that the overall protective efficacy based on vaccine coverage and incidence of disease in children under 6 years of age is about 93% (Sierra *et al.*, 1991). However, when the Cuban vaccine was tested in a case-control study in Brazil, protective efficacy was reported to vary with age. The vaccine was effective in children aged 4 years and older, but not in younger children (de Moraes *et al.*, 1992). Comparative clinical trials between the Norwegian and Cuban vaccine preparations were later conducted in Iceland and Chile in order to resolve the discrepancies. In these comparative trials the immunogenicity of the two vaccines were thought to be comparable, but the details have not yet been formally published.

It is interesting that PorA and PorB attracted a lot of attention in the 1980s and early 1990s. These proteins show considerable interstrain antigenic variation, hence their use as a basis for the serotyping and subtyping scheme for characterizing strains of *N. meningitidis*. However, they are still considered attractive candidate vaccine antigens because within a particular epidemiological setting the majority of strains causing disease belong to only a limited number of types and subtypes. An obvious drawback of vaccines based entirely on serotype and serosubtype antigens is the fact that the predominant types and subtypes associated with disease in any one area change from time to time. In an attempt to overcome the antigenic variability of PorA, outer membrane vesicle vaccines have been produced which are enriched with a mixture of several (e.g. six; hexavalent) recombinant PorA antigens obtained from prevalent meningococcal serosubtypes. Clinical trials using a hexavalent PorA-based outer membrane vesicle vaccine were largely disappointing. Apart from poor immunogenicity among infants, the vaccine induced strain-specific bactericidal activity and therefore would fail to protect against antigenically diverse meningococci (van der Voort *et al.*, 1997).

Other Approaches

Since the completion of the meningococcal genome sequence project, work on meningococcal vaccines has taken a giant leap forward. Several novel approaches have been pursued, and vaccine development has entered a new energetic race. Pizza *et al.* (2000) screened the entire genome sequence of a serogroup B meningococcal strain *in silico* and identified hundreds of putative genes coding for possible target antigens. They cloned and expressed 350 of these candidate antigens in *E. coli* and examined them for their ability to generate bactericidal antibodies in mice. They then focused on detailed characterization and vaccine assessment of seven of these antigens.

Another approach was to screen expression libraries of meningococcal genomes with human T-helper cells or antibodies and identify T-cell- and B-cell-stimulating antigens. This approach has also identified a number of potentially immunogenic vaccine candidates that are important virulence and/or survival factors in the organism. Of these antigens, some

are membrane-bound T-cell immunogens, including TspA (Kizil *et al.*, 1999). Others are surface-exposed or partially secreted proteins, including AutA, App and AspA (Ait-Tahar *et al.*, 2000; Abdel-Hadi *et al.*, 2001; Turner, Wooldridge and Ala'Aldeen, 2002).

Other studies focusing on lipooligosaccharides or their mimotopes are also underway. Given the increased interest in meningococcal vaccines and significant investment by the pharmaceutical industry, there is a great deal of optimism that we may see a series of interesting vaccine trials in the near future, culminating in the development of a protective vaccine against serogroup B meningococcal disease.

Neisseria gonorrhoeae

Catherine A. Ison

*Sexually Transmitted Bacteria Reference Laboratory, Centre for Infection,
Health Protection Agency, Colindale, London, UK*

DESCRIPTION OF THE ORGANISM

Neisseria gonorrhoeae belongs to the genus *Neisseria* and is an obligate human pathogen with no other natural host. *Neisseria gonorrhoeae* is sexually transmitted, primarily causing infection of the anogenital tract and is always considered a pathogen. This contrasts with *Neisseria meningitidis*, the only other species of the genus considered a primary pathogen, which colonises the upper respiratory tract as a commensal and occasionally invades to cause systemic disease. The other species of *Neisseria*, such as *Neisseria lactamica*, *Neisseria cinerea* and *Moraxella catarrhalis*, are generally considered commensals but have been implicated as causes of infection in immunocompromised patients.

Neisseria spp. are oxidase positive, Gram-negative cocci. The clinically important species *N. gonorrhoeae*, *N. meningitidis*, *N. lactamica*, *N. cinerea* and *M. catarrhalis* are relatively easy to distinguish from the non-pathogenic *Neisseria*. However, differentiation between the non-pathogenic species is more complex, and as a consequence, the taxonomy has been controversial (Knapp, 1988). *Neisseria* has a typical Gram-negative cell envelope, which consists of a cytoplasmic membrane, a thin layer of peptidoglycan and an outer membrane. Many of the major antigens of the cell envelope are shared between *N. gonorrhoeae* and *N. meningitidis* (Table 15.1), with the exception of the capsule which

is never expressed by *N. gonorrhoeae* but when expressed by *N. meningitidis* enhances survival in blood.

PATHOGENESIS

Attachment and Invasion

Neisseria gonorrhoeae colonises mucosal surfaces primarily of the lower genital tract and occasionally ascends to the upper genital tract or invades and colonises the blood. For infection to occur, the organism must adhere to the epithelium, enter or invade the host cells, acquire sufficient nutrients from the host to survive and evade the host's immune response. Infection with *N. gonorrhoeae* stimulates an inflammatory response, resulting in a massive infiltration of polymorphs.

If *N. gonorrhoeae* is to attach successfully to the epithelium, it must avoid being swept away by cervical secretions in women and urine in men. In addition, both the bacterial and epithelial cells are negatively charged and, therefore, would naturally repel. Pili, which are hydrophobic surface appendages, are the primary mediators of attachment, firstly, overcoming the electrostatic forces between the bacterial and host cell and then by attachment to the mucosal surface by specific receptors. *Neisseria gonorrhoeae* produces type VI pili that have multiple functions including adhesion and genetic transfer such as transformation (Merz and So, 2000). The host cell receptor for neisserial pili has been identified as CD46, a member of the complement resistance proteins (Kallstrom *et al.*, 1997). Secondary attachment is mediated mainly by the Opa proteins, but lipooligosaccharide (LOS) and the gonococcal porin Por have also been implicated in adhesion to the cell surface.

Opa proteins are a family of phase-variable proteins that confer a tight attachment to the epithelial cell, recognising one of two classes of cellular receptors, the heparan sulphate proteoglycans and distinct carcinoembryonic antigens (CD66), initiating invasion through the epithelial cell (Naumann, Rudel and Meyer, 1999; Hauck and Meyer, 2003). LOS has been described as binding to asialoglycoprotein receptors on the cell surface to aid attachment (Porat *et al.*, 1995) and as having a potential role in invasion (Song *et al.*, 2000). The gonococcal porin, Por, which functions as a channel for essential nutrients, is also associated with increased bacterial invasion (Massari *et al.*, 2003) and transcytosis. Invasion of the epithelial cell follows attachment, which is mediated by Opa proteins and other outer membrane components, through multiple mechanisms, and then the gonococci travel through the epithelial cell by transcytosis to establish colonisation in the subepithelial layer.

Table 15.1 Cell envelope antigens of *Neisseria gonorrhoeae* and their equivalent in *Neisseria meningitidis*

<i>N. gonorrhoeae</i>	<i>N. meningitidis</i>	Description	Function
Por	Class 1 (Por A)	Major (Outer membrane protein) OMP	Porin/Transcytosis
	Class 2/3 (Por B)	Major OMP	Porin/Transcytosis
Rmp	Class 4	Reduction-modified protein	Site for blocking antibody
Opa	Class 5	Family of heat-modifiable proteins	Attachment/Invasion
Pilin	Class 1 pilin	Pilin	Attachment
LOS	LOS	Lipooligosaccharide	Toxic to epithelial cells
Fbp/Frp	Fbp/Frp	Iron binding/restricted protein	Iron acquisition
Tbp A and B	Tbp A and B	Transferrin-binding protein	Iron acquisition

Infection of the epithelial cells induces cytokines, including tumour necrosis factor- α , that initiate an inflammatory response or may lead to the induction of apoptosis and loss of epithelial cells and give the bacterium access to the bloodstream.

There is no animal model for gonorrhoea; therefore, the process of colonisation has been worked out using *ex vivo* models particularly organ culture. These showed that the gonococci adhere to the microvilli of non-ciliated cells and, by producing blebs, cause damage to ciliated cells (McGee *et al.*, 1983; Harvey *et al.*, 1997). A simple model where pili initiate the primary attachment followed by invasion mediated by Opa proteins and transcytosis by Por is probably too simplistic. The interaction of the bacterium and the host cell is more complex, and it is likely that multiple mechanisms play a part in the infection process (Nassif *et al.*, 1999).

Iron Acquisition

Once colonisation has been established, *N. gonorrhoeae* needs to acquire iron to survive. Unlike other organisms that produce siderophores to chelate iron from the environment, *N. gonorrhoeae* has evolved mechanisms to acquire iron directly from human transferrin and lactoferrin (Alcorn and Cohen, 1994). It is postulated that, in the absence of sufficient iron, transcription of transferrin and lactoferrin receptors and transferring-binding proteins is induced in the organism. These receptors interact with human transferrin and lactoferrin, and iron is removed and transported across the bacterial cell membrane into the periplasmic space. During this process, there is a transient association with iron-binding proteins, and then, iron is transported across the cytoplasmic membrane. Other essential nutrients are transported through the porin, which is a polymer of the outer membrane proteins Por and Rmp.

Immune Response

On successful colonisation, the organism elicits an inflammatory and antibody response in the host (Brooks and Lammel, 1989). *Neisseria gonorrhoeae* is known to be ingested by macrophages, and this may be a primary mechanism by which the host eradicates infection. However, evidence that the phagocytosed organisms are killed is inconclusive. Sialylation of LOS (Parsons *et al.*, 1988) and the expression of the Opa proteins have been shown *in vitro* to enhance the ability of the organism to resist phagocytic killing. Antibody to *N. gonorrhoeae*, both immunoglobulin G (IgG) and IgA, is produced in response to infection, both in serum and in local secretions. The function of antibody produced in response to *N. gonorrhoeae* is not known. Systemic antibody may activate the complement pathway and play a role in limiting disseminated infection. However, it is not known whether complement-mediated lysis occurs in mucosal secretions. Antibody in secretions may inhibit attachment or phagocytosis, although there is little evidence that it affords protection against subsequent infection.

Genetic Variation

The ability of *N. gonorrhoeae* to cause repeated infection has been attributed to its ability to exhibit both phase and antigenic variation, by each new infection appearing novel. In phase variation, the control of expression is on or off, whereas in antigenic variation there is a change in the primary sequence, resulting in the expression of a different epitope on the same protein.

Proteins expressed on the cell surface of *N. gonorrhoeae*, such as Pili, Opa proteins and LOS, are genetically variable. In pili, antigenic variation occurs by intragenic recombination between the silent loci (pilS), which are normally not expressed, donating sequences to the pilin expression locus (pilE). The source of the donor sequences may be from within the same bacterial cell, but gonococci may naturally

take up species-related DNA released by spontaneous cell lysis, and hence the source may be exogenous. The result of this recombination is that non-functional pili may be produced, resulting in phase variation where expression is switched off. Expression of different antigenic variants of pili is thought to vary the functional activity of the protein, such as adhesion to different host cells (Robertson and Meyer, 1992).

Opa proteins are a family of proteins, encoded by 11 genes, of which zero to multiple forms may be expressed in any clinical isolate. Opa genes include 5' repeats of CTCTT, which are found in each gene and encode the hydrophobic core of the leader peptide. The number of these repeats determines the translational frame of the gene, and if the number of repeats is out of frame, the gene will be switched off and hence controls phase variation (Stern *et al.*, 1986). Antigenic variants may occur through homologous recombination in a similar manner to pili.

The ability of the gonococcus to control and change expression of its major outer membrane antigens enables the organism to appear novel to the host. This plays an important role in pathogenesis. It acts to prolong infections, prevent immunity to reinfection and to change the functional properties of the organism.

EPIDEMIOLOGY

The epidemiology of gonorrhoea has been influenced in the last two decades by two factors: the advent of acquired immunodeficiency syndrome (AIDS) and the development of resistance to first-line therapies such as penicillin and, more recently, ciprofloxacin.

In developing countries, the incidence of gonorrhoea is largely unknown but is considerably greater than that in industrialised countries. The global total of new cases among adults in 1999 was estimated at 62 million by the World Health Organization. There was an estimate of 17 million cases in sub-Saharan Africa and 7.5 million cases in Latin America and The Caribbean compared with 1 million in Western Europe and 1.5 million in North America. The continuing high prevalence results from the numbers of antibiotic-resistant strains circulating and from the lack of resources for effective antibiotics and/or laboratory facilities to aid the diagnosis.

In many industrialised countries, after the advent of AIDS in 1984, there was a decline in the number of cases of gonorrhoea, as well as syphilis. For example, in England and Wales, reported cases of gonorrhoea fell from approximately 50 000 before 1984 to 10 216 infections reported in 1994 (PHLS *et al.*, 2002). The decrease has been attributed to changes in sexual behaviour as a result of education campaigns and fear of a fatal disease and occurred in most groups but was most evident in men who have sex with men (MSM). It is likely that a contribution to this decline was made by good diagnostic tests, effective therapy and good contact tracing. Since 1994, there have been small but sustained increases in gonorrhoea, such that in England and Wales, the number of cases has more than doubled to 24 958 in 2002 (Health Protection Agency *et al.*, 2003). This increase which has been noted for the other bacterial sexually transmitted infections (STIs), syphilis and chlamydial infection, has been explained by a return to unsafe sexual practices, particularly failure to use condoms. This may be true now that AIDS is perceived as a treatable infection, but the ability of the organism to adapt to changes or to interventions with antimicrobial agents may play an important role.

In contrast to chlamydial infection, gonorrhoea is not evenly distributed amongst the population, with the highest rates seen in inner cities and in certain subgroups of the population such as homosexual or bisexual men, young people and ethnic minorities. This may reflect differences in sexual behaviour but may also be due to inequalities in socioeconomic status and access to health care. The greatest burden of infection is usually in young people. In England and Wales, the peak of infection is found among women aged 16–19 years of age and in men of 20–24 years of age. A greater number of men are diagnosed with gonorrhoea than women, although this will be influenced by the high percentage of symptomatic cases in men who will seek care compared to the

predominantly asymptomatic and hence undetected infection in women. The ability of the organism to cause infection on a single sexual contact (transmission rate) is unknown but is thought to be greater from infected male to uninfected female (50–60%) than from infected female to uninfected male (35%).

CLINICAL FEATURES

Neisseria gonorrhoeae is primarily an infection of mucosal surfaces (reviewed in Ison and Martin, 2003). Uncomplicated gonococcal infection (UGI) occurs when *N. gonorrhoeae* colonises the columnar epithelium of the cervix, urethra, rectum or pharynx. The cervix is the primary site in women and the urethra in men. Colonisation of the mucosa often stimulates an inflammatory response, resulting in a purulent discharge. In a minority of cases, infection spreads from the lower genital tract to the upper genital tract, which is normally sterile, causing complicated gonococcal infection, which presents as pelvic inflammatory disease (PID) or salpingitis in women and prostatitis or epididymitis in men. Disseminated gonococcal infection (DGI) where *N. gonorrhoeae* invades and colonises the blood after a primary mucosal infection is only rarely encountered. Unlike complicated infection, DGI does not result from untreated or multiple infections but is a distinct entity.

Uncomplicated infection in men usually presents as urethritis, often with dysuria. The discharge is the most common symptom and ranges from scant to copious and purulent. In women, endocervical infection is predominant, resulting in increased secretions, manifesting as a vaginal discharge. Asymptomatic infection does occur in a minority of men (usually <10%) but is more common in women. Over 50% of cases of gonorrhoea in women are asymptomatic and are usually detected by tracing contacts of infected men. Rectal gonorrhoea occurs in homosexual men practising anal intercourse and may result in symptoms that range from mild discomfort to discharge and bleeding. In women, urethral and rectal infection are often the result of contamination with vaginal discharge and only occasionally the result of true colonisation. Pharyngeal infection occurs in patients practising oral intercourse, and there is no evidence that colonisation relates to the presence of a sore throat or tonsillitis.

Complicated gonococcal infection in men is rare because most mucosal infection is symptomatic and usually receives adequate therapy. In women, where infection is often asymptomatic, the organisms ascend from the cervical canal to the fallopian tubes and subsequently to the pelvic cavity, causing pelvic pain and tenderness. These symptoms may also be caused by other STIs, such as chlamydiae, as well as by organisms found as part of the normal vaginal flora. PID caused by *N. gonorrhoeae* is uncommon in industrialised countries but is often found in developing countries where treatment and health care are often inadequate. Infertility may result from PID, and the incidence increases with sequential episodes of infection.

DGI may present as a low-grade fever, followed by a rash and arthritis. DGI is more common in women and in patients with a deficiency in the late components of the complement pathway. It has also been linked to certain nutritional variants of *N. gonorrhoeae* that exhibit hypersusceptibility to penicillin. The interplay between the host and the organism that leads to the dissemination of the infection is not understood. In the 1970s, many cases were reported particularly from Sweden and the west coast of the United States. However, in recent years, it has become increasingly less common (Ison and Martin, 2003).

LABORATORY DIAGNOSIS

The rapid and accurate detection of any STI is crucial to allow suitable therapy to be given and for transmission to be prevented. In an ideal situation, this is achieved on the first occasion the patient attends for

care. Historically, microscopy has been used for the presumptive diagnosis, and this is widely used in most parts of the world, even where resources for laboratory diagnosis are poor. In most countries, where laboratory facilities are available, it is normal practice to confirm the diagnosis of gonorrhoea by isolation and identification of *N. gonorrhoeae*. Detection using molecular methods has not been used as widely as for chlamydial infection, largely because existing methods have been considered satisfactory and less expensive. However, the use of nucleic acid amplification tests (NAATs) for chlamydia has highlighted the potential use of a combined approach to both chlamydial and gonococcal infection and the advantage of using non-invasive specimens.

Presumptive Diagnosis

Historically, the presence of intracellular Gram-negative cocci (Figure 15.1) has been used for the presumptive diagnosis of gonorrhoea. In symptomatic men, this has a sensitivity of >95% as compared with culture for *N. gonorrhoeae*. In asymptomatic men and women, the sensitivity is lower (30–50%) (Manavi *et al.*, 2003). This is probably due to reduced numbers of organisms in asymptomatic infection, which are below the detection limit of microscopy. The sensitivity is also low for rectal smears, but this is due to the large numbers of other Gram-negative organisms colonising the rectum. The sensitivity is highest if the specimen is taken through a proctoscope and if pus is seen. This is a quick and inexpensive test that is easily performed in the clinic and has a high specificity when used by experienced personnel.

Isolation

Specimens for the isolation of *N. gonorrhoeae* may be collected from the urethra, cervix, rectum and oropharynx. In heterosexual men, it is usual to take specimens only from the urethra, whereas for homosexual men, rectal and pharyngeal specimens should be taken, depending on the sexual history. In women, it is essential to sample the cervix, but it may also be helpful to take specimens from the urethra and rectum and the pharynx when appropriate.

Specimens are collected with disposable plastic loops or swabs that are made of material that is non-inhibitory to *N. gonorrhoeae*. Direct inoculation of the specimen onto the isolation medium and incubation at 36 °C until transported to the laboratory is preferred by many workers as giving the highest isolation rates. However, there is little evidence that specimens taken with a swab and placed into transport medium such as Stuart's or Amies', stored at 4 °C and sent to the laboratory as soon as possible give lower rates of isolation. The choice of method is often decided by the proximity of the clinic to the laboratory.

Neisseria gonorrhoeae is a fastidious organism that infects sites that, in some instances, are colonised by many other bacteria as part of the normal flora. An enriched medium is required that supplies nutrients such as essential amino acids, glucose and iron. Chocolate horse blood agar was used for many years, but it is now more common to use a medium containing GC agar base that is supplemented with lysed horse blood or a growth supplement such as Kellogg's, IsoVitaleX or Vitox. These are modifications of a medium originally described by Thayer and Martin (1966) that contained GC agar base supplemented with haemoglobin. Antibiotics are often added to the primary isolation medium to suppress the growth of other organisms. The cocktail that is most often preferred consists of vancomycin or lincomycin, which inhibit Gram-positive organisms, colistin and trimethoprim, which inhibit other Gram-negative organisms, and nystatin or amphotericin to prevent overgrowth by yeasts (Table 15.2). Antibiotics added to culture media to aid the selection of *N. gonorrhoeae* may also retard the growth of or inhibit certain gonococcal strains. The use of a combination of non-selective and selective media overcomes this problem, but if resources are limited, then a selective medium is preferable.

Figure 15.1 Gram-stained urethral smear showing intracellular Gram-negative diplococci.

Table 15.2 Selective agents for the isolation of *Neisseria gonorrhoeae*

Selective agent	Concentration used	Organisms inhibited
Vancomycin	2–4 mg/l	Gram-positive organisms
Lincomycin	1 mg/l	Gram-positive organisms
Colistin	7.5 mg/l	Gram-negative organisms (other than <i>Neisseria</i>)
Trimethoprim	5 mg/l	Gram-negative organisms (other than <i>Neisseria</i>)
Nystatin	12 500 IU/l	<i>Candida</i> spp.
Amphotericin	1–1.5 mg/l	<i>Candida</i> spp.

Identification

Identification of *N. gonorrhoeae* may be achieved by using specific reagents that confirm the identity of *N. gonorrhoeae* and eliminate other species of *Neisseria* or by using a battery of tests that will allow speciation into the individual members of the genus. In both

instances, the presence of Gram-negative cocci that are oxidase positive (produce cytochrome *c* oxidase) is used as presumptive identification of *Neisseria* spp. Historically, carbohydrate utilisation tests have been used for identifying *N. gonorrhoeae*, which allows both differentiation from other species and speciation of other *Neisseria*. *Neisseria gonorrhoeae* produces acid from glucose alone, whereas *N. meningitidis* also produces acid from maltose and *N. lactamica* from maltose and lactose (Knapp, 1988) (Table 15.3). Conventional carbohydrate utilisation tests use an agar base that supports the growth of *Neisseria* with added carbohydrate. These media require a heavy inoculum of a pure culture and further incubation for 24 h at 36 °C before a result can be obtained. Interpretation of the colour change may be difficult. The prolonged incubation time has been overcome by the use of liquid media or commercially available kits that require between 1 and 4 h of incubation for a result. However, all these tests should be inoculated with a heavy growth of a pure culture, which normally requires at least one subculture from the primary isolation plate. Despite these disadvantages, carbohydrate utilisation has been considered the definitive means of identifying *N. gonorrhoeae*, particularly for medicolegal purposes.

Table 15.3 Identification tests for the pathogenic *Neisseria* spp.

Organism	Glucose	Acid production from			γ -Glutamyl aminopeptidase	Propyl aminopeptidase	Butyrate esterase
		Maltose	Lactose	Sucrose			
<i>N. gonorrhoeae</i>	+	–	–	–	–	+ ^a	–
<i>N. meningitidis</i>	+	+	–	–	+	v	–
<i>N. lactamica</i>	+	+	+	–	–	–	–
<i>N. cinerea</i>	–	–	–	–	–	NA	–
<i>M. catarrhalis</i>	–	–	–	–	–	–	+

+, positive; –, negative; v, variable result.

^aThere have been reports of negative strains.

In an attempt to provide a more rapid identification of *N. gonorrhoeae* that is obtained direct from the primary isolation medium, specific antibodies to *N. gonorrhoeae* have been utilised that identify *N. gonorrhoeae* and eliminate other species of *Neisseria* but do not provide a full speciation. Monoclonal antibodies raised to specific epitopes on the two types of the major outer membrane proteins, PIA and PIB (Tam *et al.*, 1982), have been linked either to fluorescein (Microtrak *N. gonorrhoeae* Culture Confirmation Test, Trinity Biotech plc) or to staphylococcal protein A (Phadebact Monoclonal GC Test, Boule). The immunofluorescence reagent has the advantage of requiring little growth but the disadvantage that smears must be examined using a fluorescence microscope. The coagglutination reagent does not need any expensive equipment but requires sufficient growth to provide a cloudy suspension that must be boiled before use. Both the reagents have the advantage that they can be performed on non-viable organisms collected direct from the primary isolation medium. These reagents contain a mixture of specific antibodies to give a reagent that reacts with all strains of *N. gonorrhoeae* but that does not react with other species of *Neisseria*. When mixtures of antibodies are used in this manner, rather than a single antibody to a conserved epitope, there will always be the possibility that some strains will not react. Both of these reagents have been shown to be highly sensitive and specific, and any unexpected negatives can be resolved by using biochemical methods. In laboratories requiring only confirmation of *N. gonorrhoeae*, without identification of the other *Neisseria*, these immunological approaches to identification have largely replaced conventional carbohydrate utilisation tests.

Many laboratories prefer to use commercially available kits which are a combination of both carbohydrate utilisation tests and tests to detect preformed enzymes, particularly the aminopeptidases. These tests should be interpreted with caution because of many reports of gonococci that are unusually prolylaminopeptidase negative, which may lead to the misidentification of *N. gonorrhoeae* as other genera Alexander and Isan, 2005. These are useful for laboratories that isolate *N. gonorrhoeae* occasionally and have little experience of alternative methods. However, these kits are designed to differentiate between the species of *Neisseria* but are most accurate for the clinically important species.

Molecular Detection

Previous attempts at antigen detection for *N. gonorrhoeae* used primarily an immunological approach. The gonococcal antigen test that was evaluated most extensively was an enzyme-linked immunosorbent assay (ELISA) Gonozyne (Abbott Laboratories). This test had a high sensitivity and specificity when used with urethral specimens from symptomatic men, but in women, the sensitivity and specificity were lower, offering little advantage over existing tests. The antibodies used in this test showed some cross-reaction with other *Neisseria* spp., resulting in a lower specificity, which is a particular problem in low-prevalence population where the level of false positives produced may be unacceptably high. Detection of *N. gonorrhoeae* in clinical specimens using DNA-based methods has the same advantage of immunological approaches, in that they are highly sensitive, detect small numbers of organisms and detect non-viable organisms, but molecular detection can also be highly specific (Koumans *et al.*, 1998; Van Doornum *et al.*, 2001; Van Dyck *et al.*, 2001).

Molecular detection for *N. gonorrhoeae* has been achieved using DNA probes and amplification of specific sequences. The use of probes in a hybridisation test (Gene Pace 2) has proved highly sensitive and specific when used with genital specimens (Koumans *et al.*, 1998), but because of the lack of amplification they are likely to be less sensitive than using NAATs. The NAAT that has been most widely evaluated in the ligase chain reaction (LCx, Abbott Laboratory), but this test is no longer available. The two tests currently most often used amplify the DNA by the polymerase chain reaction (PCR) (Cobas Amplicor, Roche) or strand displacement (BD Probtect, Becton Dickinson). All these tests have been shown to be highly sensitive and specific for

use with urethral specimens in men and endocervical specimens in women (Van Dyck *et al.*, 2001). In common with detection of chlamydial infection, NAATs for *N. gonorrhoeae* can be used with urine for men (Palladino *et al.*, 1999; Akduman *et al.*, 2002). However, in women, the sensitivity and specificity is highest using self-taken swabs or tampons and urines are less satisfactory (Van Doornum *et al.*, 2001). The specificity of these tests with all specimens is high, but confirmation of a positive test should be considered when a single test is used to screen low-prevalence populations or if there are medicolegal implications.

The use of molecular testing for gonorrhoea has generally not been as widely used as for the detection of chlamydial infection. The emergence of commercial kits that combine the detection of *N. gonorrhoeae* and chlamydia on the same sample, for relatively little extra cost, may encourage their more extensive use. There is also increasing evidence that NAATs may be more sensitive than culture for detecting *N. gonorrhoeae*, particularly for non-invasive samples. It is likely that the increased sensitivity of NAATs indicates that they are affected less by inadequacies in specimen storage and transport than culture. None of these kits are currently licensed for use with non-genital samples, e.g. from the pharynx or the rectum. The detection of *N. gonorrhoeae* in the presence of commensal *Neisseria* in the pharynx or multiple other bacteria in the rectum requires the use of primers to detect sequences totally specific to *N. gonorrhoeae*. This has proved difficult, and if used on these specimens, it is advisable to use two tests that detect different sequences to reduce the number of false positives. However, culture for *N. gonorrhoeae* in the rectum and the pharynx is less than 100% sensitive, and so NAATs may prove a very useful diagnostic test for these sites in the future.

Typing Methods

The typing of *N. gonorrhoeae* has been used extensively as an epidemiological tool to monitor trends over time, particularly of antibiotic-resistant strains, to study reinfection versus treatment failure and in tracing contacts, such as for medicolegal purposes. Historically, the methods used have been phenotypic in nature and include antimicrobial susceptibility patterns, plasmid profiles, auxotyping and serotyping. Antimicrobial susceptibility patterns and plasmid profiles are limited in their usefulness but do give information on the development and type of resistance (Sarafian and Knapp, 1989).

Auxotyping is differentiation of strains by their nutritional requirements by using a range of chemically defined medium lacking individual amino acids (Catlin, 1973). Many auxotypes have been identified, but four types predominate in most populations – non-requiring (prototrophic or wild type), proline requiring (pro), arginine requiring (arg) and arginine, hypoxanthine and uracil requiring (AHU). AHU-requiring strains have been associated with increased susceptibility to penicillin, DGI and heterosexual gonorrhoea, whereas non-requiring and proline-requiring strains are more resistant to antibiotics. Although auxotyping has revealed some interesting associations, it is technically demanding and lacks sufficient discrimination for most purposes.

Serotyping of *N. gonorrhoeae* is achieved by the pattern of reactivity of a boiled suspension of the gonococcal strain with a panel of monoclonal antibodies linked to staphylococcal protein A, used in a coagglutination technique (Knapp *et al.*, 1984). The panel consists of 12 antibodies directed to specific epitopes on the two types of the major outer membrane proteins, Por, with six antibodies directed at PIA and six at PIB. The pattern of reactivity denotes the serovar. *Neisseria gonorrhoeae* express either PIA or PIB, and it is unusual to encounter hybrids that express both types. Serotyping is simple to perform and inexpensive and is favoured by many diagnostic laboratories. However, the endpoint is the macroscopic examination and grading of the agglutination and is subjective, and interpretation may vary between individuals. The amount and quality of antibody used also influences the result, and

hence, the reproducibility of the technique over long time periods is less than 100%. Serotyping has greatly enhanced the ability to discriminate between strains, particularly if used in combination with auxotyping to produce auxotype/serovar (A/S) classes. Problems with the availability of the antibodies in more recent years and the lack of discrimination for some purposes has led to the search for a genotypic method that could offer reproducibility and enhance discrimination. The ideal method would be as simple and easy to perform as serotyping so that it could be used in diagnostic laboratories.

Genotyping methods use the degree of variation in one or more genes to discriminate between strains that are unlinked or to confirm strains from a common source. *Neisseria gonorrhoeae* are known to exhibit a high degree of genetic variation, to be competent for gene exchange at all parts of its life cycle and to be non-clonal. If diversity in variable genes is used, a high degree of discrimination may be achieved, in contrast to a conserved or housekeeping gene(s) where less discrimination would be expected.

A wide range of techniques for genotyping *N. gonorrhoeae* have been described that have examined diversity in the whole genome, number of repetitive sequences or individual genes, resulting in different degrees of discrimination (Ison, 1998). Techniques described that target the whole genome include restriction endonuclease fingerprinting, ribotyping and pulsed-field gel electrophoresis (PFGE) (Unemo *et al.*, 2002a). Amplification by PCR using either random primers or repetitive element sequence-based primers (rep-PCR) and lip typing (Trees *et al.*, 2000) detects variation in the number of repetitive sequences. Techniques that target specific genes include opa typing that examines diversity in the family of 11 *opa* genes (O'Rourke *et al.*, 1995), sequencing or probing of part or the complete *por* gene (Unemo *et al.*, 2002b; McKnew *et al.*, 2003; Martin *et al.*, 2004) and multilocus sequence typing (MLST) (Viscidi and Demma, 2003), which examines variation in seven or more housekeeping genes. All genotypic methods have proved as or more discriminatory than phenotypic methods, although there is variation, in that ribotyping and methods that examine repetitive sequences are less discriminatory and PFGE and opa typing are probably the most discriminatory.

The considerable degree of genetic diversity exhibited by *N. gonorrhoeae* raises questions regarding the validity of monitoring the genotype over time or at different geographical locations because the genotype may vary too quickly to be useful for epidemiological purposes. There are instances, e.g. the emergence of antibiotic-resistant strains, where it would be informative to know whether the same strains are spreading between countries. This may well be best addressed through analysis of the mechanism of resistance, such as comparison of mutations in *gyrA* and *parC* genes in ciprofloxacin-resistant gonococci. Highly discriminatory methods have proved useful for studying sexual networks and outbreaks, which occur over relatively short time periods. In this instance, if diversity in a highly variable gene is used, then it is possible that each gonococcal strain will appear unique, unless linked as part of a short transmission chain. This has been used to detect clusters in populations which were not visible by epidemiological techniques alone (Ward *et al.*, 2000).

Despite considerable progress in genotyping for *N. gonorrhoeae*, a single method that is simple and inexpensive to perform, which could be used in diagnostic laboratories, has not emerged. Many techniques, largely based on the *por* gene either alone or in combination with other genes, are emerging as methods that may be useful for answering specific questions relating to outbreaks. These methods are sequence based and so can be automated and give unambiguous and manageable data. Although the availability of sequencing is increasing in many laboratories and the cost is falling, it is unlikely that it will become used universally. However, routine typing of gonococcal isolates may not give meaningful results, because of the high rate of variation, and it may be better to address specific questions, using the more complex techniques, in a limited number of specialist centres.

MANAGEMENT OF INFECTION

Gonorrhoea is often treated before the susceptibility of the infecting isolate is known, such as after a presumptive diagnosis by microscopy, treatment as a contact of an infected patient or in the absence of a susceptibility test when syndromic treatment is used. It is important to know the patterns of resistance in any geographical location, informed by surveillance programmes, to enable the outcome of therapy to be predicted with reasonable confidence. The accepted dogma is that any first-line therapy should effectively treat >95% of cases.

Penicillin, or ampicillin, was the antibiotic of choice for the treatment of gonorrhoea for many years because it was effective and inexpensive. Resistance emerged slowly and was largely overcome by increasing the dosage. However, isolates of *N. gonorrhoeae* that exhibit plasmid and/or chromosomal resistance to penicillin became disseminated worldwide by the 1980s, presenting a therapeutic problem. National and international guidelines, such as those produced by the World Health Organisation, were changed to recommend the alternatives: ciprofloxacin, 500 mg orally; ceftriaxone, 125 or 250 mg intramuscularly; or the oral cephalosporin, cefixime (400 mg) and spectinomycin 2 g intramuscularly. Ciprofloxacin has been heavily used in many parts of the world, for the treatment of many infectious diseases including gonorrhoea, and resistance emerged in gonococci and has increased to levels above 5%, such that ciprofloxacin is currently being removed as a first-line therapy in some countries.

Ceftriaxone is the preferred alternative but is given by injection, making it a less attractive first-line therapy. Cefixime is currently the only oral third-generation cephalosporin for which there is good efficacy data, but there are concerns regarding its continued availability in some parts of the worlds. Azithromycin is recommended in some guidelines and is often used, but for the treatment of gonorrhoea, the recommended dose is 2 g, which is poorly tolerated, and there is a tendency to use a 1-g dose. However, there is increasing evidence that treatment failure is increasing with both dosages (Young *et al.*, 1997), and azithromycin is not a good alternative to the highly active third-generation cephalosporins.

Antimicrobial Resistance

Neisseria gonorrhoeae is inherently susceptible to most antibiotics, but through continual usage, resistance has emerged (Table 15.4), either by the acquisition of plasmids from other organisms, such as *Haemophilus*, or by the selection of resistant mutants.

Resistance to penicillin may be plasmid or chromosomally mediated. Penicillinase-producing *N. gonorrhoeae* (PPNG) which exhibit high-level plasmid-mediated resistance (minimum inhibitory concentration, MIC, ≥ 4 mg/l) were first documented in 1976 (Ashford *et al.*, 1976; Percival *et al.*, 1976; Phillips, 1976). Isolates that originated from Africa and Asia were found to carry plasmids of 3.2 MDa and 4.4 MDa, respectively (Roberts *et al.*, 1977), and both encoded for a TEM-1 type β -lactamase, the smaller plasmid having a deletion in a non-functional

Table 15.4 Breakpoints that define categories of antimicrobial resistance in *Neisseria gonorrhoeae*

Strain nomenclature	Strain definition
CMRNG	Penicillin MIC ≥ 1 mg/l (≥ 2 mg/l*), tetracycline 2–8 mg/l
PPNG	Penicillinase-producing <i>N. gonorrhoeae</i> , tetracycline MIC < 16 mg/l
TRNG	Non-penicillinase-producing <i>N. gonorrhoeae</i> (non-PPNG), tetracycline ≥ 16 mg/l
PP/TRNG	PPNG, tetracycline MIC ≥ 16 mg/l
QRNG	PPNG, non-PPNG, TRNG, PP/TRNG or CMRNG with ciprofloxacin MIC ≥ 1 mg/l

MIC, minimum inhibitory concentration.

* NCCLS recommended breakpoint.

region of the plasmid (Pagotto *et al.*, 2000). Transfer of penicillinase plasmids may occur between strains of *N. gonorrhoeae* by conjugation, but it requires the presence of a conjugative plasmid of 24.5 MDa to mobilise the transfer (Roberts, 1989). Despite their original geographical associations, PPNG carrying these plasmids have now disseminated worldwide. PPNG carrying plasmids of differing sizes have been reported in more recent years, but these also encode for the TEM-1 type β -lactamase and have not spread so widely.

Chromosomally mediated resistant *N. gonorrhoeae* (CMRNG) exhibit low-level resistance to penicillin and also to tetracycline. Unlike PPNG which produce an enzyme that destroys penicillin, chromosomal resistance is the additive result of mutations at multiple sites which decrease the permeability of the cell envelope and hence forms a barrier against penicillin. Mutations in *penA*, *mtr*, *penB*, *ponA1* and *penC*, acquired in a stepwise manner (Ropp *et al.*, 2002), are necessary to produce a strain that is likely to fail therapy. *penA* encodes for penicillin-binding protein 2 (PBP2), and a resistant isolate exhibits a reduced affinity for penicillin (Brannigan *et al.*, 1990). The *mtr* locus consists of an operon, *mtrRCDE*, which controls susceptibility to a range of hydrophobic antibiotics and detergents, and resistance occurs through overexpression of the *mtrRCDE* efflux pump (Hagman *et al.*, 1995). However, expression of *mtr* requires the presence of the *penB* mutation, which has been correlated to a mutation in the *por* gene (Gill *et al.*, 1998). These three loci confer decreased susceptibility, but mutations in two further loci, *ponA1* (PBP1) (Ropp and Nicholas, 1997) and *penC*, are required for full resistance. The additive effect of these mutations increases the MIC from ≤ 0.06 mg/l in a susceptible strain to ≥ 1 mg/l, with an increased chance of therapeutic failure.

Ciprofloxacin, a fluoroquinolone, has been used for over a decade as an alternative to penicillin because it was highly active against *N. gonorrhoeae* and is given orally as a single dose, usually at 500 mg. However, reports of decreased susceptibility appeared soon after its introduction, and therapeutic failure is now common in many parts of the world. The targets for ciprofloxacin are the enzymes DNA gyrase (GryA) and the topoisomerase IV (ParC), which are responsible for supercoiling the bacterial DNA. Resistance occurs through mutations at multiple sites in the quinolone resistance-determining region (QRDR) of these genes (Belland *et al.*, 1994), with the highest level of resistance occurring when mutations are present in both *gyrA* and *parC* (Knapp *et al.*, 1997; Trees *et al.*, 2001). The relationship between the level of resistance and therapeutic failure was initially unknown and has been controversial. There is good agreement that high-level resistance, linked to an increased chance of therapeutic failure, correlates with an MIC ≥ 1 mg/l. However, decreased susceptibility (MIC 0.12–0.5 mg/l) has also been associated with treatment failure but occurs less often than among isolates exhibiting high-level resistance.

Tetracycline is not commonly used as a first-line treatment for gonorrhoea but is often given concurrently for the treatment of possible chlamydial infection and has been used in parts of the world where more effective therapies are not available or are too expensive. Resistance to tetracycline in *N. gonorrhoeae* may be high level and plasmid mediated (MIC ≥ 16 mg/l), which is the result of acquisition of the *tetM* determinant into the gonococcal conjugative plasmid (Morse *et al.*, 1986). This plasmid mobilises itself between gonococci and other genera found in the genital tract, and hence, resistance has spread quickly since its first description in 1985. Low-level resistance (MIC ≥ 2 mg/l) is the result of chromosomal mutations (Johnson and Morse, 1988), and its relationship to therapeutic failure is unclear.

Resistance to spectinomycin, in contrast to other antimicrobial agents, is high level and occurs in a single step, resulting in an increase in MIC from 8 mg/l to 16 mg/l to >256 mg/l, which is invariably resistant to therapy (Easmon *et al.*, 1982; Galimand, Gerbaud and Courvalin, 2000). There have been several documented episodes of spectinomycin-resistant gonorrhoea, but these have not spread widely. Spectinomycin is not commonly used as a first-line therapy and has become difficult to obtain in some countries but may still be particularly useful when resistance to the newer alternative treatments develops.

Therapeutic resistance to ceftriaxone has not been documented, although gonococcal isolates exhibiting reduced susceptibility have been reported (Schwebke *et al.*, 1995), and there are anecdotal reports of resistance. It is likely that there will be increased usage of the third-generation cephalosporins in the coming years as a result of the high levels of resistance to ciprofloxacin in many parts of the world, increasing the selective pressure for resistant mutants to appear. Azithromycin may also be used increasingly for the same reasons, but resistance has been reported (Young, Moyes and McMillan, 1997) and is increasing, and this is unlikely to be a long-term alternative for the treatment of gonorrhoea.

Susceptibility Testing

In vitro susceptibility testing is used to predict the outcome of therapy, detect the emergence of resistance and monitor drifts in susceptibility. This may be achieved by disk diffusion, breakpoint agar dilution technique or determination of the MIC by agar dilution. Susceptibility testing for *N. gonorrhoeae* may be difficult because the organism is fastidious and requires an enriched medium, which may interfere with the action of some of the antibiotics. There are methods recommended by the National Committee for Clinical Laboratory Standards (NCCLS), the World Health Organization (World Health Organization, 1989) and the British Society of Antimicrobial Chemotherapy (BSAC) (King, 2001) among others, which differ largely in medium used and concentration of antibiotic in the disk. Many laboratories use variations of these methodologies, which may be used successfully if an appropriate panel of control strains is used to aid interpretation of the results. The results of *in vitro* susceptibility testing should be correlated with therapeutic outcome wherever possible: susceptible strains having a $<5\%$ likelihood of treatment failure, resistant strains having a $>15\%$ chance of treatment failure and intermediate resistance or decreased susceptibility having a 5–15% possible treatment failure.

Although many patients with gonorrhoea are treated empirically, it is still common practice to routinely test gonococcal isolates from individual patients to ensure correct patient management. The choice of method is a matter for each laboratory, but disk diffusion is used most often. An alternative method that is appropriate for routine use is the breakpoint agar dilution technique, where a few concentrations of antibiotic are used to categorise strains into susceptible, reduced susceptibility and resistant. This has the advantage of giving a predicted range for the MIC and may be used with a multipoint inoculator, enabling multiple strains to be tested simultaneously. While the breakpoint technique is applicable to laboratories receiving large numbers of gonococcal isolates, for laboratories encountering few isolates or wishing to perform the occasional MIC, the E-test is very useful. The E-test is performed by placing a paper strip containing varying concentrations of antibiotic onto a lawn of bacteria, the resulting zone of inhibition giving an indication of the MIC. This method is commercially available and expensive but is useful and growing in popularity (Biedenbach and Jones, 1996).

Conventional susceptibility testing is reliant on obtaining a viable organism from the patient. However, there is increasing interest in using molecular tests for the diagnosis of gonorrhoea, particularly for screening in primary care settings or where facilities for culture are not available. This will result in fewer organisms being available for testing both for individual patient management and for surveillance programmes; hence, the data that are produced will be less representative. The ideal solution is to develop molecular methods for detecting resistance in *N. gonorrhoeae*, which detect resistance to the main therapeutic agents. The antimicrobial agents currently most commonly used are ciprofloxacin and ceftriaxone or an alternative third-generation cephalosporin. Resistance to ciprofloxacin is known to be the result of mutations in both the *gyrA* and *parC* gene, but the mutations occur at multiple sites on both genes, and it has been difficult to identify mutations found in all strains that would predict therapeutic failure. Levels of ciprofloxacin resistance are increasing, and it is possible that the

technical problems of detecting resistance will not be overcome before the drug is withdrawn as a useful therapy. Treatment failure to ceftriaxone is not yet described, although reduced susceptibility is known and has been attributed to the same mutations as chromosomal resistance to penicillin. However, the design of any test to detect therapeutic resistance is difficult until such resistance emerges.

Penicillin, or ampicillin, was used for many years for treating gonorrhoea, but owing to the high prevalence of resistance in many parts of the world it is used infrequently as a first-line therapy unless good surveillance data are available to indicate that the gonococcal population is susceptible. Molecular methods for detecting plasmid-mediated resistance to penicillin by using amplification by PCR (Palmer, Leeming and Turner, 2000) have been described, and the mutations responsible for chromosomal resistance to penicillin are known; therefore, if considered necessary, molecular detection of penicillin resistance is possible. Resistance to other antimicrobial agents may be of interest, particularly for surveillance purposes, such as tetracycline or azithromycin. Amplification methods are in use for plasmid-mediated resistance to tetracycline and to divide the plasmid into two types (Ison, Tekki and Gill, 1993; Xia, Pang and Roberts, 1995), which may be useful for epidemiological studies of antibiotic-resistant gonorrhoea.

It will be a challenge to continue to provide representative surveillance data in the era of NAATs. One approach is to screen for gonorrhoea by using a molecular test and a non-invasive sample and then to recall patients who have a positive test, to enable collection of specimens for the isolation of *N. gonorrhoeae*, which can then be used for susceptibility testing, before the patient is treated.

Surveillance

The efficacy of first-line therapies for gonorrhoea is dependent on good surveillance data giving patterns of susceptibility to inform the choice of an appropriate antimicrobial agent (Ison, Billon and Tapsall, 1998). It is suggested that any therapy used for gonorrhoea should be successful in at least 95% of patients; otherwise, a change in therapy should be considered. There are many established surveillance programmes worldwide, including in the United States (Schwarcz *et al.*, 1990), Canada (Dillon, 1992), Australia (Members of the Australian Gonococcal Surveillance Programme, 1984) and the Netherlands (Van de Laar *et al.*, 1997), that have longitudinal data that are useful to show temporal changes. The World Health Organization initiated a global antimicrobial surveillance programme (GASP) in 1990, but it is currently most active in the Americas and the Caribbean and the Western Pacific Region. More recently, additional programmes have been initiated as resistant gonorrhoea continues to spread. In England and Wales, national surveillance was initiated in 2000 (Paine *et al.*, 2001) and has already provided information regarding the rapid increase in ciprofloxacin resistance above the 5% level (Fenton *et al.*, 2003). This information has been used to inform a change in national guidelines for the first-line treatment of gonorrhoea from ciprofloxacin to ceftriaxone. The WHO WPR (Western Pacific Region) surveillance programme (2001) has demonstrated alarming levels of resistance to penicillin, approaching 100% in some countries and continuing increases in ciprofloxacin resistance.

The challenge for surveillance programmes is to produce comparable data between countries. There are many methodologies used worldwide, but it is unlikely that a common methodology will be agreed upon. The use of a well-defined panel of control strains reflecting different categories of susceptibility and resistance to therapeutic agents, together with regular participation in national and/or international quality assessment programmes, where panels of isolates are circulated for testing, is likely to be a more successful approach.

PREVENTION AND CONTROL

Gonorrhoea is the second most common bacterial STI. Although it is a treatable infection, the number of cases continues to rise. There has

been considerable interest in producing a vaccine that may give protection particularly against complicated infection in women, because of the sequelae of PID and infertility, but attempts to induce protection by vaccination have been largely unsuccessful. This is due to the antigenic variability of the major surface antigens such as pili. The first major trial of a gonococcal vaccine in men using purified pili from a single strain was unsuccessful because antibody produced was strain specific (Boslego *et al.*, 1991). Alternative candidates including the major outer membrane protein, Por, and proteins involved in iron acquisition have shown promise but have not been developed for large-scale trials. An additional problem in developing a vaccine has been the lack of knowledge on the host response required to induce protection. Control of gonococcal infection is, therefore, dependent on good access to care, rapid and accurate diagnostic tests and effective therapy. This must be allied to an efficient system to trace and treat sexual contacts. The impact of health education may be seen following the fall in gonorrhoea incidence associated with the publicity surrounding the human immunodeficiency virus (HIV) epidemic.

Gonorrhoea, together with other bacterial STIs, has been linked to the transmission of HIV infection (Fleming and Wasserheit, 1999), and in some studies, aggressive treatment of bacterial STIs has reduced the acquisition of HIV (Grosskurth *et al.*, 2000). It is, therefore, imperative that all efforts be taken to control infections such as gonorrhoea, to aid the control efforts for AIDS. In the absence of a vaccine that provides long-term protection, control is dependent on public health interventions, which in turn require resources. Therefore, in resource-poor settings, control and prevention measures are least effective and the prevalence of gonorrhoea is usually high.

Acinetobacter spp.

Peter Hawkey^{1,2} and Eugenie Bergogne-Berezin³

¹The Medical School, University of Birmingham; ²Health Protection Agency, Birmingham Heartlands Hospital, Birmingham, UK; and ³Faculty of Medicine Bichat, University Paris 7, Paris, France

INTRODUCTION

Aerobic non-fermentative Gram-negative bacilli have increasingly become important as human pathogens over the last 20 years. *Pseudomonas aeruginosa* has been well studied, and most other Gram-negative aerobic bacilli such as *Acinetobacter* spp., *Stenotrophomonas* spp., *Flavobacterium* spp. and *Alcaligenes* (*Achromobacter* spp.) have been recognised more recently as pathogens. In a survey of Gram-negative bacilli isolated from 396 intensive care units (ICUs) in the United States, *P. aeruginosa* (19.7% strains) was the second most common isolate after *Escherichia coli*, followed by *Acinetobacter* spp. (5.3%) and *Stenotrophomonas maltophilia* (3.7%) (Quinn, 1998). We have also included *Flavobacterium* and *Achromobacter* as, although these are rare causes of infection, they may cause substantial nosocomial outbreaks. After many years of confusing and erratic taxonomy of these organisms, molecular taxonomic and identification methods have defined new species and genera.

They are saprophytic bacilli, present in the environment (soil, water and phytosphere) and may be recovered from the hospital environment and from colonised or infected patients or from staff, predominately on the hands. As opportunistic pathogens, these bacilli are responsible for nosocomial infections, mainly severe pneumonia, septicaemia and urinary tract infections (UTIs). Infections caused by them are often difficult to treat because of their frequent multiple resistance to many antibiotics (Gales *et al.*, 2001), which, combined with their persistence in different hospital environments, has resulted in an increased interest in their biology.

ACINETOBACTER

Among Gram-negative bacteria causing nosocomial infections (particularly in ICUs), *Acinetobacter* spp. have attracted increasing attention during the last two decades (Baker and Hawkey, 2004). *Acinetobacter* spp. are implicated in a wide spectrum of infections (e.g. bacteraemia, nosocomial pneumonia, UTIs, secondary meningitis and superinfections in burn patients). One of the most striking features of *Acinetobacter* spp. is their extraordinary ability to express multiple resistance mechanisms against major antibiotic classes: many strains have become resistant to broad-spectrum β -lactams (third-generation cephalosporins, carboxypenicillins and, increasingly, carbapenems). They produce a wide range of aminoglycoside-inactivating enzymes, and many strains are resistant to fluoroquinolones. Among *Acinetobacter* spp., *Acinetobacter baumannii* is the most frequent species involved in nosocomial infections (Seifert *et al.*, 1993) and by far the most resistant to major antibiotic classes. The quest for understanding the epidemiology of *Acinetobacter* spp. has given rise to studies using

increasingly sophisticated techniques for typing these organisms isolated from patients and from the hospital environment.

Microbiology

Definition

Acinetobacter spp. are aerobic Gram-negative bacilli commonly present in soil and water as free-living saprophytes. They are also isolated as commensals from skin, throat and various secretions of healthy people, as well as causing human infections (Joly-Guillou and Brunet, 1996; Bergogne-Berezin, 2001). Morphologically, they are aerobic Gram-negative coccobacilli and usually found in diploid formation or chains of variable length. They are not motile, hence their scientific name from the Greek word ($\alpha\kappa\iota\nu\epsilon\tau\omicron\zeta$), i.e. 'unable to move', although the cells display a 'twitching motility', presumably because of the presence of polar fimbriae. They are strictly aerobic and grow easily on all common media at temperatures from 20 to 30 °C, with, for most strains, the optimum at 33–35 °C. Growth at 41 and 44 °C occurs for a few species and is a discriminating phenotypic characteristic. The key features for identifying *Acinetobacter* spp. are an oxidase-negative, catalase-positive, indole-negative, nitrate-negative, Gram-negative bacillus. Production, or not, of acid from D-glucose, D-ribose, D-xylose and L-arabinose (utilised oxidatively as carbon sources) had been used in early identification methods for strains formerly designated var. *anitratum* or var. *lwoffii* (Table 16.1). These phenotypic characteristics included in commercial identification systems with 20 biochemical tests (API 20NE, Bio-Merieux) are not considered a sufficiently reliable identification method: more precise and accurate identification requires DNA-based methods, which are increasingly used.

Taxonomy

Acinetobacter spp. have undergone considerable changes in taxonomy over the years: strains were designated *Bacterium anitratum*, *Herellea vaginicola*, *Mima polymorpha*, *Achromobacter*, *Micrococcus calcoaceticus*, *Diplococcus*, B5W and *Cytophaga* (Juni, 1984), until the genus *Acinetobacter* was reclassified in 1986 by Bouvet and Grimont using modern genotypic methods (genetic transformation, DNA–DNA hybridisation and RNA sequence comparison) into genomic species including *A. baumannii* (Bouvet and Grimont, 1986). Since then, a variety of new genotypic methods [ribotyping, tRNA spacer fingerprinting, amplified fragment length polymorphism (AFLP) and amplified ribosomal DNA restriction analysis (ARDRA)]

Table 16.1 Major properties for identifying the most frequently isolated *Acinetobacter* spp.

have identified more than 20 genomic species and new species have been created: *Acinetobacter nannii* (formerly *Acinetobacter calcoaceticus* var. *anitratius* and *Acinetobacter glucidotylica non liquefaciens*), *Acinetobacter haemolyticus*, *Acinetobacter junii*, *Acinetobacter johnsonii* and *Acinetobacter radioresistens*. The definition of *Acinetobacter* is based on phenotypic characteristics (biotyping) and on the identification of genotypic species. The evolution of taxonomy and the main characteristics of 'new' *Acinetobacter* spp. are summarised in Tables 16.1 and 16.2, respectively. Species designation can also include previous designations such as *A. anitratius* for glucose-positive strains, *Acinetobacter lwoffii* for glucose-negative strains. '*Acinetobacter calcoaceticus*' was used in relatively recent literature. The ability to produce acid from glucose (oxidation of glucose to produce gluconic acid) is not regarded any more as a characteristic of taxonomic significance.

Genetics

The only complete genome sequence of an *Acinetobacter* that is available are sequence assemblies of *A. calcoaceticus* ADP1 (BD413), from www.genoscope.cns.fr. This strain has been extensively studied as an environmental bacterium capable of degrading a variety of chemicals including aromatic hydrocarbons. This strain is also naturally transformable and has been used to sample the environment for recombinant DNA sequences (Palmen and Hellingwerf, 1997). An *recA*-independent system for gene amplification has been described in ADP1, which, if present in the clinically significant species, could be important in upregulated chromosomally located antibiotic resistance genes (Reams and Neidle, 2004). Until whole genome sequence information from *A. baumannii* or other clinically significant genospecies is available, there is only a limited understanding of the genetics of *Acinetobacter*. A survey of predominantly *A. baumannii* from around the world showed that 17 of 25 isolates carried integrons and all but one were class 1, usually carrying aminoglycoside-modifying enzyme genes. The integrons showed similarities to each other, despite being carried by isolates with distinct genotypes (Seward and Towner, 1999).

Pathogenesis of *Acinetobacter* Infection

Virulence of *Acinetobacter* spp.

Although considered originally to be a relatively low-grade pathogen (Juni, 1978), *Acinetobacter* has many putative virulence factors that have been identified (Avril and Mensard, 1991). The presence of a polysaccharide capsule formed of L-rhamnose, D-glucuronic acid and D-mannose renders the cell surface of strains more hydrophilic, hydrophobicity being greater in *A. baumannii* isolated from catheters or tracheal devices (Rosenberg *et al.*, 1983; Kaplan *et al.*, 1985). *Acinetobacter* cells adhere to human epithelial cells probably via the capsule and fimbriae (Rosenberg *et al.*, 1982). The lipopolysaccharide (LPS) of *Acinetobacter* has been shown to be active in *in vitro* assays against eukaryotic cells and to stimulate cytokine release (Garcia *et al.*, 1999). A homologue of the *traT* gene responsible for serum resistance in *E. coli* has been found in *Acinetobacter* (Montenegro *et al.*, 1985). Lipases (butyrate esterase, caprylate esterase and leucine arylamidase) produced by *Acinetobacter* may damage tissue lipids (Bergogne-Berezin and Towner, 1996). No DNAase, elastase, haemolysin, trypsin or chymotrypsin production has been detected in *Acinetobacter* strains. A novel catechol siderophore has been identified in *A. baumannii* 8399 which came from a patient with nosocomial pneumonia, and the biosynthetic and transport proteins have been characterised (Dorsey *et al.*, 2003). The virulence of *Acinetobacter* has been studied in many animal models of systemic infections (Bergogne-Berezin and Towner, 1996), including an experimental pneumonia model in immunosuppressed mice (Joly-Guillou *et al.*, 1997).

Host Predisposing Factors

Various risk factors predisposing to severe *Acinetobacter* infection have been identified, including the presence of a severe underlying disease, e.g. malignancy, burns, immunosuppression and major surgery, both elderly and neonatal patients being at increased risk (Bergogne-Berezin and Towner, 1996). The setting for infection is usually the medical/surgical ICU, renal or burns unit, where catheters of all kinds act as portals of entry. The role of antibiotics in predisposing to infection is important as acquisition of multidrug-resistant *Acinetobacter* is significantly associated with prior antibiotic treatment as well as the factors listed above (Smolyakov *et al.*, 2003).

Epidemiology

Strains of *Acinetobacter* are widely distributed in nature and are found in virtually all samples of soil and fresh water when appropriate culture techniques are used (Bergogne-Berezin and Towner, 1996). A range of species have been identified from soil, sewage, plants and food products, although the species associated with human disease are not normally found in such sites.

Human Carriage

Human carriage of *Acinetobacter* has been demonstrated in normal individuals: it forms part of the bacterial flora of the skin and has been found in the axillae, groin and toe webs of normal individuals. *Acinetobacter* colonises the oral cavity, the respiratory tract and the gastrointestinal tract and is found predominantly in moist skin areas (Bergogne-Berezin and Towner, 1996). Studies of the carriage of *Acinetobacter* on human skin and mucous membranes show *A. lwoffii* (47%), *A. johnsonii* (21%) and *A. radioresistens* (12%) and genospecies 3 (11%) to be the most common in both patients and controls. *Acinetobacter baumannii* and genospecies 13, which are the most common nosocomial species, were very rare in controls (6.5% and 1%) (Seifert *et al.*, 1997). A study in Hong Kong found genospecies 3 to be the most common (36%) and *A. lwoffii/A. johnsonii* to be rare (1.6%) in controls from the community, whereas in patients, *A. baumannii* was the most common (35%), emphasising variation in species carried between different geographical locations (Chu *et al.*, 1999). The community is not likely to be a reservoir for *A. baumannii* (identified phenotypically), as suggested by data from a study of hand carriage in New York, where multidrug-resistant strains typical of nosocomial isolates were absent from the community (Zeana *et al.*, 2003).

Sources and Spread in Nosocomial Infections

Sporadic cases of *Acinetobacter* infections are seen in many hospitals and in a variety of patient settings. However, outbreaks of infection caused by endemic strains are being increasingly described, particularly in ICUs. The carriage rate of *Acinetobacter* on the skin of hospitalised patients is significantly higher than the community, and this site has been thought to be an important source (Seifert *et al.*, 1997). This has been postulated to be due to reduced hygiene standards among hospitalised patients and the warm, humid atmosphere of hospital beds, which is supported by the observation that colonisation is more frequent in summer months. However, two recent studies using DNA-based identification techniques have demonstrated that much of this colonisation is due to species of *Acinetobacter* not commonly associated with clinical infection (Seifert *et al.*, 1997; Berlau *et al.*, 1999).

In contrast, very high rates of *A. baumannii* carriage have been described during outbreaks of infection in ICUs. Frequent colonisation of the skin, throat, respiratory and digestive tract has been described in

Table 16.2 Current nomenclature of non-fermentative, Gram-negative bacilli (list limited to those potentially involved in infections) (after Bruckner and Colonna, 1995)

ICU patients. It is likely that respiratory and genitourinary colonisation are the most important sources of nosocomial infection. In one study of adult patients in a French ICU, 33% developed oropharyngeal or rectal carriage of *A. baumannii* and/or *Klebsiella pneumoniae* within a median period of 9 days (Garrouste-Org *et al.*, 1996). Studies of burns patients have demonstrated colonisation rates with *A. baumannii* of over 50%, mainly due to superficial wound colonisation (Fujita, Lilly and Ayliffe, 1982; Sherertz and Sullivan, 1985; Wisplinghoff, Perbix and Seifert, 1999). High rates of colonisation of the respiratory tract have also been described in outbreaks involving mechanically ventilated patients (Allen and Green, 1987; Mah *et al.*, 2001). In one study, 45% of tracheostomies were found to be colonised with *Acinetobacter* spp. (Rosenthal, 1974). Although colonisation of the digestive tract is not generally considered to be as an important source of *Acinetobacter*, several studies have demonstrated significant rectal carriage of *A. baumannii* in ICU patients (Timsit *et al.*, 1993; Corbella *et al.*, 1996).

A wide range of hospital environment sites, both moist and dry, have been shown to be contaminated with *Acinetobacter* spp. (Bergogne-Berezin and Towner, 1996). Materials in contact with colonised patients act as sources after or during admission of the patient, particularly if moist. This has been seen with outbreaks associated with wet contaminated mattresses with breaks in the plastic covers in a burns unit (Sherertz and Sullivan, 1985). *A. baumannii* has been found to be a cause of nosocomial infection amongst cats/dogs and horses in veterinary hospitals, spreading in a very similar fashion to human infections (Boerlin *et al.*, 2001).

Other items of equipments, such as curtains, keyboards, arterial pressure transducers and, particularly, ventilator equipment, may be sources of outbreaks (Cefai *et al.*, 1990; Bergogne-Berezin and Towner, 1996; Baker and Hawkey, 2004). Once the hospital equipment has become contaminated, the ability particularly of the clinically important genospecies (e.g. *A. baumannii*, genospecies 3, 7 and 13) to survive desiccation may be exceptional (Jawad *et al.*, 1996). Genospecies of *Acinetobacter* associated with nosocomial infection were found to have significantly greater desiccation tolerance, as were freshly isolated strains (Jawad *et al.*, 1996). Bacteria from the equipment may then contaminate the hands of staff and be transmitted to patients. In one outbreak, environmental contamination correlated closely with the number of colonised patients, and improved cleaning was thought to contribute to termination of the outbreak (Denton *et al.*, 2004).

CLINICAL FEATURES OF ACINETOBACTER INFECTIONS

Acinetobacter spp. have been implicated in many nosocomial/opportunistic infections. The predominant sites of *Acinetobacter* nosocomial infections have varied with time and local epidemiological factors. In early reports, UTIs predominated in ICUs, but more recently the incidence of UTIs has decreased, possibly in relation to a better care of urinary catheters, whereas the incidence of nosocomial pneumonia has increased significantly (Bergogne-Berezin, 2001). A European survey of causative agents in nosocomial pneumonia carried out in seven countries using the same protocol has established an overall incidence of approximately 10% for *Acinetobacter* (Bergogne-Berezin, 2001). Less common infections such as meningitis, endocarditis, skin and soft-tissue infections, peritonitis or surgical wound infections have been seen as sporadic cases (Bergogne-Berezin and Towner, 1996). *Acinetobacter* species are involved in superinfection in burn patients (Bergogne-Berezin, Joly-Guillou and Vieu, 1987).

Respiratory Tract Infections

Acinetobacter pneumonia does not differ clinically from most severe Gram-negative pneumonias. A combination of clinical signs including

fever, neutrophilia, purulent sputum production and appearance of new infiltrates on radiograph or computed tomographic (CT) scan must lead to microbiological investigation. The aetiologic agent is best isolated from bronchial aspirates, bronchial brushings or bronchoalveolar lavage. *Acinetobacter* respiratory tract infections occur predominantly in mechanically ventilated patients (Bergogne-Berezin and Towner, 1996). In the United States, the National Nosocomial Infection Surveillance (NNIS) reports that 4% of all nosocomial pneumonias are caused by *Acinetobacter* (Schaberg, Culver and Gaynes, 1991). In the European Prevalence of Infection in Intensive Care (EPIIC) study, *Acinetobacter* accounted for 10% of all pneumonia. The most severe form is bacteraemic pneumonia, often associated with shock and sepsis occurring in the presence of risk factors (underlying severe pathologies, high APACHE II Acute Physiology And Chronic Health Evaluation score and broad-spectrum antibiotic therapy) (Lortholary *et al.*, 1995; Husni *et al.*, 1999).

Crude mortality rates in *Acinetobacter* pneumonia ranging from 30 to 75% are reported, with the highest rate in ventilated patients (Fagon *et al.*, 1989; Torres *et al.*, 1990). A recent Spanish ICU study demonstrated an attributable mortality of 53% in patients with *A. baumannii* infections (Garcia-Garmendia *et al.*, 1999). When compared with a control group, the excess length of stay was 13 days and the odds ratio for death was 4.0. Rare cases of community-acquired pneumonia have been reported, being implicated in 10% of patients (particularly alcoholics) in a report from Northern Australia (Anstey, Currie and Withnall, 1992).

Bacteraemia

Risk factors predisposing to bacteraemia and predominant sources of the organism are pneumonias, trauma, surgical procedures, presence of catheters or intravenous lines, dialysis and burns (Chastre *et al.*, 1996; Cisneros *et al.*, 1996; Weinbren *et al.*, 1998; Cisneros and Rodriguez-Bano, 2002). Immunosuppression or respiratory failure at admission increased the risk of bacteraemia by threefold, with increased risk for nosocomial pneumonia. Prolonged hospital stay, previous admission to another hospital, enteral feeding and previous use of third-generation cephalosporins are all identified as risk factors for colonisation/infection with *Acinetobacter* and are therefore indirectly risk factors for *Acinetobacter* bacteraemia (Mulin *et al.*, 1995; Scerpella *et al.*, 1995). Relevant clinical signs to define true bacteraemic episodes were fever, leukocytosis and successive positive blood cultures with the same genotypic isolate of *Acinetobacter* (Darveau *et al.*, 1991; Craig and Ebert, 1992; Decre, Benoit and Joly-Guillou, 1995; Dijkshoorn, 1996; Lai *et al.*, 1999). The incidence of *Acinetobacter* bacteraemia ranks second after pneumonias, and its prognosis is determined by the underlying condition of the patient (Lai *et al.*, 1999). Bacteraemia may be caused by both sporadic strains and epidemic strains that are localised to particular hospitals, as shown by molecular typing in five hospitals studied in a US multicentre study (Wisplinghoff *et al.*, 2000). Outcome depends on the underlying condition of the patient, but septic shock may occur in 20–30% of patients (Seifert, Strate and Pulverer, 1995).

Urinary Tract Infections

Several reviews have attributed to *Acinetobacter* spp. extremely variable rates, ranging from 2 to 61%, of nosocomially acquired UTIs, and recent epidemiological surveys have indicated an overall incidence of up to 30.5% of acquired UTIs (Joly-Guillou *et al.*, 1992; Bergogne-Berezin, 1996). Risk factors for UTIs do not differ from those involved in bacteraemia. The presence of indwelling urinary catheter is an additional factor, and removal of the catheter is recommended as an efficient measure to control *Acinetobacter* bacteraemia.

Skin and Soft-Tissue Infections

Colonisation of burns and traumatic and postoperative wounds with *Acinetobacter* spp. is not uncommon, particularly in ICU settings. Differentiating between wound colonisation and infection may often be difficult. However, cellulitis surrounding intravenous catheter sites caused by *Acinetobacter* has been described (Gervich and Grout, 1985). There have been infrequent reports of extensive soft-tissue necrosis adjacent to colonised wounds (Cisneros *et al.*, 1996) and synergistic necrotising fasciitis in conjunction with *Streptococcus pyogenes* (Allen and Hartman, 2000). *Acinetobacter* colonisation of extremity wounds was frequently observed in casualties of the Vietnam War. In many of these cases, colonisation of wounds was followed 3–5 days later by bacteraemia (Tong, 1972). In several large case series, 4–27% of all *Acinetobacter* bacteraemias occurred as a result of infected surgical or burn wounds (Seifert, Strate and Pulverer, 1995; Cisneros *et al.*, 1996; Wisplinghoff *et al.*, 2000).

Colonisation of burns with *Acinetobacter* spp. is seen in specialist units and in most burns patients when a frequency of isolation similar to *P. aeruginosa* has been reported (Santucci *et al.*, 2003).

Meningitis

Nosocomial meningitis is an infrequent manifestation of *Acinetobacter* infection. Cases of meningitis due to this organism have been reported after neurosurgical procedures, but rare cases of primary meningitis, especially in children, have also occurred. *Acinetobacter* meningitis may result from the introduction of the organism directly into the central nervous system (CNS) following intracranial surgery, myelography or ventriculography as well as after transnasal aspiration of craniopharyngioma or lumbar puncture (Siegmán-Igra *et al.*, 1993). The course of the disease has been described as a relatively indolent bacterial meningitis with meningeal signs, high fever, lethargy or headache. However, an acute clinical course may also occur and problems in diagnosis may occur since the organism mimics meningococci or *Haemophilus influenzae*.

Acinetobacter Infections in Children

Recent studies have highlighted the occurrence of paediatric *Acinetobacter* infections, [previously considered rare or misidentified] (McDonald *et al.*, 1998; Mishra *et al.*, 1998; Nagels *et al.*, 1998). Multivariate analysis showed that infants with peripheral intravenous catheters were more likely to develop *Acinetobacter* nosocomial infection, and environmental cultures had revealed that after installation of a new air conditioner, the incidence of cases had increased by airborne dissemination of the bacteria. In a preterm infant ICU, the role of *A. baumannii* in infections was related to mechanical ventilation in 15 preterm infants (McDonald *et al.*, 1998): despite satisfactory conditions of care and hygiene, infants were colonised when ventilation was longer than that in controls, with body temperatures greater than 37 °C for a longer time than controls. However, no fatalities occurred in that particular study.

Surveillance and Control of *Acinetobacter* Nosocomial Infections

With the increasing importance of *Acinetobacter* infection worldwide, the development of local, large national or international surveys has resulted in a better understanding of the epidemiological profile of this organism. The annual incidence of *Acinetobacter* infection increased from 1980 to 1990, reaching up to 560 isolates per year in ICUs only, representing approximately 9–10% of infecting organisms. Since 1991, their number decreased significantly, being as low as 150 isolates per year, representing 0.5% of admissions in ICUs: changes in therapeutic strategies and improved hospital infection control have probably

been favourable factors for decreased incidence of *Acinetobacter* infections (Bergogne-Berezin, 2001). An international survey on *Acinetobacter* infection was carried out in 1995–1996 (6 months), collecting data from France, Germany, Spain, Israel, the United Kingdom and South Africa. The results showed that the following:

1. the incidence of *Acinetobacter* infections was higher in large Hospitals (>800 beds) (9–14% of total *Acinetobacter* infections) versus less than 5% in small hospitals (<500 beds);
2. the incidence was higher during prolonged hospital stays (>10 days);
3. infection was rare in paediatric hospitals (unpublished data; presented as a communication at the 4th International Symposium on *Acinetobacter*, Eilat, Israel, 1996).

The application of highly discriminatory molecular typing techniques [AFLP and pulsed-field gel electrophoresis (PFGE)] to examples of three major ribotype groups of isolates from European hospitals confirmed the correlation of ribotypes 1 and 2 with the newly defined clones I and II. A third widely disseminated clone designated III was identified as a new epidemic clone (van Dessel *et al.*, 2004). Analysis of US data collected through the NNIS system between 1987 and 1996 shows a consistent increase in isolates of *Acinetobacter* spp. in the summer months (McDonald, Banerjee and Jarvis, 1999). Interestingly, such a clear seasonal variation was not seen in data from Latin America (Gales *et al.*, 2001).

LABORATORY DIAGNOSIS

Isolation

All the frequently encountered species of *Acinetobacter* grow readily on common laboratory media. In investigating outbreaks, commonly used selective and/or differential media [e.g. MacConkey agar, cystine lactose electrolyte-deficient (CLED) agar] have been made more selective for particular strains with specific antibiotic resistance patterns by the addition of antibiotics (Allen and Green, 1987). Alternatively, a selective medium such as Leeds *Acinetobacter* medium may be used for the selective isolation of most *Acinetobacter* spp. (Jawad *et al.*, 1994). When looking for small numbers in environmental specimens, liquid enrichment in minimal media with vigorous shaking has been useful (Bergogne-Berezin and Towner, 1996). Although *A. baumannii*, genomospecies 3 and 3TU have growth optima of 37 °C, a lower temperature such as 30 °C will ensure that all species are isolated.

Identification

The differentiation of the different genomospecies is not possible using phenotypic characteristics, although some level of discrimination is possible. Some key test findings are summarised in Table 16.1. The great majority of clinical isolates when carefully identified belong to *A. baumannii* (genomospecies 2), with genomospecies 3, *A. johnsonii*, *A. lwoffii* and *A. junii* being found much less frequently (Seifert *et al.*, 1993). Few clinical laboratories have the facilities for the molecular identification of genomospecies and rely on commercial phenotypic systems (e.g. API2ONE [BioMérieux]). Several studies have shown a poor correlation with DNA-based methods (Bernards *et al.*, 1996; Jawad *et al.*, 1998). Ribotyping (Germer-Smidt, 1992) and RNA sequencer fingerprinting (Janssen and Dijkshoorn, 1996), AFLP (Ehrenstein *et al.*, 1996) and ARDRA should all accurately identify individual genomospecies, particularly differentiating 1, 2, 3 and 3TU.

Strain Typing

Besides sporadic cases of *Acinetobacter* infection, outbreaks of nosocomial infections due to *Acinetobacter* spp. have been widely

reported in the medical literature, and they have become an increasing concern in hospitals. To determine the source (environment and/or cross-contamination) and the mode of spread of strains, many typing systems have been developed, from early phenotypic typing (phage typing, serology and bacteriocin typing), to more reliable molecular techniques such as ribotyping (Biendo *et al.*, 1999), analysis of restriction length polymorphisms in chromosomal DNA by PFGE (Gouby *et al.*, 1992; Seifert and Gerner-Smidt, 1995), PCR fingerprinting, ARDRA (Bernards *et al.*, 1997), random amplified polymorphic DNA analysis (RAPD) (Mathai *et al.*, 2001; Levidiotou *et al.*, 2002), AFLP fingerprinting (Janssen and Dijkshoorn, 1996; Koeleman *et al.*, 1997), infrequent restriction site PCR (IRS-PCR) (Wu *et al.*, 2002) and repetitive extragenic palindromic sequence-based PCR (REP-PCR) (Snelling *et al.*, 1996). All of these methods have shown excellent discrimination between clinical isolates, but at present there is no agreed standard method. Moreover, in most clinical laboratories, these techniques are not available. Instead, antibiogram and biotyping are used, although they remain relatively unreliable typing approaches. Improvement in typing methods and their wider adoption is necessary to identify relatedness between strains during outbreaks of infections and in wards with endemic *Acinetobacter* infection, in order to apply suitable measures.

TREATMENT

One problem associated with *Acinetobacter* spp. has been their intrinsic resistance to multiple antibiotics and their particular propensity to rapidly acquire antibiotic resistance. Since 1975, increasing resistance in clinical isolates of *Acinetobacter* spp. has been described. In the most recent surveillance reports, a high incidence of resistance among clinical isolates of *Acinetobacter* spp. has been reported to a range of antibiotics including aminoglycosides, third-generation cephalosporins, fluoroquinolones, extended-spectrum penicillins and monobactams (Hanberger *et al.*, 1999; Gales *et al.*, 2001). In a study conducted in more than 100 ICUs in five European countries, resistance rates to ciprofloxacin, gentamicin, piperacillin and ceftazidime frequently exceeded 50% (Hanberger

et al., 1999). There was a wide variation in resistance patterns detected in different countries, which is likely to reflect both species distribution and differences in the use of antibiotics. A recent study of 595 *Acinetobacter* spp. isolates in the United Kingdom demonstrated that 89% of *A. baumannii* was resistant to ceftazidime and more than 40% showed resistance to ciprofloxacin or gentamicin (Henwood *et al.*, 2002). The carbapenems retain the most activity, but recent reports have demonstrated increasing resistance to both imipenem and meropenem (Afzal-Shah and Livermore, 1998; Da Silva, Leitao and Peixe, 1999). Outbreaks of infection have been described in which sulbactam or colistin are the only antibiotics to which isolates of *A. baumannii* are susceptible (Corbella *et al.*, 2000; Fierobe *et al.*, 2001).

Species of *Acinetobacter* other than *A. baumannii* such as *A. lwoffii*, *A. johnsonii* and *A. junii* are less commonly associated with nosocomial infections and are generally more susceptible to antibiotics (Bergogne-Berezin and Towner, 1996). However, there is some evidence that resistance in these species is increasing.

β -Lactams

β -Lactamase production is the most common resistance mechanism, and *Acinetobacter* spp. produce a wide variety of enzymes (Table 16.3).

Carbapenems

Imipenem remains one of the most efficient drugs in treating *Acinetobacter* infections, and it has been used worldwide. At the time of writing, emergence and spread of imipenem-resistant strains has been observed in outbreaks, particularly when imipenem has been heavily used (Weinbren *et al.*, 1998; Zarrilli *et al.*, 2004). β -Lactams capable of destroying imipenem have been described (Table 16.3). Other mechanisms, particularly loss of outer membrane proteins, have been described as mechanisms for carbapenem resistance (Bou *et al.*, 2000).

Table 16.3 Summary of the properties of some of the β -lactamases identified in *Acinetobacter* spp.

β -Lactamase	Location of gene	Substrate	Properties	References
TEM-1/2	Plasmid	Penicillins	Common in nearly all Gram-negative bacterial. Inhibited by clavulanic acid	Vila <i>et al.</i> (1993)
CARB-5	Plasmid	Penicillins	Inhibited by clavulanic acid	Paul <i>et al.</i> (1989)
ACE-1	Chromosomal	Cephalosporins	Confers resistance to cephalosporins. Possesses some activity against penicillins. No activity against aztreonam or the broad-spectrum cephalosporins, only ACE-1 hydrolyses cefuroxime	Segal, Nelson and Elisha (2004)
ACE-2				
ACE-3				
ACE-4				
Amp-C				
PER-1	Plasmid	ESBL ^a	Confers resistance to all β -lactam antibiotics including aztreonam but not cefotaxim. No activity against carbapenems. Inhibited by clavulanic acid	Vahaboglu <i>et al.</i> (1997)
VEB-1	Plasmid	ESBL ^a		Poirel <i>et al.</i> (2003)
OXA-21	Plasmid	Carbapenems	Class D, non-metalloenzymes with weak carbapenemase activity	Paton <i>et al.</i> (1993), Bou, Oliver and Martinez-Beltran (2000), Afzal-Shah, Woodford and Livermore (2001)
ARI-1 (OXA-23)				
OXA-24–27				
IMP-1	Plasmid and integrons	Carbapenems	Metalloenzymes with potent carbapenemase activity. Confers resistance to carbapenems and all β -lactam classes except monobactams	Chu <i>et al.</i> (2001), Da Silva <i>et al.</i> (2002), Yum <i>et al.</i> (2002), Nishio <i>et al.</i> (2004)
IMP-2				
IMP-4				
IMP-5				
VIM-2				

^a Extended-spectrum β -lactamase.

Aminoglycosides

Aminoglycosides can be inactivated by a large range of aminoglycoside-modifying enzymes, and none of them (including the most active against *Acinetobacter*, amikacin) is totally immune from enzymatic inactivation (Seward, Lambert and Towner, 1998).

Fluoroquinolones

When first introduced, fluoroquinolones were highly active against *Acinetobacter*, but particularly the acquisition of mutations in the *gryA* and *parC* genes has resulted in a high incidence of fluoroquinolone resistance (Moreau *et al.*, 1996; Brisse *et al.*, 2000). A novel efflux pump has been described in *Acinetobacter* (Magnet, Courvalin and Lambert, 2001).

Other Antibiotics

Tetracycline resistance is mediated by the efflux proteins TetA and B in *A. baumannii* (Guardabassi *et al.*, 2000). Plasmid-mediated resistance to both trimethoprim and chloramphenicol has also been described (Bergogne-Berezin and Towner, 1996).

Therapeutic Options for Treatment of *Acinetobacter* Infection

The therapeutic options for treating *Acinetobacter* nosocomial infection are restricted because of the high levels of antimicrobial resistance. Based on the results of animal models of *Acinetobacter* pneumonia (Joly-Guillou *et al.*, 1997), carbapenems or carboxypenicillins have been used, in most cases in combination with an aminoglycoside, as an empirical treatment for nosocomial pneumonia. Other strategies have used β -lactamase inhibitors, and among them, sulbactam has demonstrated therapeutic efficacy largely because of its intrinsic activity as a single drug against *Acinetobacter* (Rodríguez-Hernández *et al.*, 2001; Wood *et al.*, 2002). Although sulbactam has been shown to be superior to clavulanic acid and tazobactam, it does not enhance the activity of β -lactams (Higgins *et al.*, 2004).

Single Drug versus Combination Therapy

In vitro studies have shown that bactericidal activities of β -lactams including imipenem and the β -lactamase inhibitor sulbactam are very slow acting, as time-dependent drugs, whereas aminoglycosides, fluoroquinolones and rifampicin are rapidly bactericidal (concentration-dependent drugs) (Xirouchaki and Giamarellou, 1992; Joly-Guillou *et al.*, 1995; Marques *et al.*, 1997). Therefore, combinations of drugs remaining active against *Acinetobacter* spp., such as an aminoglycoside plus a β -lactam (ticarcillin or third-generation cephalosporin or imipenem), could offer synergistic and highly bactericidal effects (Marques *et al.*, 1997). For isolates highly resistant to aminoglycosides and/or fluoroquinolones, non-conventional and/or unusual combinations have been proposed, based on *in vitro* data, and outcomes favourably observed in treating patients (Xirouchaki and Giamarellou, 1992; Joly-Guillou *et al.*, 1995; Bajaksouzian *et al.*, 1997; Marques *et al.*, 1997). Owing to multiple mechanisms of resistance in clinical isolates, each strain must be tested carefully to individual and combined antibiotics, using appropriate *in vitro* techniques, and the choice of a suitable combination should take into account data obtained from animal models (Wolff *et al.*, 1999). Despite increasing development of resistance to ciprofloxacin, options using a new fluoroquinolone, levofloxacin, in combination with imipenem or amikacin in an animal model constitute promising therapeutic strategies. Extrapolation from *in vitro* data is questionable, whereas experimental infection in animal models had a better correlation with outcome.

OTHER AEROBIC GRAM-NEGATIVE BACILLI

INTRODUCTION

There are a large number of aerobic Gram-negative bacilli, other than *Acinetobacter* spp., identified as non-fermenters. They include three genera that are important in medical bacteriology: *Stenotrophomonas*, *Flavobacterium* and *Alcaligenes*. They have undergone many changes in taxonomy in recent years: previously classified on a phenotypic basis (morphology, motility and metabolism), the taxonomy of these bacteria has been revised using genetic information, and the position of the species has been reassigned to different genera on the basis of nucleic acid hybridisation. The current nomenclature of the species belonging to these three genera is summarised in Table 16.2. The other objective of this table is to summarise the previous designations of each species and changes in nomenclature. Table 16.2 includes genera and species of minor clinical importance, but as saprophytic bacteria present in the environment, they are found in water, soil and foodstuffs. In the hospital environment, moist items may be contaminated with such bacteria.

STENOTROPHOMONAS MALTOPHILIA (PREVIOUSLY *XANTHOMONAS*)

Taxonomy

Stenotrophomonas maltophilia (1994) was transferred from the genus *Xanthomonas* identified as *Pseudomonas maltophilia* according to *Bergey's Manual* (Juni, 1984). *Pseudomonas maltophilia* had been previously assigned to the genus *Xanthomonas* on the basis of phenotypic and genotypic characteristics (Swings, De Vos and Van den Mooter, 1983). These bacteria are characterised by the presence of a single or a small number of polar flagella (motile bacteria), frequently pigmented colonies (yellow or yellowish-orange), oxidase-negative reaction and acidified sugars (except for rhamnose or mannitol). They are generally proteolytic. *Stenotrophomonas maltophilia* is the most clinically important species of the genus.

Habitat and Pathogenicity of *S. maltophilia*

Isolated from soil, plants, water and raw milk, this ubiquitous bacterium is frequent in the hospital environment and is an emerging opportunistic pathogen (Denton and Kerr, 1998). It has been isolated from ventilatory equipment (thermal humidifying units), moist respirometers, dialysis fluids and antiseptic solutions. In patients, *S. maltophilia* may be isolated from multiple sites of nosocomial infections: respiratory tract, endocarditis, bacteraemia, meningitis and UTI. *Stenotrophomonas maltophilia* is implicated also in severe cutaneous infections, cellulitis and abscesses. This bacterium produces proteolytic enzymes and other pathogenic extracellular enzymes such as DNAase, RNAase, elastase, lipase, hyaluronidase, mucinase and haemolysin which contribute to the severity of these infections in otherwise immunodepressed patients in ICUs (Von Gravenitz, 1985; Denton and Kerr, 1998). A high incidence of infection with *S. maltophilia* occurs in patients with cancer, leukaemia or lymphoma, and *S. maltophilia* is increasingly implicated in pulmonary superinfections in cystic fibrosis (CF) patients. A molecular epidemiological study of patients with CF and strains from both the hospital and home environment showed some evidence of cross-infection from the hospital, but most strains carried by patients were unique and probably represented acquisition from water and other home environments (Denton *et al.*, 1998). This hypothesis is supported by the finding that clinical and environmental strains do not separately cluster when examined for intraspecies diversity (Berg, Roskot and Smalla, 1999). *Stenotrophomonas maltophilia* is frequently associated with other bacteria at sites of infection. However, it is increasingly isolated as the sole pathogen because of its high natural

resistance to most major antibiotics and to the selective pressure exerted by antibiotic treatments in ICUs (Rolston, Messer and Ho, 1990; Wolff, Brun-Buisson and Lode, 1997; Denton and Kerr, 1998).

Bacteriological Characteristics of *S. maltophilia*

Stenotrophomonas maltophilia does not produce pigments, and colonies are pale yellowish or non-pigmented. Selective media are used for isolating *S. maltophilia* from the environment (Juhnke and des, 1989) or from human specimens with the addition of imipenem (10 mg/l) because of the intrinsic resistance of the organism to carbapenems and/or vancomycin to inhibit Gram-positive bacteria when the specimen is contaminated. The oxidase reaction is negative or weakly and slowly positive. The main biochemical characteristics are summarised in Table 16.4. Four characteristics are important for identifying *S. maltophilia*: it produces lysine decarboxylase, hydrolyses aesculin and gelatin, and requires L-methionine for growth (50 mg/l in synthetic mineral broth) (Swings, De Vos and Van den Mooter, 1983). Other tests – indole, urease and ornithine decarboxylase production – are negative. Identification by more specific tests and/or automated methods has been described (Gilardi, 1985; Kampfner and Dott, 1988; Tenover, Mizuki and Carlson, 1990).

Stenotrophomonas maltophilia Susceptibility/Resistance to Antibiotics

Stenotrophomonas maltophilia is intrinsically resistant to most antibiotics by chromosomally mediated mechanisms. Variation in susceptibility is often seen, even on repeat testing of the same isolate. This is probably due to differential expression of the two chromosomally located β -lactamases L1 and L2 (Avison *et al.*, 2002). L1 is a metallo-enzyme responsible for the intrinsic resistance to carbapenems, and L2 is a broad-spectrum cephalosporin (Denton and Kerr, 1998). The availability of Zn^{++} in the media has the effect on the minimum inhibitory concentration (MIC) values for imipenem but not meropenem (Cooke *et al.*, 1996). Production of a metallo- β -lactamase can be detected using a diffusion gradient strip combined with ethylenediamine-tetraacetic acid (EDTA) (Etest) (Walsh *et al.*, 2002). Fluoroquinolone resistance is probably due to mutation in *gyrA/parC*, and two efflux pump genes have been described with both fluoroquinolones and β -lactams as substrates (Poole, 2004).

β -Lactams

Stenotrophomonas maltophilia is susceptible only to latamoxef and to combinations of ticarcillin and clavulanic acid or piperacillin plus tazobactam. It is naturally resistant to imipenem and meropenem

by production of a carbapenemase. In addition, mutants exhibit high-level expression of constitutive L1 and L2 β -lactamases (Akova, Bonfiglio and Livermore, 1991).

Aminoglycosides

Only a few strains are susceptible to gentamicin, neomycin and kanamycin; although AAC6' has been described, most resistance is probably due to reduced uptake (Denton and Kerr, 1998).

Fluoroquinolones

Stenotrophomonas maltophilia is generally resistant to quinolones. New agents such as temafloxacin and sparflaxacin seem to be more active than ciprofloxacin. Resistance to quinolones in *S. maltophilia* is generally associated with resistance to chloramphenicol and to doxycycline in more than 50% of cases. This resistance is associated with alteration of outer membrane proteins (Lecso-Bornet *et al.*, 1992).

Other Antibiotics

Clinical strains of *S. maltophilia* are variably susceptible to minocycline, rifampicin and the combination trimethoprim–sulphamethoxazole. Nosocomial infections due to *S. maltophilia* require combination therapy including rifampicin plus fluoroquinolone or ticarcillin plus clavulanic acid, associated with tobramycin or amikacin or even a trimethoprim–sulphamethoxazole combination. The new tetracycline derivative tigecycline shows promising activity (Betriu *et al.*, 2002).

CHRYSEOBACTERIUM (PREVIOUSLY FLAVOBACTERIUM)

Definition and Taxonomy

The genus *Chryseobacterium* (*Flavobacterium* spp.) is a large group of non-motile, oxidase-positive (except for *Chryseobacterium odoratum*), Gram-negative, strictly aerobic, non-fermentative bacilli. Species belonging to the genus *Chryseobacterium* are summarised in Table 16.2. The taxonomy of the genus has been evolving (MacMeekin and Shewan, 1978; Bruckner and Colonna, 1995), and two *Flavobacterium*-like species, initially designated groups Iif and Iij, have been transferred recently to the genus *Sphingobacterium* and designated species *Weeksella virosa* and *Weeksella zoohelcum*, respectively, in the new proposed nomenclature (Bruckner and Colonna, 1995). These latter species differ from *Flavobacterium* spp., in that they do not metabolise sugars: they are rarely recovered from human specimens, and unlike *Flavobacterium* spp., they are very susceptible to most antibiotics.

Table 16.4 Main characteristics and tests for identifying aerobic Gram-negative bacilli

Genera	Morphology	Oxidase	G + C%	Characteristics
<i>Acinetobacter</i>	Non-motile, diplobacilli, coccobacilli	–	38–55	No pigment. Glucose acidified by genospecies 1–4 (<i>A. baumannii</i> , <i>A. calcoaceticus</i> , <i>A. haemolyticus</i>)
<i>Stenotrophomonas</i>	Motile, polar flagella	– (<i>S. maltophilia</i> , negative or weak, slowly positive)	62	Yellowish-orange or lemon (straw) pigment, gelatin hydrolysis
<i>Alcaligenes</i>	Motile, degenerated, peritrichous	+	57–69	No pigment, no gelatine hydrolysis (<i>A. denitrificans</i> subsp. <i>xylooxidans</i> : carbohydrate assimilation)
<i>Flavobacterium</i>	Non-motile	+	30–42	Bright yellowish-orange pigment or light yellow, non-diffusible
<i>Burkholderia</i>	Motile, polar lophotrichous, flagella	+	67.4–69.5	Diffusible pigment yellow or violet, greenish-yellow or brownish-black (in 10% of strains)
<i>Pseudomonas</i>	Motile, polar monotrichous, flagella	Generally +	57–70	Pigments, bluish-greenish-yellow (<i>P. aeruginosa</i> : pyocyanin, pyoverdin; <i>P. fluorescens</i> : pyoverdin, greenish; <i>P. stutzeri</i> : wrinkled rough colonies, carotenoid pigment)

G + C%, DNA base composition (mol%).

Five other *Flavobacterium* spp. have been renamed as *Sphingobacterium* spp. and *Pseudomonas paucimobilis* is designated *Sphingomonas paucimobilis* (Table 16.2): these 'new species' are of minor clinical significance. Several other taxonomic changes have occurred regarding *Flavobacterium* spp. (Bergogne-Berezin, 1996), and the genus *Flavobacterium* is 'survived' by the transfer to this group of several unnamed species (CDC groups Ve2, Iie, Iih, Iii; *Pseudomonas oryzihabitans* becoming *Flavimonas oryzihabitans*), these species being of low pathogenicity (Esteban *et al.*, 1993) (Table 16.2).

Epidemiology and Pathogenicity

Chryseobacterium spp. are ubiquitous organisms and are found in the hospital environment. Environmental studies have traced their source from contaminated water, ice machines and humidifiers (Pichinoty *et al.*, 1985). Epidemiological markers used for delineating outbreaks of *Flavobacterium meningosepticum* infections were phenotypes of resistance and serology based on the 0 antigenic type. Nine 0 serovars have been identified: A–H and K. The C serovar is isolated in the Far East, whereas serovar G predominates in European countries and has been isolated from clinical samples in ICUs (tracheal aspirations, expectorations and sinuses). New typing procedures, such as ribotyping (Colding *et al.*, 1994), based on molecular biology are being investigated. These bacteria are implicated in various nosocomial infections: *Chryseobacterium meningosepticum* and *Chryseobacterium multivorum* are the predominant species isolated in septicaemia, meningitis and endocarditis (Brunn *et al.*, 1989; Hsueh *et al.*, 1996). Many cases of meningitis due to *F. meningosepticum* have been observed in neonates (Abrahamsen, Finne and Lingaas, 1989) and, infrequently, in immunocompromised patients. In adults, *F. meningosepticum* has been isolated from cases of pneumonia, postoperative bacteraemia and meningitis, usually associated with severe underlying pathologies. Rare cases of community-acquired *C. meningosepticum* meningitis have been cited, and *Chryseobacterium indologenes* has been associated with infections on indwelling devices (Hsueh *et al.*, 1996).

Bacteriology

Chryseobacterium spp. grow between 5 and 30 °C, but the strains isolated from clinical material grow at 35 °C. On nutrient agar, they produce colonies 1–2 mm in diameter, frequently pigmented light yellow or yellowish-orange because of a non-diffusible pigment. The degree of pigmentation may be more pronounced at lower temperatures (15–20 °C). The metabolism is strictly aerobic, and sugars are metabolised by the oxidative pathway [except for *C. odoratum* and *Sphingobacterium multivorum* (Pichinoty *et al.*, 1985) which do not acidify glucose] (Table 16.3). Indole-positive species (*Chryseobacterium breve*, *C. meningosepticum* and *C. indologenes*) are usually strongly proteolytic. Aesculin, citrate and urease tests are variably positive (Bruckner and Colonna, 1995).

Antimicrobial Susceptibility

Chryseobacterium strains isolated from clinical specimens are resistant to many antibiotics: they are generally resistant to all aminoglycosides, third-generation cephalosporins, penicillins (mezlocillin, piperacillin and ticarcillin), aztreonam and imipenem. The most active antibiotics against *C. meningosepticum* are rifampicin, clindamycin (MICs 1–4 mg/l) and ciprofloxacin, which has proven efficacious in treating pneumonia in paediatric patients. Cases of neonatal septicaemia have been treated with clindamycin combined with piperacillin. Other antibiotic combinations have been used in treating *Chryseobacterium* infections (Von Gravenitz, 1985; Raimondi, Moosdeen and Williams, 1986). Susceptibility to β -lactams can be recovered by combining β -lactamase inhibitors with β -lactam antibiotics.

ALCALIGENES

Taxonomy

An early description of *Bacillus alcaligenes faecalis* made by Petrusky in 1896 reported the observation of a Gram-negative motile bacillus, isolated from beer and from human stools. Later, many species have been included in the genus *Alcaligenes* on the basis of DNA–DNA and DNA–rRNA hybridisations. Major taxonomic changes have occurred: *Achromobacter xylosoxidans* has been transferred to the genus *Alcaligenes* as *Alcaligenes xylosoxidans* subsp. *xylosoxidans*. An additional group, *Agrobacterium* spp., has been included in the species *Alcaligenes* and has been isolated in clinical conditions (Popoff *et al.*, 1984) (Table 16.2). All *Alcaligenes* strains are short rods (0.5–2.6 μ m), Gram-negative, motile, with one to eight peritrichous (non-polar) flagella, usually described as degenerated. They are oxidase and catalase positive. Other species included in the genus *Alcaligenes* – *Alcaligenes faecalis*, *Alcaligenes piechaudii* and *Alcaligenes xylosoxidans* subsp. *denitrificans* – are not saccharolytic. The only saccharolytic species is *A. xylosoxidans* subsp. *xylosoxidans*. Not all *Alcaligenes* spp. possess specific physiological or biochemical characteristics (Table 16.4), and those most commonly involved in nosocomial infections are *A. faecalis* and *A. xylosoxidans* subsp. *denitrificans*.

Epidemiology and Pathogenicity

Alcaligenes faecalis and *A. denitrificans* are isolated from various environmental sources such as respirators, haemodialysis systems, intravenous solutions and even disinfectants (Duggan *et al.*, 1996; Gomez-Cerezo *et al.*, 2003). They have occasionally been isolated from a variety of human specimens: blood, faeces, sputum, urine, cerebrospinal fluid, wounds, burns and swabs from throat, eyes and ear discharges. *Alcaligenes* strains do not seem to possess any specific virulence determinants, and they are an infrequent cause of hospital-acquired infection in patients with severe underlying disease. Rare cases of peritonitis, pneumonia, bacteraemia or UTI are found in the literature. In many instances, the organism is considered as a coloniser, and its pathogenic role remains somewhat controversial. Nosocomial outbreaks are usually associated with an aqueous source of contamination (Von Gravenitz, 1985; Duggan *et al.*, 1996). Recent findings have underlined that *Alcaligenes* spp. were isolated predominantly from respiratory tract specimens, particularly from sputum of CF patients (Saiman *et al.*, 2001).

Bacteriology

Identification of *Alcaligenes* spp. is based on the main characteristics cited above. In addition, alkalisation of a series of substrates (malonate, acetamide, allantoin, histidine and itaconate), gelatin hydrolysis (*A. faecalis* and *A. piechaudii*) and several negative characteristics help identify *Alcaligenes* spp., usually by using commercial multitest systems (Kampfer and Dott, 1988; Tenover, Mizuki and Carlson, 1990). Assimilation tests (carbohydrates) and the presence of nitrate and nitrite reductases contribute to the precise identification of species. A combination of substrate assimilation tests and automated ribotyping has been shown to be a rapid and simple approach to the identification of this difficult group of bacteria (Clermont *et al.*, 2001).

Antimicrobial Susceptibility/Resistance

Most strains are resistant to aminoglycosides, chloramphenicol and tetracyclines. They are variably susceptible to trimethoprim–sulphamethoxazole and to newer β -lactams. *Alcaligenes xylosoxidans* subsp. *xylosoxidans* has been shown to be susceptible to ureidopenicillins, latamoxef, imipenem and some fluoroquinolones (ciprofloxacin and

ofloxacin (Mensah, Philippon and Richard, 1989; Philippon *et al.*, 1990; Bizet, Tekaiia and Philippon, 1993). There have been several reports of multiple β -lactam resistance in *A. xylosoxidans* to broad-spectrum penicillins, with two resistance phenotypes (Philippon *et al.*, 1990): these phenotypes result from constitutive β -lactamase production. Moreover, three different types of cephalosporinases and the presence of other β -lactamases have been demonstrated. Treatment of infections due to this uncommon opportunistic organism requires combination therapy including extended-spectrum β -lactams (piperacillin and imipenem) and fluoroquinolones (ciprofloxacin and sparfloxacin) or amikacin with fluoroquinolones (levofloxacin) or trimethoprim-sulphamethoxazole.

MISCELLANEOUS AEROBIC GRAM-NEGATIVE BACILLI

Many aerobic, non-fermentative, Gram-negative bacilli which either are poorly characterised as species or have an uncertain positive taxonomy may occasionally be isolated from patients with predisposing medical conditions. Some species have been excluded from the genus *Pseudomonas*, such as *Pseudomonas cepacia* (Goldmann and Klinger, 1986; Rabkin *et al.*, 1989; Werneburg and Monteil, 1989), *Pseudomonas gladioli* and *Pseudomonas pickettii*, and form a new group, designated *Burkholderia* spp. (Yabuuchi *et al.*, 1992), with corresponding species *Burkholderia cepacia*, *Burkholderia pickettii* and *Burkholderia gladioli*, as listed in Table 16.2. These organisms are cited in clinical conditions, with the presence of *B. cepacia* in the hospital environment (Drabick *et al.*, 1996; Pankhurst and Philpott-Howard, 1996) and in patients with CF superinfection (Walters and Smith, 1993; Simpson *et al.*, 1994; Govan and Deretic, 1996; Segonds *et al.*, 1996) or of *B. pickettii* in nosocomial infection (Poty, Denis and Baufine-Ducrocq, 1987). Included recently in the *Burkholderia* genus, *Burkholderia mallei* and *Burkholderia pseudomallei* are environmental organisms predominantly found in Asian countries: they are responsible for infections in animals and may be transmitted in humans, the name of the disease being melioidosis (severe pneumonia with subacute cavitating forms) (Sookpranee *et al.*, 1991). Still classified in the genus *Pseudomonas*, *Pseudomonas stutzeri* is an organism of low pathogenicity and has been isolated in pneumonia and septicaemia (Potvliege *et al.*, 1987). The new group *Comamonas* (Table 16.2) has been formed of *Pseudomonas testosteroni* and *Pseudomonas acidovorans* (Tamaoka, Ha and Komagata, 1978), which are ubiquitous organisms, potentially pathogenic as saprophytic opportunistic species. Listed in the *Alcaligenes* spp., *A. xylosoxidans* (Table 16.2), renamed *Alcaligenes xylosoxidans*, is involved in human infections such as osteomyelitis (Walsh, Klein and Cunha, 1993). Among these multiple Gram-negative bacilli with taxonomic uncertainties, the most frequent and significant is *B. cepacia*, which is increasingly isolated from pulmonary sites of infections, particularly in CF patients. They produce a variety of virulence factors, mainly exoenzymes, and the organism is responsible for rapid pulmonary deterioration in CF patients (Goldmann and Klinger, 1986; Segonds *et al.*, 1996).

Haemophilus spp.

Derrick W. Crook¹ and Derek W. Hood²

¹Department of Clinical Microbiology, John Radcliffe Hospital, Oxford, UK; and ²Molecular Infectious Diseases, Department of Paediatrics, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK

INTRODUCTION

Haemophilus influenzae is the most important cause of human disease among the species belonging to this genus. It is a free-living, human-adapted organism without another reservoir (Kilian, 1976). Its principal habitat is the nasopharynx, but it is found inhabiting other mucosal surfaces including the genital tract and occasionally the intestinal tract. Despite being a fastidious organism which is relatively difficult to grow, it was first isolated and named in 1890 by Pfeiffer who mistakenly thought it was the cause of the contemporaneous influenza pandemic (Turk, 1982). The name *H. influenzae* persisted, even though it was soon recognized that influenza virus caused flu.

Haemophilus influenzae has come to prominence in many unexpected ways. Despite the erroneous suggestion it caused flu, it was soon recognized to be a leading cause of spontaneous childhood meningitis and other life-threatening infections (Pittman, 1930, 1931). It was the first organism where a vaccine made of its polysaccharide capsule conjugated to a carrier protein successfully produced protective immunity in children (Eskola *et al.*, 1990). The impressive success of this vaccine in nearly eliminating childhood *H. influenzae* disease led the way to the development of further conjugate vaccines to the major childhood pathogens, *Streptococcus pneumoniae* and *Neisseria meningitidis*. Restriction enzymes (*Hind*II and *Hind*III), one of the essential tools of recombinant technology, were discovered from studies into the molecular biology of *H. influenzae*, and Werner Arber, Daniel Nathans and Hamilton O. Smith were awarded the Nobel Prize for this discovery. Most recently, *H. influenzae* was the first free-living organism to be whole sequenced using novel methodology developed by Craig Venter and The Institute for Genomic Research which was a crucial building block in making it possible to sequence whole genomes including the human genome (Fleischmann *et al.*, 1995).

DESCRIPTION OF THE ORGANISM

Taxonomy

The full taxonomic root of this bacterium is Phylum *Proteobacteria*, class *Gammaproteobacteria*, order *Pasteurellales*, family *Pasteurellaceae*, genus *Haemophilus* and species *influenzae*. A 16S phylogenetic tree is depicted in Figure 17.1 and shows the relationship of the human members of the genus in relationship to *Escherichia coli*. The closely related, human-adapted *Haemophilus* spp. include *H. parainfluenzae* (the most plentiful colonizing member of this genus), *H. haemolyticus*, *H. aegyptius*, *H. ducreyi*, *H. segnis*, *H. aphrophilus* and *H. paraphrophilus*. Relatively little is known of these other

commensal *Haemophilus* spp., and they will be referred to briefly at the end of the chapter.

Characteristics

Haemophilus influenzae is a small (0.2–0.3 to 0.5–0.8 µm) Gram-negative, nonmotile, coccobacillus (Plate 9). The organism grows well on rich medium and produces 2–3-µm grey translucent colonies after 18–25 h of incubation. It is a fastidious microorganism and has specific growth requirements that are used in routine clinical microbiology for identification. It does not grow on nutrient agar, such as Columbia agar, without the growth supplements X factor (haemin) and V factor (NAD). By contrast *H. parainfluenzae* only requires V factor for growth. Rich medium such as chocolate agar supports the growth of *Haemophilus* spp. and is the preferred solid medium for propagation of the organism. Growth is enhanced in the presence of 5% CO₂. The precise differentiation of human *Haemophilus* spp. as outlined in Table 17.1 is beyond the scope of most diagnostic laboratories; however, satisfactory differentiation can be achieved using X or V dependence and growth characteristics on a blood agar (preferably horse blood) exhibiting presence or absence of haemolysis and satellitism to a staphylococcal streak. Speciation using sequence analysis of ribosomal genes is a better method for speciation of haemophili than biochemical tests; however, this technology is currently available only to some reference laboratories.

Population Genetics

The population of *H. influenzae* has an unusual organization. There is a minority population of capsulate (serotypable) and an abundant population of noncapsulate (nonserotypable) strains consisting of independently evolving lineages. The capsulate strains produce one of six chemically and antigenically distinct polysaccharide capsules, a, b, c, d, e and f. The evolutionary origins of their capsules are unclear; however, the capsulate strains form a relatively nondiverse population of organisms consisting of few lineages compared to the much more diverse population of noncapsulate strains (Plate 10). This suggests that capsule may have been acquired relatively recently in the evolutionary past of *H. influenzae*. The outstanding and dramatic feature arising from this differentiation of *H. influenzae* into capsular types by Margaret Pittman in 1930 was the recognition that childhood invasive disease was caused almost exclusively by type b capsulate strains (Pittman, 1930, 1931). More detailed characterization of the population structure of the species shows that the majority of childhood invasive type b isolates cluster in a relatively small number of related lineages.

Figure 17.1 A neighbour-joining tree of 16s sequences of the main members of the genus *Haemophilus* compared to other important related *Pasteurellaceae* and rooted on *Escherichia coli* as an out-group (data were obtained from the RDP website: <http://rdp.cme.msu.edu/html/analyses.html>). The bootstrap values on the nodes indicate low values (i.e. <70) for many of the tree branches and limited confidence for the topology represented here (tree produced by MEGA version 2.1: <http://www.megasoftware.net/>). However, this represents an approximate estimate of the relationship between these species.

Table 17.1 Characteristics of *Haemophilus* species

Species	Factor requirement		Haemolysis	Fermentation			
	X	V		Glucose	Sucrose	Lactose	Mannose
<i>H. influenzae</i>	+	+	-	+	-	-	-
<i>H. haemolyticus</i>	+	+	+	+	-	-	-
<i>H. ducreyi</i>	+	-	-	-	-	-	-
<i>H. parainfluenzae</i>	-	+	-	+	+	-	+
<i>H. parahaemolyticus</i>	-	+	+	+	+	-	-
<i>H. segnis</i>	-	+	-	+	+	-	-
<i>H. paraphrophilus</i>	-	+	-	+	+	+	+
<i>H. aphrophilus</i>	-	-	-	+	+	+	+

The appreciation of the population structure of *H. influenzae* described above has been substantially advanced by the development of a sequence-based typing scheme based on multilocus sequence typing (MLST) (Plate 8) (Meats *et al.*, 2003). This is accessible through the Internet (<http://haemophilus.mlst.net>). MLST and modifications of this scheme for studying the population of *H. influenzae* is giving new insights into the relationships between lineages of this organism. This powerful technique has effectively replaced other typing schemes such as outer membrane protein (OMP) or restriction fragment length polymorphism typing schemes and will facilitate investigation of the changing epidemiology of *H. influenzae*. It is likely that improvements in characterizing *H. influenzae* by MLST will be made by including further and more variable genes in the typing scheme.

PATHOGENICITY

Haemophilus influenzae expresses a number of cell-surface features that are required for establishment of colonization in the nasopharynx

within individual hosts and importantly play a role in the virulence of bacteria in susceptible hosts (virulence factors).

Capsule

Haemophilus influenzae can express one of six antigenically distinct (serotype a-f) polysaccharide capsules that exist loosely associated with the outer surface of the bacterium. Expression of a capsule is considered a prerequisite for *H. influenzae* to be able to cause invasive disease and correspondingly bacteria expressing serotype b capsule account for the majority of invasive disease isolates (Zwahlen *et al.*, 1989). The serotype b capsule consists of a negatively charged phosphodiester-linked linear polymer of disaccharide units of polyribosyl ribitol phosphate (PRP). The genes required for its synthesis are located on a large DNA segment (*cap* locus) that is a compound transposon (Kroll, Loynds and Moxon, 1991). Serum antibody to serotype b capsular polysaccharide is protective, and the Hib vaccine, designed to elicit production of this antibody, is now

routinely used in national childhood immunization schemes. The vaccines currently in use contain PRP conjugated covalently to a protein carrier. The proposed roles for capsular polysaccharide in *H. influenzae* are increased resistance to phagocytic host defences in the bloodstream, by interfering with binding of serum components, and increased resistance to desiccation during host-to-host passage.

Lipopolysaccharide

Lipopolysaccharide (LPS) is a complex glycolipid found on the Gram-negative bacterial cell wall that is essential for membrane integrity. In *H. influenzae*, the LPS comprises two distinct, covalently linked regions, the lipid A and the core oligosaccharide (Richards *et al.*, 2001). LPS is an important virulence determinant of *H. influenzae*, playing a key role in the processes of bacterial colonization, persistence and survival in the human host, but also represents an ideal target for bactericidal as well as endotoxin-neutralizing antibodies (Bouchet *et al.*, 2003). The lipid A portion of *H. influenzae* LPS is embedded in the outer membrane and mediates the endotoxic effects of the LPS molecule responsible for some of the pathophysiology associated with severe infection. The host response to *H. influenzae* lipid A is primarily mediated by activation of Toll-like receptor 4 (TLR4), facilitated by binding of LPS-binding protein (LBP) and the host cell receptor, CD14 (Lazou Ahren *et al.*, 2001; Wang *et al.*, 2002). This interaction triggers a cascade of signalling events, resulting in secretion of a variety of potent mediators and cytokines produced primarily by activated macrophages and monocytes. The overproduction of these effector molecules, such as interleukin-1 and tumour necrosis factor- α , contributes to the pathophysiology of endotoxic shock, which can include hypotension, disseminated intravascular coagulopathy and multiorgan failure. The structure of *H. influenzae* oligosaccharide can be characterized in terms of a conserved inner core region and a variable outer core region which can display significantly different patterns of sugars between strains. The oligosaccharide can influence interactions of the bacteria with host cells and components of the host immune system.

Pili and Other Adhesion Proteins

Successful colonization by *H. influenzae* requires that the bacterium binds to host cells, particularly at its normal site of colonization in the nasopharynx. Fundamental to this binding are a number of cell-surface proteins that act as adhesins. Pili (or fimbriae), typically polymeric hair-like structures that extend from the bacterial cell surface, are associated with binding to respiratory epithelial cells. Not all *H. influenzae* express pili, and other nonpili membrane proteins are involved in the attachment process. At least four other major adhesins have now been identified in Hib and NTHi, including the Hap, HMW1, HMW2 and Hia/Hsf proteins, the distribution of which is highly variable between strains (Kubiet *et al.*, 2000; Hardy, Tudor and St Geme III, 2003).

Phase and Antigenic Variation

Bacterial pathogens must be able to adapt to the changing microenvironments within and between hosts. *Haemophilus influenzae* has evolved a mechanism to alter the expression of cell-surface proteins, or enzymes required for the biosynthesis of the LPS molecule, through the inclusion of microsatellites within the respective genes. These microsatellites, typically composed of tetranucleotide repeats, are unstable and promote random on-off switching of expression of the respective genes within a population (phase variation). This mechanism provides considerable flexibility in the patterns of antigens that can be expressed at any given time within a population of *H. influenzae* (Bayliss, Field and Moxon, 2001).

EPIDEMIOLOGY

Understanding the host-organism relationship is benefited by splitting the consideration of epidemiology into first capsulate *H. influenzae* type b (Hib) and second noncapsulate or nonserotypable *H. influenzae*. An important general characteristic applicable to both categories of the organism is that it is a human-restricted commensal without another reservoir. Also, the emergence of antibiotic resistance is equally applicable to all types of *H. influenzae*.

Haemophilus influenzae type b

Haemophilus influenzae type b (Hib) is a major cause of childhood infectious disease. Understanding the transmission of Hib is important to a better understanding of the distribution and occurrence of disease. Acquisition probably occurs by close bodily contact, and the main source is other children (Barbour *et al.*, 1995). Acquisition is usually followed by carriage where the organism dwells for months harmlessly in the nasopharynx; however, in a few susceptible individuals, acquisition appears to be the point in time when invasive disease commences. Carriage rates vary after birth, and risk factors for carriage are the following: advancing age from birth until 4 years, underdeveloped country, crowding, day-care attendance and presence of siblings. The major preventative factor is Hib immunization which near eliminates carriage and produces a marked herd effect protecting against disease (Barbour *et al.*, 1995).

Disease caused by Hib has been near eliminated by the highly efficacious conjugate Hib vaccine (Peltola, 2000). Consequently, the epidemiology of disease deals with either the prevaccine era in developed countries or those parts of the world where vaccine has not been nationally implemented. It is estimated that as much as 60% of the world's children are unimmunized and therefore are unprotected (Peltola, 2000).

The main disease manifestations of Hib disease are meningitis, primary bacteraemia, pneumonia, epiglottitis and arthritis (Figure 17.2) (Peltola, 2000). The major burden of disease caused by Hib is meningitis. Its relative importance varied or varies between countries or regions of the world. In the USA, before implementation of vaccine, it was the most important cause of childhood meningitis accounting for 80% of cases (Schlech III *et al.*, 1985; Schuchat *et al.*, 1997) (Figure 17.3). In UK, it accounted for approximately 50% of cases in the pre-Hib vaccine era. By contrast, it was a much less prominent cause of meningitis in the meningitis belt of Africa where meningococcal meningitis causes the vast majority of cases.

There are a large number of factors that affect the epidemiology of disease (Frazer, 1982; Broome, 1987). Age is a major factor. Neonates are protected, and disease peaks by 9 months of age and declines to very low levels by 4 years. The age-specific disease incidence is inversely related to serum antibodies to Hib. Male gender is a risk factor of disease. Disease incidence varies by country and ethnic origin. For example, the incidence among Native Americans less than 4 years of age exceeded 150 cases/100 000/year compared to an

Figure 17.2 A pie chart showing Hib disease manifestations in percentages.

Figure 17.3 Incidence of *H. influenzae*, *N. meningitidis* and *S. pneumoniae* in the USA prior to Hib immunization.

Figure 17.4 Cases of Hib-invasive disease in England and Wales per annum in children aged less than 14 years. The data were obtained from the HPA website <http://www.hpa.org.uk>

incidence for the whole country of 50 cases/100 000/year (Peltola, 2000). Mortality from Hib meningitis in resource-rich countries was approximately 5%. Long-term morbidity occurred in at least 10% of meningitis cases and consisted of deafness and neurological and learning deficits (Peltola, 2000).

Implementation of Hib-conjugate vaccine has had the largest impact on the epidemiology of disease. It has near disappeared from North America and Europe. There has been a similar dramatic decline in the Gambia, a resource-poor country with a very high incidence before the implementation of a national immunization programme (Peltola, 2000). There has been a striking re-emergence of Hib disease in UK over the past 5 years (Trotter, Ramsay and Slack, 2003) (Figure 17.3). There is compelling data suggesting that Hib disease occurring in Hib-immunized cases was associated with receiving combined Hibacellular pertussis vaccine that is associated with lower Hib antibody levels (McVernon *et al.*, 2003). This formulation was introduced in UK during 2000. As UK disease was increasing before this date and a similar, but smaller, rise has been reported in the Netherlands (Rijkers *et al.*, 2003), it raises the prospect that other factors may also be contributing to the re-emergence of Hib-invasive disease.

Noncapsulate or Nonserotypable *H. influenzae*

Noncapsulate or nonserotypable *H. influenzae* (Nc-hi) is acquired soon after birth, and 20–80% of people of all ages carry the organism.

These organisms rarely cause bacteraemia and meningitis. However, it is prominently associated with otitis media, sinusitis, chronic bronchitis and pneumonia (Murphy and Apicella, 1987; Murphy, 2003). Otitis media is one of the most common childhood diseases, and *H. influenzae* is one of the leading bacterial species cultured from middle ear fluid of cases. In a comprehensive Finnish study where bacteria were grown from middle ear fluid, 23% were *H. influenzae*, 23% were *Moraxella catarrhalis* and 26% were *Streptococcus pneumoniae* (Kilpi *et al.*, 2001). The other diseases are largely conditions of adults. Chronic bronchitis and pneumonia associated with *H. influenzae* occur more frequently with advancing age.

Antibiotic Resistance

Until the early 1970s all strains of *H. influenzae* were susceptible to antibiotics. In 1973 the first isolate resistant to ampicillin and producing β -lactamase was reported. Thereafter, not only did the prevalence of β -lactamase-producing strains rapidly rise in most parts of the world, but strains resistant to tetracycline, chloramphenicol and trimethoprim or multiresistant to the same antibiotics emerged in all parts of the world (Powell, 1988). Prevalence of resistance has remained reasonably constant over the past 10 years and in Europe and ranges from 10 to 20% in most countries (Schito, Debbia and Marchese, 2000). Large integrative and conjugative resistance elements encode most of the ampicillin (TEM β -lactamase producing), tetracycline and chloramphenicol resistance (Dimopoulou *et al.*, 1997; Dimopoulou *et al.*, 2002). Ampicillin resistance also arises from ROB- β -lactamase probably associated with small plasmids. Increasingly, strains are being isolated, which are β -lactamase negative, and the mechanism of resistance in these strains has been shown to be associated with mutations in penicillin-binding protein genes (Ubukata *et al.*, 2001). Trimethoprim resistance arises from mutations in chromosomal dihydrofolate reductase (de Groot *et al.*, 1988).

CLINICAL FEATURES

Hib-Invasive Disease

Clinical features of invasive disease in infants vary from a mild febrile illness, a feature of so-called occult bacteraemia, to fully blown sepsis syndrome with meningitis. Presentation of meningitis in children varies largely depending on age. Infants may present with as little as fever and irritability. Severe cases of all ages present with altered mental status, stiff neck and systemic features of sepsis, which in a few cases may be associated with disseminated intravascular necrosis including a purpuric rash and septicaemic shock. Examination of CSF and blood culture is the main means of identifying the bacterial aetiology. Obtaining CSF from cases must be performed with care, and steps must be taken to ensure that there is no evidence of cerebral oedema, usually by head CT (only in older children).

Epiglottitis is a particularly acute life-threatening manifestation of invasive Hib disease and is a medical emergency. Presentation of this disease manifestation is dramatic and may result in rapid death from sudden respiratory obstruction. Cases usually have general features of sepsis consisting of fever, tachycardia and tachypnoea. Pronounced local signs and symptoms consisting of rapid progression, sore throat, hoarseness, barking cough and stridor are encountered. The epiglottitis is inflamed and swollen on visualization, but great care must be taken in examining these cases, as they may suddenly obstruct during examination of the epiglottitis.

Pneumonia is a major and relatively unrecognized manifestation of Hib disease. Its recognition came principally from studies in the Gambia (Mulholland *et al.*, 1997). The main features are fever with tachypnoea and other features of respiratory distress such as nasal

flaring and intercostal in drawing. Chest examination and X-ray are the key means of diagnosing pneumonia.

Septic arthritis presents with general features of sepsis and local features of arthritis. In a child this is often manifested by unwillingness to use a limb and pain on moving the joint. Examination and culture of joint fluid is the key procedure to make the diagnosis.

A rare manifestation is cellulitis in children. An unusual and specific form of cellulites involving the neck in adults has been described. This presents as a severe septic illness with marked oedema of the skin and an associated violaceous rash. The skin is exquisitely tender to palpation.

Many of these disease manifestations have also been associated with cases of invasive disease caused by *H. influenzae* type f. This has become more apparent as the implementation of Hib-conjugate vaccine (Campos *et al.*, 2004).

Noncapsulate *H. influenzae*

The main disease manifestation associated with Nc-hi is otitis media (Murphy, 2003). This is one of the leading childhood illnesses and is associated with irritability and on otoscopy an inflamed tympanic membrane. In a proportion of cases the eardrum will perforate and pus will discharge from the ear. Tympanocentesis is the most reliable means of diagnosing and determining the aetiology of otitis media.

A high proportion of cases of conjunctivitis in children will be caused by Nc-hi. *Haemophilus aegyptius* has a particular proclivity for causing conjunctivitis. Culture of conjunctival swabs is the main test for making a diagnosis. One extreme clinical manifestation of disease caused by *H. aegyptius* is Brazilian purpuric fever, a fulminant septicæmic and often fatal disease.

Sinusitis is another disease manifestation associated with Nc-hi. Sinusitis is principally associated with local features of infection. There is local pain, a sense of pressure in the head and occasionally visible pus draining from the ostia of the sinuses. Occasionally there may be local facial oedema and in very severe cases spread to involve adjacent structures such as the orbit and even the meninges and brain. Diagnosis is based mainly on radiological examination, either skull X-ray with special views or CT scan. There will be opacification of the sinus and often a fluid level. Aspiration, examination and culture of fluid from the affected sinus are the best direct means of determining the aetiology of sinusitis.

Chronic bronchitis and exacerbations of bronchitis are the main disease manifestations associated with Nc-hi in adults. The exact aetiological role of bacteria in chronic bronchitis and exacerbations of bronchitis is not conclusively established. However, *H. influenzae* and *S. pneumoniae* are cultured from sputum of up to 50% of cases, and many clinicians believe these bacteria play a role in the disease.

Severe invasive disease may be caused by Nc-hi. Neonatal sepsis has been well described and has features similar to group B streptococcal neonatal sepsis (Wallace Jr. *et al.*, 1983). In adults the main manifestation is pneumonia, particularly among the elderly (Murphy and Apicella, 1987; Murphy, 2003). An unusual manifestation is meningitis, usually in association with previous head trauma, particularly skull fracture (Kaufman *et al.*, 1990).

LABORATORY DIAGNOSIS

Direct examination of CSF and sterile site aspirates using Gram stain is valuable. Pleomorphic Gram-negative coccobacilli are often visible, though it may require careful scrutiny of the sample, as counter staining is poor with neutral red. Some labs use safranin or carbol fuchsin to better stain the organism.

Direct culture (whether from a sample or a blood culture bottle) on chocolate agar and incubation in 5–10% CO₂ is the best way of growing *H. influenzae* on solid medium. Blood culture using any of the major commercial systems is effective at growing *H. influenzae*.

Differentiation of *Haemophilus* spp. in the routine laboratory can be satisfactorily achieved by using X, V and X&V requirements. In addition, further confirmation can be achieved by culture on blood agar in the presence of a staphylococcal streak for satellitism and haemolysis.

Antibiotic susceptibility testing using antibiotic discs must be done on media supplemented to support the growth of *Haemophilus* spp. Susceptibility testing by discs is frequently inaccurate, and it is important that disc zone size readings are supplemented by measurement of β -lactamase activity. One simple method is an acidometric paper strip method (Slack, Wheldon and Turk, 1977). Chloramphenicol disc susceptibility is also frequently inaccurate and should be supplemented with an assay for chloramphenicol-acetyl-transferase activity (Azemun *et al.*, 1981).

Direct detection of capsular type b antigen has been used as a means of rapidly diagnosing the presence of Hib in CSF, sterile-site fluid or urine. This is seldom used since the implementation of Hib vaccine. PCR of CSF has been developed for diagnosing *Haemophilus* spp. meningitis (van Ketel, de Wever and van Alphen, 1990; Radstrom *et al.*, 1994; Corless *et al.*, 2001).

Capsular typing of *H. influenzae* can be performed serologically; however, it is subject to error. A PCR-based method has been developed; it overcomes many of the problems of cross-reactions and is used in reference laboratories to characterize strains (Falla *et al.*, 1994).

TREATMENT OF INFECTION

The first-line antibiotic treatment of Hib-invasive disease is a third generation cephalosporin with good CSF penetration. Ceftriaxone and cefotaxime, in meningitis doses and depending on age, are both effective for treating *H. influenzae* meningitis and septicaemia. Cefuroxime must not be used for treating cases of meningitis, as it is less effective than the third generation cephalosporins (Schaad *et al.*, 1990). Adjunctive steroid therapy has been shown to reduce the rate of deafness in children with Hib meningitis (McIntyre *et al.*, 1997). In resource-poor countries, chloramphenicol alone (depending on the prevalence of chloramphenicol resistance) or in combination with ampicillin is effective therapy.

The antibiotic treatment of noninvasive infections such as otitis media, sinusitis and chronic bronchitis is much less clear. There are large meta-analyses that have not demonstrated a clear-cut advantage to administer antibiotics to all cases (Froom *et al.*, 1990; Saint *et al.*, 1995; Del Mar, Glasziou and Hayem, 1997; Glasziou *et al.*, 2004). There is some suggestion that subgroups are benefited by antibiotic treatment. Even with limited data supporting the use of antibiotics, many clinicians administer antibiotics. There are reasonable grounds for giving amoxicillin orally as the first-line. Alternatives include amoxicillin-clavulinate, trimethoprim, tetracycline (for adults only) and quinolones (for adults only).

PREVENTION AND CONTROL

The main preventative measure for controlling Hib disease is PRP-conjugate vaccines. There are a number of highly efficacious conjugate vaccine preparations. They consist of the capsular antigen PRP conjugated to one of the following: tetanus toxoid (PRP-T), outer membrane protein (PRP-OMP) or mutant diphtheria toxoid (PRP-CRM, HbOC). The vaccine is administered as part of childhood immunization in most resource-rich countries, and depending on the country, three doses are given at intervals between 2 and 6 months of age. Many countries give a booster dose at 1–2 years of age.

Antibiotic prophylaxis of close contacts of cases has been used to prevent secondary cases; however, this is only rational where the contacts have not received Hib vaccine. Rifampicin 20 mg/kg orally once a day for 4 days eradicates carriage and is believed to prevent secondary cases.

OTHER HAEMOPHILUS SPP.

Haemophilus ducreyi

Haemophilus ducreyi is the aetiological agent of the sexually transmitted disease soft chancre. This is rarely encountered in resource-rich countries. However, it is more prevalent in resource-poor countries and is more particularly associated with prostitution. A major feature of infection is the potentiation of HIV transmission and possible modification of the disease in HIV-infected people (Nasio *et al.*, 1996; Lewis, 2003).

The incubation is approximately 2 weeks. The main disease manifestations are painful genital ulcers from a few mm to 2 cm in size with a defined margin that start as an erythematous papule. The margin may be ragged in some cases and has a grey base which is relatively friable and bleeds. Inguinal lymphadenopathy occurs in most cases and in half they will suppurate and discharge spontaneously.

Diagnosis is essentially clinical. The organism is fastidious and difficult to grow without highly specialized media and prolonged culture. Nucleic acid amplification using PCR offers the best prospect for a reliable laboratory diagnostic test for this infection (Lewis, 2003). Treatment is with antibiotics. The following regimens are recommended by the CDC or WHO: azithromycin 1 gm as a single dose orally, ciprofloxacin 500 mg PO twice a day for 3 days, cephtriaxone 250 mg IM in a single dose, amoxicillin clavulanate (500/125 mg) PO three times a day for 7 days and trimethoprim-sulfamethoxazole (TMP-SMX) two tablets twice a day for 7 days.

Haemophilus parainfluenzae

Haemophilus parainfluenzae is the most abundant colonizing *Haemophilus* spp. It is a well-adapted commensal; all people are colonized soon after birth, and it is rarely associated with disease. Case reports of infective endocarditis, neurosurgical meningitis and prosthetic device infection have been published. It has been isolated from brain and liver abscesses. Its role in lung disease and nephropathies is less clear.

Rare Species

Haemophilus aphrophilus, *H. paraphrophilus* and *H. segnis* are very rare causes of disease. The best recognized disease manifestation is infective endocarditis. However, they account for less than 2% of all the cases of infective endocarditis. Given that these species are slow growing, they may be missed if blood cultures are not incubated for prolonged periods. These species may be rarely found causing brain or lung abscess. They can also be cultured from empyaema fluid.

Bordetella spp.Qiushui He¹, Jussi Mertsola² and Matti K. Viljanen³¹National Public Health Institute, Kiinamyllynkatu; ²Department of Pediatrics; and ³Department of Medical Microbiology, University of Turku, Kiinamyllynkatu, Turku, Finland**INTRODUCTION**

Bacteria of the genus *Bordetella* are small, aerobic and Gram-negative coccobacilli. Currently, the genus consists of seven species: *Bordetella pertussis*, *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. hinzii*, *B. holmesii* and *B. trematum*. The species can be distinguished from each other based on their phenotypic characteristics (Table 18.1). All but *B. avium* have been isolated from humans. Of these *Bordetella* species, *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* are the most important human pathogens.

THE GENUS BORDETELLA***Bordetella pertussis***

Bordetella pertussis was first isolated in 1906 (Bordet and Gengou, 1906) and classified as *Haemophilus pertussis* because of the requirement of blood in laboratory media. However, unlike *Haemophilus*, *B. pertussis* does not need growth factors X (haematin) and V (nicotinamide adenine dinucleotides). From the 1960s on, *Bordetella* was used as a new genus name in honour of Bordet who was the first to report its isolation.

Bordetella pertussis is the most important cause of pertussis (whooping cough) in humans. No animal or environmental reservoir is known for this organism. *Bordetella pertussis* is fastidious and grows slowly (mean generation time 2.3–5 h) (Rowatt, 1957; Hoppe, 1999a). The colonies of *B. pertussis* on culture plates usually become visible after 3–4 days of incubation.

Bordetella parapertussis

Bordetella parapertussis was first described in 1937 (Bradford and Slavin, 1937; Eldering and Kendrick, 1937; Eldering and Kendrick, 1938). *Bordetella parapertussis* usually causes cough with posttussive vomiting that is similar to, but often milder than, that due to *B. pertussis*. Some severe cases of parapertussis have also been reported (Heininger *et al.*, 1994). The incidence of human *B. parapertussis* infections has not been definitely established. Current estimations may be too low (He *et al.*, 1998). *Bordetella pertussis*, *B. parapertussis* and *B. bronchiseptica* share a number of virulence factors and tropism for the ciliated cells of the respiratory tract. Unlike *B. pertussis*, *B. parapertussis* does not secrete pertussis toxin (Table 18.2). *Bordetella parapertussis* is less fastidious than *B. pertussis*. The colonies of *B. parapertussis* on culture plates usually become visible after 2–3 days of incubation.

Table 18.1 Characteristics of *Bordetella* species^a

Characteristics	<i>B. pertussis</i>	<i>B. parapertussis</i>	<i>B. bronchiseptica</i>	<i>B. avium</i>	<i>B. hinzii</i>	<i>B. holmesii</i>	<i>B. trematum</i>

^b Included in acellular pertussis vaccines.

^c Production of tracheal cytotoxin is not regulated by the *bvg* locus.

Bordetella parapertussis has also been found in lambs, in which it causes chronic nonprogressive pneumonia (Hoppe, 1999b). Human and ovine strains have been found to be genetically different (Table 18.3), suggesting that transmission between sheep and humans is unlikely.

Bordetella bronchiseptica

Bordetella bronchiseptica is a common respiratory pathogen in a wide range of mammalian species, including cats, dogs, horses, rabbits and swine (Woolfrey and Moody, 1991). In humans, reports of respiratory disease caused by *B. bronchiseptica* remain rare and usually involve children and immunocompromised patients. As early as in 1926, *B. bronchiseptica* was isolated from a child with signs and symptoms compatible with pertussis (Lautrop, 1960).

Bordetella bronchiseptica shares substantially similar sets of virulence factors with *B. pertussis* and *B. parapertussis*. *Bordetella bronchiseptica* does not produce pertussis toxin (Table 18.2). *Bordetella bronchiseptica* grows faster on culture plates than *B. pertussis* and *B. parapertussis*, and the colonies usually become visible after 24 h of incubation.

Table 18.3 Insertion sequence elements (copy number) in the genomes of *Bordetella* species^a

Species (hosts)	IS481	IS1001	IS1002
<i>B. pertussis</i>	+(80–100)	–	+(4–7)
<i>B. parapertussis</i> (human)	–	+(20–21)	+(9)
<i>B. parapertussis</i> (sheep)	–	+(23–29)	–
<i>B. bronchiseptica</i> (mainly pig)	–	+(1–7)	–
<i>B. bronchiseptica</i> (guinea pig/horse)	+(1–2)	–	–
<i>B. bronchiseptica</i> (koala)	–	–	+(1)
<i>B. holmesii</i> (human)	+(8–10)	+	–
<i>B. avium</i>	–	–	–
<i>B. hinzii</i>	–	–	–
<i>B. trematum</i>	–	–	–

+, presence of insertion sequence (IS) element; –, absence of IS element.

^a Adapted from van der Zee *et al.* (1997), Gerlach *et al.* (2001) and Reischl *et al.* (2001).

Other *Bordetella* species

Bordetella avium, first described in 1984 (Kerstens *et al.*, 1984), is a respiratory pathogen of birds. *Bordetella avium* infections have not been identified in humans. *Bordetella hinzii* was isolated from the respiratory tracts of birds, where it appears to be nonpathogenic (Vandamme *et al.*, 1995) and has rarely been found in immunocompromised patients. *Bordetella holmesii*, first described in 1995 (Weyant *et al.*, 1995), was originally isolated from blood cultures of young adults. Recently, it has been isolated from the nasopharyngeal samples of schoolchildren with cough (Yih *et al.*, 1999). *Bordetella trematum* has been isolated from wounds and ear infections in humans (Vandamme *et al.*, 1996). *Bordetella petrii* was recently isolated from an anaerobic, dechlorinating bioreactor culture enriched from river sediment. This *Bordetella* species has been proposed as a member of the genus *Bordetella* and is the first member of the genus isolated from the natural environment and capable of anaerobic growth (Von Wintzingerode *et al.*, 2001).

Bordetella genome

The genome sequencing of *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* has been completed (Table 18.1) (<http://www.sanger.ac.uk/projects/Microbes/>). The sequencing of the *B. avium* genome has been just finished. The representative strains selected for sequencing were Tohama I of *B. pertussis*, strain 12822 of *B. parapertussis* and strain RB50 of *B. bronchiseptica*. Tohama I was isolated in the 1950s in Japan (Kasuga *et al.*, 1954) and was later widely used in laboratory studies and in the production of some acellular pertussis vaccines. *Bordetella parapertussis* strain 12822 was isolated in Germany in 1993 (Heininger *et al.*, 2002). *Bordetella bronchiseptica* strain RB50 was isolated from the naris of a 3-month-old New Zealand White rabbit (Cotter and Miller, 1994). The genome of *B. pertussis* has been found to be significantly smaller than that of *B. bronchiseptica* and *B. parapertussis*. It remains to be shown whether the adaptation of *B. pertussis* to humans as the only host has resulted from the deletion of some genes of the *B. bronchiseptica* strain or whether the adaptation has also required the acquisition of significant amounts of novel genetic material by horizontal transfer (Gerlach *et al.*, 2001). The genome of *B. avium* is also much smaller than that of *B. bronchiseptica*.

Systematics and Evolution

Genetically, *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* are closely related and should be considered subspecies of a single species (*B. bronchiseptica* cluster) with different host adaptation (Musser *et al.*, 1986; Arico *et al.*, 1987; Gerlach *et al.*, 2001). They have probably also diverged from a common ancestor. However, typical differences among the three species have been found. As for virulence factors, pertussis toxin and tracheal colonization factor are only produced by *B. pertussis* (Arico and Rappuoli, 1987; Finn and Stevens, 1995). A large genetic locus required for O antigen biosynthesis has been identified in *B. parapertussis* and *B. bronchiseptica* (Preston *et al.*, 1999). This locus is replaced by an insertion sequence (IS) in *B. pertussis*. Three IS elements have been characterized among the *Bordetella* species (van der Zee *et al.*, 1996b, 1997) (Table 18.3). IS481 and IS1002 have been found in all *B. pertussis* strains, whereas IS1001 has only been found in some *B. bronchiseptica* isolates. Regarding *B. parapertussis*, both IS1002 and IS1001 have been identified in human isolates and only IS1001 in sheep isolates. Human *B. parapertussis* isolates are homogeneous, whereas sheep *B. parapertussis* isolates are heterogeneous (van der Zee *et al.*, 1996b, 1997; Yuk *et al.*, 1998). The IS481 element was identified in *B. holmesii* isolates, whereas none of the three IS elements occur in *B. avium*, *B. hinzii* and *B. trematum* (Gerlach *et al.*, 2001; Reischl *et al.*, 2001).

PATHOGENESIS

The putative virulence factors of *B. pertussis* can be divided into adhesins and toxins. The adhesins facilitate the adherence of the bacterium to host ciliated respiratory epithelial cells and immune effector cells, and the toxins are involved in the clinical disease process by acting locally or systemically. The pathogenesis of infectious diseases caused by *B. pertussis*, *B. parapertussis* and *B. bronchiseptica* has been extensively studied, whereas very little is known about the pathogenesis of infections caused by the other *Bordetella* species. The expression of nearly all adhesins and toxins is positively regulated by the products of the *bvgAS* locus (Matto *et al.*, 2001). BvgA and BvgS comprise a two-component signalling system that mediates transition between three identifiable phases – a virulent (Bvg⁺) phase, an avirulent (Bvg⁻) phase and an intermediate (Bvgⁱ) phase – in response to specific environmental signals (Cotter and Miller, 1997; Matto *et al.*, 2001). The Bvg⁺ phase has been shown to be necessary and sufficient for respiratory tract colonization. The Bvgⁱ phase is characterized by the expression of a subset of Bvg-activated factors as well as factors maximally expressed in this phase. The Bvgⁱ phase is assumed to be involved in aerosol transmission. In the Bvg⁻ phase, *B. pertussis* and *B. bronchiseptica* express different sets of proteins. The Bvg⁻ phase of *B. bronchiseptica* has been shown to be necessary and sufficient for survival under nutrient-restricted conditions. The interplay between *B. pertussis* and host cells is a complex process. Using high-density DNA microarrays, a recent *in vitro* study showed that *B. pertussis* induces mucin gene transcription of human bronchial epithelial cells and then counters this defence by using mucin as a binding substrate. The early transcriptional response of these cells to *B. pertussis* is dominated by altered expression of cytokines, DNA-binding proteins and NF- κ B-regulated genes (Belcher *et al.*, 2000).

Adhesins

Filamentous Hemagglutinin (FHA)

Filamentous haemagglutinin (FHA) is a 220-kDa surface-associated protein which functions as the major adhesin of *B. pertussis*. The gene for FHA, *fhaB*, has coding potential for a protein of 367 kDa (Delisse-Gathoye *et al.*, 1990; Domenighini *et al.*, 1990). More than one-third of this precursor protein is later cleaved in a complex posttranslational maturation process to unveil the biologically active polypeptide (Locht *et al.*, 1993). FHA contains an Arginine-Glycine-Aspartic acid (Arg-Gly-Asp) peptide sequence, which binds sulfated glycosaminoglycans on cell-surface proteoglycans (Brennan and Shahin, 1996). Deletion of the *FHA* gene in mutant *B. pertussis* strains reduces bacterial adherence to epithelial cells by 70% (Menozzi *et al.*, 1994). A recent *in vitro* study shows that secreted and cell-associated FHA can elicit proinflammatory and proapoptotic responses in human monocytic cells and bronchial epithelial cells, suggesting a previously unrecognized role for FHA in *B. pertussis*-host interaction (Abramson, Kedem and Relman, 2001).

Immunization with FHA protects mice against aerosol challenge with *B. pertussis* (Oda *et al.*, 1984; Sato and Sato, 1984). In humans, addition of FHA to an acellular pertussis vaccine containing only PT increased protection against pertussis in a vaccine efficacy trial (Ad Hoc Group for the Study of Pertussis Vaccines, 1988; Storsaeter and Olin, 1992). FHA is included in all multicomponent acellular pertussis vaccines.

Fimbriae

Fimbriae (FIM), also known as pili and agglutinogens, are long filamentous protrusions that extend from the bacterial cell surface and facilitate binding of the bacterium to host cells. *Bordetella pertussis*

produces two antigenically different fimbriae, named serotype 2 and serotype 3. These are constructed of a major subunit, encoded by *fim2* and *fim3* genes, respectively, and a minor subunit encoded by *fimD* (Willems, van der Heide and Mooi, 1992). Fim2 and Fim3 are proteins of 22 and 22.5 kDa (Steven *et al.*, 1986; Ashworth *et al.*, 1988). Both Fim2 and Fim3 play a role in the attachment of *B. pertussis* to the cells of immune systems, including monocytes, their FimD interacting with the host integrin (Hazenbos *et al.*, 1995; Geuijen *et al.*, 1997).

Purified Fim have been shown to protect mice against respiratory infection with *B. pertussis* (Oda *et al.*, 1985; Ashworth *et al.*, 1988). The protection is serotype specific (Robinson *et al.*, 1989). In humans, the protection provided by whole-cell vaccines is to some extent serotype specific (Preston and Carter, 1992). Acellular vaccines including Fim, in addition to PT, FHA and Prn, are more effective against pertussis than those without Fim (Gustafsson *et al.*, 1996; Olin *et al.*, 1997).

Pertactin

The pertactin (Prn) of *B. pertussis* is a 69-kDa outer membrane protein occurring in all virulent strains. The sizes of Prn molecules produced by *B. parapertussis* and *B. bronchiseptica* are 70 and 68 kDa, respectively (Montaraz, Novotny and Ivanyi, 1985; Li *et al.*, 1991). Prn has been shown to play a role in attachment to and invasion in host cells (Leininger *et al.*, 1991; Brennan and Shahin, 1996). Like FHA, Prn has an Arg-Gly-Asp-binding site interacting with host integrins (Brennan and Shahin, 1996). Prn has two immunodominant regions, 1 and 2, composed of repeating units of five (GGXXP) and three (PQP) amino acids, respectively (Charles *et al.*, 1991). Region 1 is adjacent to the Arg-Gly-Asp motif. The crystal structure of Prn indicates that region 1 forms a loop protruding from a β -sheet (Emsley *et al.*, 1996).

Prn elicits protective immunity in both animals and humans (Brennan *et al.*, 1988; Shahin *et al.*, 1990; Cherry *et al.*, 1998; Storsaeter *et al.*, 1998). In a vaccine efficacy trial, addition of Prn to an acellular vaccine containing PT and FHA provided increased protection against pertussis (Greco *et al.*, 1996; Gustafsson *et al.*, 1996; Olin *et al.*, 1997). Prn is included in most acellular pertussis vaccines.

Recently, divergence was found between the Prn of *B. pertussis* vaccine strains and that of circulating strains (Mooi *et al.*, 1998; Mastrantonio *et al.*, 1999; Mooi *et al.*, 1999; Cassidy *et al.*, 2000; Fry *et al.*, 2001). This polymorphism is essentially limited to region 1. The three most prevalent Prn variants are Prn1–3. Vaccine strains produce Prn1 (Boursaux-Eude *et al.*, 1999; Mooi *et al.*, 2000), whereas Prn2 is the predominant type found in circulating strains. Prn1 and Prn3 are similar, with a difference of only two amino acids, whereas Prn2 has an additional repeat. The biologic importance of this variation remains to be determined. A recent study showed that individuals infected with Prn2 strains have significantly less antibodies to Prn1 than those infected with Prn3 strains or those immunized with a booster dose of acellular vaccines containing Prn1 (He *et al.*, 2003). Moreover, in contrast to vaccine recipients and subjects infected with Prn3 strains, individuals infected with Prn2 strains had hardly any antibodies to the variable region of Prn1.

Polymorphisms have also been reported in the Prn of *B. bronchiseptica*. The variation occurs in both immunodominant regions (Boursaux-Eude and Guiso, 2000; Register, 2001). The Prn of *B. parapertussis* appears to be more conserved than that of *B. pertussis* and *B. bronchiseptica* (Boursaux-Eude and Guiso, 2000).

Toxins

Pertussis Toxin

Pertussis toxin (PT) is a 106-kDa hexameric protein with many biological activities *in vivo*. It is a member of the A-B bacterial toxin

superfamily and consists of five distinct subunits, S1–S5 (Tamura *et al.*, 1982). The molar ratios of the subunits in the native molecule are 1:1:1:2:1. The A portion or S1 subunit has enzymatic activities, catalyzing the transfer of the ADP-ribose moiety of NAD⁺ to a family of G proteins which are involved in signal transduction pathways within the host cell. The B oligomer (S2–S5) facilitates attachment of PT to the host cell and delivers the toxic action of the S1 subunit to the cell (Tamura *et al.*, 1982). The genes encoding the PT subunits are clustered in an operon typical of many other bacterial toxins. Genetic analysis has shown that each subunit is translated separately and equipped with an aminoterminal signal sequence that is cleaved during transport to the periplasmic space. The holotoxin is then assembled in the periplasmic space and secreted through the outer membrane into the environment of the bacterium (Locht and Keith, 1986; Nicosia *et al.*, 1986).

Immunization with PT has been found to protect against both intracerebral and aerosol challenges with *B. pertussis*. PT has been included in all acellular pertussis vaccines. Divergence has been found in the PT S1 subunit between *B. pertussis* vaccine strains and circulating strains (Mooi *et al.*, 1998; Mastrantonio *et al.*, 1999; Mooi *et al.*, 1999; Cassidy *et al.*, 2000; Fry *et al.*, 2001). Almost all currently circulating strains in Europe and USA have PTs different from those of vaccine strains. The biologic significance of this antigenic variation is not known.

Of the *Bordetella* species, only *B. pertussis* produces PT. Although *B. parapertussis* and *B. bronchiseptica* contain a PT operon, these organisms cannot produce the toxin because a number of mutations occur in the promoter regions of the genes coding for PT subunits (Arico *et al.*, 1987).

Other Virulence Factors

Adenylate cyclase toxin is a bifunctional protein of the RTX (repeat in toxin) family. The toxin is activated by calmodulin (Ladant *et al.*, 1989) inside the cell, where it catalyses the formation of high levels of cyclic AMP (Greenlee, Andreasen and Storm, 1982). Immunization with adenylate cyclase toxin provides protection against bacterial colonization in animal models (Guiso, Szatanik and Rocancourt, 1991). Serum antibodies against the toxin have been found in humans with pertussis (Arciniega *et al.*, 1991).

BrkA (*Bordetella* resistance to killing) protein is a Bvg-regulated molecule, which mediates the serum resistance and adherence of the bacterium (Fernandez and Weiss, 1994). It shares sequence identity with *B. pertussis* Prn and is a member of the diverse group of proteins found in Gram-negative bacteria secreted via an autotransporter mechanism. Sera taken from acellular vaccine recipients or individuals with a history of a recent infection with *B. pertussis* fail to kill wild-type *B. pertussis* but kill BrkA mutant strains (Oliver and Fernandez, 2001). The BrkA protein prevents killing of *B. pertussis* by the antibody-dependent classical pathway of complement (Barnes and Weiss, 2003).

In Gram-negative bacteria, lipopolysaccharide (LPS) generally comprises lipid A, a core oligosaccharide and a long polysaccharide O antigen. The LPS molecule of *B. pertussis* lacks the O antigen because its genetic locus required for O antigen biosynthesis is replaced by an IS element (Preston *et al.*, 1999). The *B. pertussis* LPS molecule has antigenic and immunomodulating properties. LPS may act in synergy with tracheal cytotoxin or other toxins (Amano, Fukushi and Watanabe, 1990; Watanabe *et al.*, 1990; Schaeffer and Weiss, 2001; Ausiello *et al.*, 2002). In addition, it has endotoxin activities.

Tracheal cytotoxin is a specific fragment of *B. pertussis* cell-wall peptidoglycan that causes ciliostasis and damage to ciliated epithelial cells (Hewlett, 1997). Its toxicity is mediated by intracellular production of interleukin-1 and nitric oxide (Heiss *et al.*, 1994).

Tracheal colonization factor (Tcf) is a virulence factor encoded by the *tcfA* gene (Finn and Stevens, 1995). Tcf is pro-

duced by *B. pertussis* but not by *B. parapertussis* or *B. bronchiseptica*. Its C-terminal half shows more than 50% homology to the C terminus of the precursors of Prns of *Bordetella* species, and its N-terminal half contains three Arg-Gly-Asp motifs. When a strain of *B. pertussis* lacking this protein is used to infect mice with an aerosol challenge, the number of bacteria isolated from the tracheas is only 10% of that obtained with the parental strain (Finn and Stevens, 1995). Polymorphism in *tcfA* gene has been reported (Van Loo *et al.*, 2002).

EPIDEMIOLOGY

Epidemiologic Characteristics of Pertussis

Pertussis is an endemic disease with epidemic peaks occurring every 2–5 years (Cherry, 1984). The seasonal pattern of the disease is not clearly marked (Gordon and Hood, 1951; Cherry, 1984). The changing seasonal profile of pertussis was documented in a recent report of a large outbreak in British Columbia, Canada (Skowronski *et al.*, 2002). During this outbreak in 2000, pertussis reports began to increase in March, peaked in June and markedly dropped in July. However, in the past 10 years, during outbreak and nonoutbreak periods, pertussis reports have begun to increase in July, peaking between late August and November.

Transmission is by aerosol from coughing individuals. Contagiousness is highest during the first 2 weeks of illness. The attack rate among vulnerable individuals is 50–100%, depending on the nature of exposure (Lambert, 1965; Mertsola *et al.*, 1983a; Long, Welkon and Clark, 1990). Pertussis morbidity and mortality is higher in females than in males. Immunized contacts can become transiently colonized and remain asymptomatic or symptomatic (Lambert, 1965; Mertsola *et al.*, 1983a; Long, Welkon and Clark, 1990; He *et al.*, 1994). Long-term carriers of *B. pertussis* have not been identified. Pertussis affects all races equally.

Infections caused by *B. parapertussis* are not rare (Heininger *et al.*, 1994; He, Viljanen *et al.*, 1998). The clinical picture of patients infected with *B. parapertussis* is indistinguishable from that of pertussis. However, the disease tends to be less severe than pertussis and its duration shorter than that for pertussis. Lymphocytosis is not found in parapertussis, as *B. parapertussis* does not produce PT. Dual infections caused by *B. pertussis* and *B. parapertussis* have been reported (Reizenstein *et al.*, 1996; Linnemann and Perry, 1977; He, Viljanen *et al.*, 1998).

Incidence and Mortality

In the prevaccine era, almost all children contracted pertussis. In the United States, pertussis was the leading cause of death from vaccine preventable diseases among children less than 14 years of age (Long, 1997). Since the 1950s, standard pertussis vaccines prepared from killed whole-cell *B. pertussis* have been available and are used in most European countries and the USA. After widespread use of vaccines in these countries, incidence and mortality have dramatically decreased (Trollfors, 1984; Cherry *et al.*, 1988). At present it is estimated that, annually, there are 40 million cases of pertussis and that pertussis causes more than 300 000 deaths (Anonymous, 1996). Most deaths occur in infants too young to receive any or all doses of pertussis vaccine.

Pertussis in Older Children and Adults

Studies from countries with high vaccination coverage have shown that pertussis has shifted from infants to older age groups, indicating that pertussis immunizations and childhood pertussis do not provide lifelong immunity (Nelson, 1978; Mertsola *et al.*, 1983a; Thomas, 1989; He *et al.*, 1994; Grimpel *et al.*, 1996; Skowronski *et al.*, 2002). In recent prospective studies conducted in France, the UK and the USA with high vaccination coverage, the incidence of pertussis among

adults ranged from 330 to 508 per 100 000 person-years (Miller *et al.*, 2000; Strelbel *et al.*, 2001; Gilberg *et al.*, 2002). However, the reported incidences of pertussis among adults were only 0–4 over the same period. These figures may reflect poor efficacy of pertussis diagnostics in adults. The pool of undiagnosed pertussis cases in older children and adults provides a reservoir for severe infections in unvaccinated infants (Heininger, Stehr and Cherry, 1992; Wirsing von König *et al.*, 1995; Wang *et al.*, 2002). The role of adults as a source of transmission of pertussis in households is stressed by the findings in 16 families of 23 infants dying of pertussis (Wortis *et al.*, 1996). Thirteen (81%) had been exposed by other family members with cough. Adults accounted for at least 46% of those contacts.

Re-Emergence of Pertussis in Immunized Population

In the past 10 years, resurgence of pertussis has been seen in countries with high coverage of vaccinations with whole-cell vaccines (Bass and Wittler, 1994; De Serres *et al.*, 1995; Andrews, Hecceg and Roberts, 1997; de Melker *et al.*, 1997; Skowronski *et al.*, 2002). In 1996, a sudden increase in pertussis incidence was reported from the Netherlands (total number of reported cases: 319 in 1995 vs. 2778 in 1996) (de Melker *et al.*, 1997). With epidemic cycles expected every 3–5 years and a recent outbreak in 1994, this increase was unexpected. The reported number of cases has since remained high. In 2000, 4837 cases were reported from the Netherlands (WHO, 2002). Many explanations may be given for the re-emergence of pertussis in countries of good vaccination coverage: better awareness of pertussis by clinicians, improved surveillance systems, use of molecular diagnostic tools, waning vaccine-induced immunity, quality of vaccines used in some countries and adaptation of *B. pertussis* to vaccine-induced immunity. As stated above, antigenic divergence has been found between *B. pertussis* vaccine strains and circulating strains in several countries.

CLINICAL MANIFESTATIONS

The incubation period of pertussis ranges from 6 to 20 days. After incubation, the signs and symptoms of the catarrhal stage merge. A typical clinical course of pertussis has three stages: catarrhal, paroxysmal and convalescent. The catarrhal stage usually lasts for less than 2 weeks. The cough of the catarrhal stage becomes increasingly severe and gradually leads to the paroxysmal stage which lasts from 1 to 4 weeks. During the paroxysms, the patient may lean forward with the eyes bulging and tears streaming. Gradually, the face becomes flushed or even cyanotic, and finally, the typical whoop develops after an inspiratory gasp. However, the whoop is not frequently seen in older children or adults. The convalescent stage begins with a decrease in the severity of cough and frequency of paroxysms. The stage can last for several weeks and even months. In an immunized population, mild and atypical clinical cases often occur. Most complications of pertussis, such as pneumonia, pulmonary sequelae, encephalitis and death, occur during the paroxysmal stage. Pertussis is most severe in young infants.

The characteristics of reported cases of pertussis among infants younger than 12 months in the United States were analysed (Tanaka *et al.*, 2003). Of the 18 500 cases reported in 1990s, 91% had paroxysmal cough, 68% had vomiting, 60% had whoop, 56% had apnea, 22% had pneumonia, 1.9% had seizures and 0.3% had encephalopathy. Of these patients, 67% were hospitalized and 0.5% died. Of the 93 fatal cases, 85% had pulmonary infiltrates on admission, 73% had apnea, 41% had pulmonary hypertension, 19% had seizures and 12% had encephalopathy (Vitek *et al.*, 2003).

LABORATORY DIAGNOSIS

The laboratory diagnosis of pertussis is important, particularly in immunized populations, because the signs and symptoms of pertussis

patients are often mild or atypical. The laboratory methods can be generally divided into two main categories: tests detecting the pathogen and its components including culture, polymerase chain reaction (PCR) and the direct fluorescent antibody (DFA) test, and tests assessing the host response to the pathogen, including bacterial agglutination and enzyme immunoassay (EIA). As all methods have limitations in their sensitivity, specificity or practicality, an optimal diagnosis often requires a combination of methods (Onorato and Wassilak, 1987; Müller, Hoppe and Wirsing von König, 1997).

Detection of the Bacterium and Its Components

Bacterial Culture

Culture has remained the gold standard of diagnosis. The specimens should be taken from the posterior nasopharynx, preferably by intranasal aspiration or by swab. Both calcium alginate and Dacron swabs are recommended. Calcium alginate swab is better for culture than Dacron swab (Hoppe and Weiss, 1987). However, Dacron swab on a plastic shaft is preferred for PCR because both the alginate component and the aluminum shaft of calcium alginate swab are found to inhibit a PCR-based assay (Wadowsky *et al.*, 1994). The specimens should be plated immediately onto selective media. Charcoal agar supplemented with 10% horse blood and 40 mg/l of cephalexin is currently the medium of choice (Hoppe, 1999a). *Bordetella* are first identified by colony morphology and gram stain. *Bordetella parapertussis* grows faster than *B. pertussis* and is oxidase negative, whereas *B. pertussis* is oxidase positive. In addition, *B. parapertussis* shows urease activity and pigment formation on tyrosine agar. The two species are also identified by slide agglutination with antisera.

The prevalence of positive cultures is often highest during the first 2 weeks of illness, whereas cultures are seldom positive if cough has lasted for more than 4 weeks. Usually, the sensitivity of culture is less than 50% (higher in unvaccinated infants), and false-negative results are common. Culture plates should be incubated for at least 7 days before being discarded as negative. Extension of incubation of culture plates to 12 days may improve the recovery of *Bordetella* species (Katzko, Hofmeister and Church, 1996).

Polymerase Chain Reaction

Because of its merits in specificity, sensitivity and rapidity, numerous versions of PCR have been developed for the diagnosis of pertussis. Several genes of *B. pertussis* have been used as targets of PCR; the two most common of them are the IS481 and the PT promoter region. PCR has proved superior to culture in the analysis of nasopharyngeal specimens. In some countries, the method has been applied to routine diagnosis of pertussis (He *et al.*, 1996).

Recently, LightCycler real-time PCR has been used for diagnosis of pertussis (Kösters *et al.*, 2002; Sloan *et al.*, 2002). The IS481 has been the target gene of these PCRs. The reactions in the LightCycler system occur in closed glass capillaries. The accumulation of the PCR products is followed online, and the products are subsequently identified using fluorescent hybridization probes or dyes binding to double-stranded DNA (SYBR green I). Product identification can be supported by assessing the specific melting characteristics of the PCR product. Therefore, gel electrophoresis or handling of PCR products is not needed, which reduces the risk of contamination frequently associated with post-PCR amplicon manipulation.

Two studies have shown that IS481-based PCR detects *B. holmesii* in addition to *B. pertussis* (Loeffelholz *et al.*, 2000; Reischl *et al.*, 2001). Further sequencing and restriction fragment length polymorphism analysis have shown that IS481 is present in *B. holmesii*. These results and culture of *B. holmesii* from nasopharyngeal specimens of patients with cough (Yih *et al.*, 1999) suggest that the specificity and predictive value of IS481-based PCR assays for the

diagnosis of pertussis may be compromised. The prevalence of *B. holmesii* infections in humans remains to be determined.

PCR has been applied to the diagnostics of paraptussis, and IS1001 has been used as the target gene. PCR has proved specific and superior to culture in the analysis of nasopharyngeal specimens (van der Zee *et al.*, 1996a; He, Viljanen *et al.*, 1998; Kösters *et al.*, 2002).

Direct Fluorescence Antibody Test

DFA has been used since 1960. This test uses polyclonal or monoclonal fluorescein-labelled antibodies to *B. pertussis* for direct detection of the organism in nasopharyngeal specimens (Hoppe, 1999a; McGowan, 2002). It has the advantage of being rapid and independent of viable organisms. Like culture, DFA is likely to be positive in early disease. Although widely used, this test is compromised by inadequate sensitivity and specificity (Friedman, 1988; Halperin, Bortolussi and Wort, 1989; Ewanowich *et al.*, 1993). False-positive results have occurred because of cross-reactions of antibodies used with the organisms of the nasopharyngeal flora as well as errors of the microscopist (Ewanowich *et al.*, 1993). The DFA test should only be used in combination with culture (Müller, Hoppe and Wirsing von König, 1997).

Detection of Serum Pertussis Antibodies

Various methods have been used to assess serum antibody responses to *B. pertussis*. They include functional antibody assays such as agglutination and toxin neutralization as well as EIAs (Goodman, Wort and Jackson, 1981; Granström *et al.*, 1982; Viljanen *et al.*, 1982; Mertsola *et al.*, 1983b; Meade, Mink and Manclark, 1990; Müller, Hoppe and Wirsing von König, 1997). Agglutination assays do not differentiate between antibody isotypes and have been found less sensitive than EIAs (Mertsola *et al.*, 1983b). Toxin neutralization assays are more laborious and less sensitive than EIAs (Granström *et al.*, 1988). In recent years, EIA has thus become the method of choice in the serologic diagnostics of pertussis (Meade, Mink and Manclark, 1990; Müller, Hoppe and Wirsing von König, 1997).

In EIA, purified antigens of *B. pertussis* such as PT, FHA and Prn are preferable because the assays using them as antigens have better specificity than those using crude bacterial extracts (Mertsola *et al.*, 1990; Isacson *et al.*, 1995; Stehr *et al.*, 1998; De Melker *et al.*, 2000). Demonstration of a rise in the concentration of IgG antibodies to *B. pertussis* in paired sera is usually definite proof of the diagnosis of pertussis. Measurement of IgA antibodies may improve diagnostic efficacy even further (Heininger, 2001). Single-specimen analysis is more practical for routine purposes because paired samples are not easy to obtain (Viljanen *et al.*, 1982; De Melker *et al.*, 2000). For this approach, cut-off values based on the analysis of age-matched controls are needed. EIA has been widely used for the study of pertussis in schoolchildren and adults (Miller *et al.*, 2000; Strebel *et al.*, 2001; Gilberg *et al.*, 2002).

In general, the laboratory confirmation of pertussis is difficult in immunized populations. Combinations of culture, PCR and EIA should be used.

Serotyping

Bordetella pertussis strains produce different combinations of the three fimbrial antigens (1, 2 and 3), which are detected by bacterial agglutination with absorbed antisera or with monoclonal antibodies against these antigens (Mooi *et al.*, 2000). The antigen of serotype 1 is part of the lipooligosaccharide. As it does not change, this antigen is not used for serotyping. Strains of *B. pertussis* with three serotypes (types 1, 2; 1, 2, 3; 1, 3) are circulating in human populations and cause

disease. The use of monoclonal antibodies is currently recommended for serotyping (Mooi *et al.*, 2000).

Genotyping

In the past 10 years, several methods have been developed and applied to the genotyping of *B. pertussis*. They include gene typing by sequencing, multilocus sequence typing, restriction fragment length polymorphism (RFLP) and pulsed-field gel electrophoresis (PFGE).

Gene Typing

PCR-based sequencing of the two virulence genes *Prn* and *PT* (S1 subunit) has been successfully used to detect antigenic shifts in *B. pertussis* populations (Mooi *et al.*, 2000). One of the main advantages of gene typing is that sequencing data can be easily compared between laboratories. However, consensus about the genes and the gene segments to be analysed is required for comparisons (Mooi *et al.*, 2000). An alternative to sequencing, based on LightCycler real-time PCR, has been developed for rapid identification of *Prn* and *PT* variants (Mäkinen *et al.*, 2001, 2002). The method is especially suitable for large-scale monitoring of gene variation in *B. pertussis* isolates.

Multilocus Sequencing Typing

Multilocus sequencing typing (MLST) is derived from the principle of multilocus enzyme electrophoresis, but it also takes advantage of the speed and simplicity of automated DNA sequencing (Enright and Spratt, 1999). Generally, 450–500-bp internal fragments of seven housekeeping genes are sequenced from each isolate. DNA of this length can be accurately sequenced on both strands using a single pair of primers. In most bacterial pathogens, MLST can show sufficient variation for the identification of many different alleles within the bacterial population (Enright and Spratt, 1999).

Because *B. pertussis* is a very homogeneous species and very little polymorphism has been found in its housekeeping genes, genes encoding for surface proteins have been analysed for typing purposes. A low level of allelic variation was seen when 15 genes coding for surface proteins were studied (Van Loo *et al.*, 2002). In the Dutch isolates from 1949 to 1999, polymorphism is only seen in genes encoding the S1 and S3 subunits of PT, tracheal colonization factor and Prn. Although *Prn* gene is polymorphic, it has not been used for MLST typing, as variation in it is mainly due to insertion or deletion of repeats, a process that is expected to occur relatively frequently. Thus, only genes coding for the PT subunits and tracheal colonization factor are used to define MLST types. When 196 strains isolated from different countries were analysed, nine MLST types were identified (Van Loo *et al.*, 2002).

Restriction Fragment Length Polymorphism

The genome of *B. pertussis* harbours two IS elements, IS481 and IS1002 (Table 18.3). Only four to seven copies of IS1002 occur in the genome, whereas the number of IS481 copies may be 80–100. Because of the high copy number, IS481-based fingerprinting patterns are too complicated even for computer-assisted analysis (van der Zee *et al.*, 1996b). Therefore, IS1002-based RFLP has been used for studying the population structure of *B. pertussis*. In comparison to PFGE, IS1002 fingerprinting is easy to perform and less laborious. However, because of the low copy number of IS1002 in the genome of *B. pertussis*, the discriminatory power of this method does not match that of PFGE (Mooi *et al.*, 2000).

Pulsed-Field Gel Electrophoresis

To construct a restriction map of *B. pertussis* chromosome, Stibitz and Garletts used several rare-cutting restriction enzymes in PFGE (Stibitz and Garletts, 1992). Two enzymes, XbaI and SpeI, cleaved the *B. pertussis* chromosome into 25 and 16 fragments, respectively, suggesting that these two enzymes could be used in the typing of *B. pertussis* isolates by PFGE. Later, several studies have shown that the PFGE using these two enzymes is a very efficient tool in the typing of *B. pertussis* (Khattak, Matthews and Burnie, 1992; Khattak and Matthews, 1993; Nouvellon *et al.*, 1999; Prevost *et al.*, 1999; Brennan *et al.*, 2000; Bisgard *et al.*, 2001; Weber *et al.*, 2001), *B. parapertussis*, *B. bronchiseptica* and *B. holmesii* (Khattak and Matthews, 1993). PFGE has also shown its power in studies assessing the transmission of pertussis in schools and hospitals (Nouvellon *et al.*, 1999; Brennan *et al.*, 2000). An important advantage of PFGE is good comparability of data from different laboratories.

Antimicrobial Sensitivities

The antimicrobial susceptibility tests of *B. pertussis* and *B. parapertussis* have not been standardized (Hoppe and Haug, 1988). Various methods have been used. Testing by broth dilution methods has usually resulted in higher minimal inhibitory concentrations than that by agar dilution methods. Mueller-Hinton broth supplemented with 5% horse blood has been recommended for testing the activity of erythromycin (Hoppe and Tschirner, 1995). Erythromycin-containing plates should be incubated at room temperature for 48 h for *B. parapertussis* and 72 h for *B. pertussis*. The E-test has been evaluated for susceptibility testing of *B. pertussis* and found to be a good alternative to agar dilution testing (Hoppe, 1996).

Erythromycin has been the drug of choice in the treatment and prophylaxis of pertussis, and, until recently, no routine susceptibility testing of *B. pertussis* has been needed, as all strains have been susceptible to this drug. Erythromycin resistance of *B. pertussis* was first recognized in Arizona in 1994. Since then, three additional resistant isolates have been identified in the USA. The rate of erythromycin resistance was found to be <1% when 1030 *B. pertussis* strains were recently isolated and analysed in the USA (Wilson *et al.*, 2002).

The new macrolides show *in vitro* activity against *B. pertussis* similar to that of erythromycin (Hoppe and Eichhorn, 1989). Several quinolones are very active against *B. pertussis* and *B. parapertussis in vitro* (Hoppe and Simon, 1990). Other agents showing good *in vitro* activity against *B. pertussis* are piperacillin and mezlocillin, ceftazidime, cefotaxime and ceftriaxone (Kerr and Preston, 2001).

THERAPY AND CONTROL

Antimicrobial Therapy

Erythromycin is still the standard recommended treatment for pertussis (American Academy of Pediatrics, 2000). Erythromycin estolate is preferred with a dose of 40 mg/kg/day (maximum 2 g/day). It has been shown that erythromycin therapy resulted in elimination of *B. pertussis* from the nasopharynx in 2–7 days (mean 3.6 days), and it is usually considered that 5 days after initiation of the erythromycin treatment the patient is not anymore contagious (Baraff, Wilkins and Wehrle, 1978). The recommended duration of treatment is 14 days. For vaccinated children, 7 days therapy has shown to be effective (Halperin *et al.*, 1997). New macrolides have good *in vitro* activity against *B. pertussis*. Small studies have showed promising results with clarithromycin (10 mg/kg/day, twice a day for 7 days) or azithromycin (10 mg/kg/day, once a day for 5 days) (Aoyama *et al.*, 1996). Cotrimoxazole is considered as an alternative for those who do not tolerate macrolides, and based on *in vitro* results, quinolones could also be an alternative for adults.

PREVENTION AND CONTROL

Chemoprophylaxis

There are several reports showing wide spread of pertussis in families, schools, nursing homes and hospitals. Prompt use of chemoprophylaxis (macrolides with the same dosage as for treatment) in household contacts is effective. The clinical problem usually is that the spread of the infection has already occurred when the index case is diagnosed. The prophylaxis is especially indicated in families with unvaccinated infants.

Use of macrolides in schools or in hospitals is problematic, and some studies indicate that many adults do not complete their prophylaxis. The general value and the practicability of the wide use of prophylaxis in the community are questionable. It is important to increase awareness of pertussis disease in adults and schoolchildren in the population, to start treatment as early as possible in the catarrhal phase of pertussis and to give prophylaxis to those in high risk if infected (infants, other high-risk patients). During outbreak conditions it is important to stress the importance of proper immunizations in children.

Vaccines

Immunization is considered the most effective method of preventing and controlling pertussis in the population. Whole-cell and acellular pertussis vaccines are currently used worldwide.

Whole-Cell Pertussis Vaccines

Shortly after the isolation of *B. pertussis*, attempts were made to develop a vaccine (Madsen, 1933; Lapin, 1943). Since the 1950s, standard pertussis vaccines containing killed whole *B. pertussis* cells have been available in most developed countries (Cherry *et al.*, 1988). The widespread use of these vaccines has been highly successful in decreasing the incidence and mortality of pertussis in these countries (Cherry *et al.*, 1988). However, concern about a possible relationship between immunization and permanent neurologic complications (Kulenkampff, Schwartzman and Wilson, 1974; Miller *et al.*, 1981) resulted in decreased vaccine uptake in several countries, such as the UK, Japan and Sweden. Large pertussis epidemics then emerged in these countries. Although extensive and well-designed studies failed to confirm any evidence of permanent neurologic complications attributable to the whole-cell vaccine (American Academy of Pediatrics Committee on Infectious Diseases, 1991, 1996), extensive efforts have been made to develop less reactogenic acellular vaccines.

Acellular Pertussis Vaccines

Acellular vaccines are based on purified *B. pertussis* antigens. Vaccines containing only PT and FHA were first developed in Japan and introduced into general use as early as 1981 (Sato, Kimura and Fukumi, 1984; Kimura and Kuno-Sakai, 1990). Although extensive use of such vaccines in Japanese children provided evidence of low reactogenicity and satisfactory efficacy (Mortimer *et al.*, 1990), the data showing the safety and efficacy of these vaccines in infants were considered inadequate (Noble *et al.*, 1987). Furthermore, no consensus prevailed on the optimal antigen(s), and their concentrations to be included in acellular vaccines. As a result, manufacturers developed a variety of candidate preparations, 13 of which were evaluated in large phase 1–2 trials in the early 1990s (Decker *et al.*, 1995; Edwards *et al.*, 1995). Acellular vaccines caused much less frequent and less severe adverse reactions than whole-cell vaccines (Decker *et al.*, 1995). Furthermore, most acellular vaccines induced antibody responses to vaccine antigens that equalled or exceeded those induced by whole-cell

vaccines (Edwards *et al.*, 1995). In the last decade, nine controlled efficacy trials of acellular vaccines have been carried out in different countries (Hewlett, 1997; Plotkin and Cadoz, 1997). The vaccines tested were either monocomponent ones containing only PT, bicomponent containing PT and FHA, tricomponent containing PT, FHA and Prn or multicomponent containing PT, FHA, Prn and FIM. The vaccines were produced by different manufacturers, and diphtheria-tetanus whole-cell pertussis vaccines or diphtheria-tetanus vaccines served as controls. In most trials, three primary doses were administered to infants less than 6 months of age. The trials showed that acellular vaccines prevent pertussis and cause less adverse reactions than whole-cell vaccines (Cherry, 1997). Because of their low reactogenicity, acellular pertussis vaccines are suitable for booster immunizations of older children and even adults (Tran Minh *et al.*, 1999).

Response to Immunization and Persistence of Immunity

Active and passive immunizations in mice have shown that antibodies to PT, FHA and Prn of *B. pertussis* can confer various degrees of protection against intracerebral or respiratory challenge by the bacterium (Oda *et al.*, 1984; Sato and Sato, 1984; Robinson *et al.*, 1985; Shahin *et al.*, 1990). High levels of antibodies to these components have been found in the convalescent sera of humans with pertussis (Viljanen *et al.*, 1982; Mertsola *et al.*, 1983b; Robertson *et al.*, 1987; He *et al.*, 1993; Nenning *et al.*, 1996; Long, 1997). In the 1940s, high levels of agglutinating antibodies against *B. pertussis* were found to be associated with clinical protection (Miller *et al.*, 1943; Sako, 1947). However, it is now known that the protective effect seen in those studies was partly due to antibodies against FIM and PRN (Mink *et al.*, 1994). In the vaccine efficacy trials, high levels of antibodies against vaccine antigens were reported. Although high levels of antibodies to Prn, FIM or PT in pre-exposure sera are associated with a lower likelihood of pertussis acquisition in households (Cherry *et al.*, 1998; Storsaeter *et al.*, 1998), no single serologic marker or combination of markers has been found to indicate definite protection against pertussis. This suggests that, in addition to antibodies, other arms of the immune system are involved in protection.

Bordetella pertussis was found to be able to survive in mammalian cells, and a role for cell-mediated immunity (CMI) in controlling *B. pertussis* infection was evident from studies of mice. Therefore, CMI induced after immunization and disease was investigated (Zepp *et al.*, 1996; Ausiello *et al.*, 1997; He, Tran Minh *et al.*, 1998; Ryan *et al.*, 1998; Tran Minh *et al.*, 1999). In general, the data obtained so far suggest that immunity conferred by whole-cell vaccines, such as natural immunity, is mediated by T helper 1 cells, whereas both Th1 and Th2 cytokine profiles have been seen in individuals immunized with acellular vaccines.

It is known that neither immunization nor natural infection provides long-term immunity. The protection provided by whole-cell vaccines is short-lived with an estimated duration of 6–12 years. However, the data of protection by acellular vaccines are limited. Preliminary studies show that the efficacy of multicomponent and some monocomponent or bicomponent acellular vaccines may be sustained for several years (Storsaeter and Olin, 1992; Gustafsson *et al.*, 1996; Taranger *et al.*, 1997; Salmaso *et al.*, 1998). The persistence of immunity depends on the vaccine used, the schedule followed, the number of doses used and the epidemiologic background of the study populations.

Immunization Schedules

Pertussis vaccines and immunization programs vary from country to country, as shown in Table 18.4. In most European countries, the recommendation is three diphtheria-tetanus-pertussis (whole-cell or acellular) doses before the age of 7 months and a booster dose at 11–18 months of age. In the United States, the recommendation is

Table 18.4 Current pertussis immunization schedules in European countries^a

Country	Vaccine used ^b	Months
Austria	DTaP	2, 3, 4, 13
Belgium	DTaP	2, 3, 4, 15
Denmark	DTaP	3, 5, 12
Finland	DTwP	3, 4, 5, 18–24
France	DTaP or DTwP	2, 3, 4, 16
Germany	DTaP	2, 3, 4, 11
Greece	DTwP or DTaP	2, 4, 6, 18–24
Iceland	DTaP	3, 5, 12 or 2, 4, 6
Italy	DTaP	2, 4, 10
Luxembourg	DTaP	2, 3, 4, 11
The Netherlands	DTwP	2, 3, 4, 11
Norway	DTaP	3, 5, 11
Portugal	DTwP	2, 4, 6, 15
Spain	DTwP or DTaP	2, 4, 6, 18–24
Sweden	DTaP	3, 5, 12
Switzerland	DTaP	2, 4, 6, 15
UK	DTwP	2, 3, 4

^a Adapted from Schmitt *et al.* (2003).

^b DTaP or DTwP is used in combination with other vaccines.

DTaP for both primary series at 2, 4 and 6 months of age and booster doses at ages 15–18 months and 4–6 years. In Scandinavia, several countries have recently adopted a schedule of 3, 5 and 12 months.

The increased incidence of pertussis in schoolchildren, adolescents and adults stresses the importance of booster immunizations in these populations. In Finland, a second booster dose given at 4–6 years of age has been recently introduced into immunization programs. In France and Germany, a second booster dose given at 11 years of age has already been introduced.

In conclusion, although acellular pertussis vaccines have proved highly effective against pertussis disease, the following important issues remain to be dealt with: 1) the optimal antigens and their quantities in an acellular vaccine – as antigenic divergence with respect to Prn and PT has been found between *B. pertussis* vaccine strains and circulating strains, it remains to be shown whether acellular vaccines provide equal protection against *B. pertussis* representing vaccine and nonvaccine type strains; 2) the rates of waning of pertussis immunity after immunizations with different vaccines; 3) the optimal strategy of boosting (universal – targeted) for the prevention of pertussis in adolescents and adults; 4) the mechanisms of the increase of local reaction often seen after booster immunizations; 5) a better understanding of antigens in terms of interference with reactogenicity and immunogenicity when vaccines are used in combination; 6) provision of effective vaccines for the developing countries at reasonable price.

Brucella spp.

Edward J. Young

Department of Internal Medicine, Baylor College of Medicine, Veterans Affairs Medical Center, Houston, TX, USA

INTRODUCTION

Brucellosis is primarily a disease of animals (zoonosis), but it was first recognized for the illness it caused in humans. Jeffery Allen Marston, an assistant surgeon in the Royal Army Medical Corps (RAMC), is credited with the first reliable description of brucellosis based on his experience with the disease. In 1886, David Bruce, another RAMC physician, isolated the organism later called *Brucella melitensis*, the causative agent of Malta fever, as the disease was known (Vassallo, 1992). Between 1904 and 1907, the Mediterranean Fever Commission, established to investigate epidemic brucellosis in Malta, published landmark studies on the nature of the disease (Williams, 1989). In the *Third Report* (1905), Themistocles Zammit, a Maltese physician, reported that native goats were the reservoir of the infection, and in the *Seventh Report* (1907), fresh goat's milk was reported as the vehicle of transmission from animals to humans (Vassallo, 1996).

Meanwhile, in 1895, Bernhard Bang, a Danish physician, isolated *Brucella abortus* from cyetic tissue of cattle suffering from contagious abortions. In 1921, human infection with the agent of Bang's disease was reported in Rhodesia by Bevan and, in 1924, in the United Kingdom by Orpan; however, similarities between the goat and cattle organisms were not immediately apparent. The third major nomen species, *Brucella suis*, was isolated from aborted swine in 1914 by Jacob Traum, a bacteriologist with the US Department of Agriculture (USDA). Keefer reported the first human infection with the swine organism in 1924 in Baltimore, although it was initially believed to be of bovine origin (Spink, 1956). The close taxonomic relationship between the agents of Malta fever and Bang's disease was finally recognized by the work of Alice Evans at the USDA. Evans suggested that the caprine, bovine and swine agents formed a distinct genus, and she proposed the name *Brucella* to honor Bruce. Additional species (*Brucella ovis* and *Brucella neotomae*) were added to the genus, but they do not appear to cause human infection. In 1966, Carmichael and associates isolated *Brucella canis* from kennel-bred dogs suffering from contagious abortion; however, it is a rare cause of human infection.

Since 1994, *Brucella* spp. with phenotypic and phylogenetic characteristics different from those of previously recognized nomen species have been reported from a variety of marine mammals including cetaceans, seals and otters. Initially termed *Brucella maris*, host preferences and DNA polymorphisms indicate the existence of at least two distinct new species (Bricker *et al.*, 2000). The names *Brucella pinnipediae* and *Brucella ceteceae* have been proposed for the seal and cetacean isolates, respectively (González *et al.*, 2002).

Human infection with the marine organism has been reported (Sohn *et al.*, 2003) (Table 19.1).

Table 19.1 Pathogenicity of *Brucella* species and biovars

Nomen species	Biovars	Preferred host	Pathogenicity for humans
<i>B. melitensis</i>	1–3	Goats, sheep	High
<i>B. abortus</i>	1–6, 9	Cattle	Moderate
<i>B. suis</i>	1	Swine	High
	2	Swine	Low
	3	Swine	High
	4	Reindeer/caribou	Moderate
	5	Rodents	High
<i>B. canis</i>	None	Dogs	Low
<i>B. ovis</i>	None	Sheep	None
<i>B. neotomae</i>	None	Desert wood rats	None
<i>B. maris</i> ^a	–	Marine mammals	Low

^a Pending nomenclature. (Includes *B. pinnipediae* and *B. ceteceae*.)

DESCRIPTION OF THE ORGANISM

Morphology

Brucella are small, Gram-negative coccobacilli that lack capsules, endospores or native plasmids. The cell wall consists of an outer layer of lipopolysaccharide (LPS) protein approximately 9 nm thick. Thin-section electron micrographs reveal an electron-dense layer 3–5 nm thick consisting of a highly cross-linked muramyl–mucopolysaccharide complex associated with lipoproteins. Matrix and porin proteins penetrate the peptidoglycan layer at irregular intervals. A low-density periplasmic space separates the peptidoglycan layer from the cell membrane.

Classification

The genus *Brucella* consists of seven nomen species, some containing several biovars, differentiated on the basis of cultural, metabolic and antigenic characteristics (Tables 19.2 and 19.3). However, taxonomic studies employing DNA and DNA–rRNA hybridization reveal a high degree of homology among nomen species, indicating that the genus is monospecific (Verger *et al.*, 1985; Gándara *et al.*, 2001). Nevertheless, by current convention, the original nomen species classification, based in part on natural host preferences, is retained for epidemiological purposes. In fact, genomic fingerprints and restriction length polymorphisms of conserved loci indicate that the present taxonomy is relevant. For example, the *omp 2* gene locus is conserved in all *Brucella* sp., and complete sequence analysis of these loci reveals nucleotide differences among nomen species (Ficht *et al.*, 1990). Phylogenetically, *Brucella* sp. appears to have a common origin with

Table 19.2 Characteristics of *Brucella* species and biovars

Nomen species	Biovars	Requirement for CO ₂	Production of H ₂ S	Urease activity	Growth on media containing dyes ^a		Agglutination by monospecific antiserum ^b

free-living, soil-dwelling bacteria. Based on 5S and 16S rRNA sequences, *Brucella* is included in the α -2 subdivision of the Protobacteriaceae, closely related to human pathogens such as *Bartonella* sp. and plant pathogens and symbionts such as *Agrobacterium tumefaciens* and *Sinorhizobium meliloti* (Del Vecchio *et al.*, 2002; Paulsen *et al.*, 2002).

Genetics

Restriction endonuclease techniques have shown that the genome of *B. melitensis* comprises two circular chromosomes of 2.1 Mb and 1.15 Mb (Michaux *et al.*, 1993). The physical maps of the genomes of six nomen species showed only small differences from those of *B. melitensis*, except for a large 640 Kb inversion in the small chromosome of *B. abortus* 544 (Michaux-Charachon *et al.*, 1997). In contrast, strains of the four biovars of *B. suis* varied in chromosome number and size, having either one 3.1 Mb chromosome (biovar 3) or two chromosomes of smaller size (biovars 1, 2 and 4) (Jumas-Bilak *et al.*, 1998). These differences appear to represent rearrangements in three rRNA operons. There is pronounced asymmetry of the genes in different functional categories between the two *Brucella* chromosomes; however, each contains genes that are essential for structural and metabolic integrity, hence qualifying as true chromosomes and not plasmids (Paulsen *et al.*, 2002).

Antigens

Lipopolysaccharide

The major surface component of *Brucella* sp. is LPS consisting of an outer O-polysaccharide chain linked through a core oligosaccharide to lipid A which anchors the complex in the outer cell membrane. Smooth (S) strains contain the complete complex, whereas rough (R) strains lack the O-side chain. The O-antigen contains several epitopes, including the A and M antigens of Wilson and Miles (Wilson and

Miles, 1932). The A epitope predominates in *B. abortus* strains and consists of a linear homopolymer of α -1,2-linked 4-formamido-4,6-dideoxy-D-mannose (*N*-formyl perosamine) (Perry and Bundle, 1990). In *B. melitensis* strains, the O-chain consists of repeating units of five *N*-formyl perosamine residues, four α -1,2-linked and one α -1,3-linked. A common, or C epitope, is present in all brucellae that accounts for serological cross-reactivity. The presence of perosamine in the *Brucella* LPS also explains the cross-reactivity with other Gram-negative bacteria such as *Escherichia coli* O:157, *Salmonella* O:30, *Vibrio cholerae* and *Yersinia enterocolitica* O:9.

The structure of the core oligosaccharide has not been fully elucidated; however, the presence of mannose and 2-amino-2,5-dideoxy-D-glucose (quinovosamine) and 2-keto-3-deoxyoctulosonic acid (KDO) is known (Moriyón and López-Goñi, 1998).

The lipid A moiety is a disaccharide of 2,3-diamino-2,3-dideoxyglucose in α -1,6 linkages, to which are attached a large proportion of long chain fatty acids (>C16), very small amounts of hydroxylated fatty acids, no –OH myristic acid and a proportion of amide- and ester-linked fatty acids (Qureshi *et al.*, 1994). Ethanolamine and arabinosamine, often present in the lipid A of Enterobacteriaceae, have not been found, which may explain differences between *Brucella* and classical endotoxins. For example, *Brucella* endotoxin is only weakly pyrogenic for rabbits, does not elicit the dermal Shwartzman reaction, and is a much less potent inducer of interleukin-1 (IL-1) and TNF- α from human monocytes (Goldstein *et al.*, 1992).

Outer Membrane Proteins

Several outer membrane proteins (OMPs) of brucellae have been identified. They were first classified according to their apparent molecular mass into group 1 (88–94 kDa), group 2 (35–39 kDa) and group 3 (25–31 kDa) proteins. In addition, a lipoprotein similar to the Braun antigen in *E. coli* has been partially characterized. The genes encoding these OMPs have been sequenced, and studies are underway to clarify their precise roles (Moriyón and López-Goñi, 1998; Guzmán-Verri *et al.*, 2002).

+, oxidized by all strains; -, not oxidized by any strain; ±, oxidized by some strains; L, lysis; NL, no lysis at routine test dilution (RTD) by *Brucella* phages.

Periplasmic Proteins

Among the periplasmic proteins that have been identified is a Cu–Zn superoxide dismutase that inactivates reactive oxygen intermediates.

Cytoplasmic Proteins

Several stress proteins such as GroEL, GroES, DnaK and HtrA as well as a bacterioferritin and a lumazine synthetase have been identified. The latter has been proposed as a potential serodiagnostic antigen (Goldbaum *et al.*, 1999); however, it appears to be less sensitive than LPS antigens for this purpose. The L7/L12 ribosomal protein appears to play a role in stimulating T-helper-1 (Th-1)-type cellular immunity.

PATHOGENESIS

Intracellular Survival

Brucella spp. are facultative intracellular pathogens that have evolved mechanisms to evade destruction by phagocytic cells of the host. Although the mechanisms are incompletely understood, several pathogen virulence factors have been proposed. *O*-Polysaccharide is considered important since smooth strains resist phagocytosis and kill better than rough strains. In addition, virulent strains of *B. abortus* contain a Cu–Zn superoxide dismutase enzyme that inhibits reactive oxygen radicals. Two nucleotide-like substances (5'-guanosine monophosphate and adenine) have been recovered from culture filtrates of *B. abortus* that inhibits phagolysosome fusion and suppresses the myeloperoxidase–H₂O₂–halide killing mechanism of neutrophils (Canning, Roth and Deyoe, 1986).

Host Defenses

Intact skin is an effective barrier to the entry of brucellae, but even minute abrasions may permit the ingress of bacteria. The low pH of gastric juice also provides some protection against oral infection, and antacids or histamine blockers appear to increase susceptibility (Steffen, 1977). Normal human serum has moderate anti-brucella activity, and complement opsonizes the organism for phagocytosis. Human neutrophils destroy some brucellae; however, they lack activity against *B. melitensis* (Young, 1985). Organisms that escape killing by neutrophils enter the lymphatics where they localize within organs rich in elements of the reticuloendothelial system (lymph nodes, spleen, liver and bone marrow).

Immune Responses

Innate immunity to *Brucella* infection has been demonstrated in swine and cattle. Macrophages from naturally resistant strains of cattle are better able to control intracellular replication of *B. abortus*, a process that appears to be controlled by the bovine homologue of the *Nramp1* (natural resistance associated macrophage protein 1) gene (Feng *et al.*, 1996; Adams and Templeton, 1998).

Acquired immunity involves both humoral and cellular factors, although the latter predominates, as with other intracellular pathogens. The humoral response is characterized by the appearance of immunoglobulin M (IgM) antibodies directed principally against LPS within the first week of infection. This is followed by a switch to IgG synthesis after the second week. Thereafter, both subclasses of Igs increase over time.

Cellular immunity involves T-cell-dependent activation of macrophages, the main cellular reservoir for brucellae. CD4⁺ T cells appear to play a role in protection against *Brucella* infection, either by activating CD8⁺ T cells or by secreting cytokines that mediate

macrophage activation (Araya *et al.*, 1989). Among the cytokines involved in activating anti-brucella activity of macrophages, interferon- γ (IFN- γ) is of particular importance (Jiang and Baldwin, 1993). Nevertheless, it is likely that both humoral and cellular immune mechanisms work in concert for recovery from, and resistance to, *Brucella* infection (Casadevall, 2003).

EPIDEMIOLOGY

Brucellosis exists worldwide in domestic and wild animals and is especially prevalent in countries bordering the Mediterranean, throughout the Arabian peninsula, in the Indian subcontinent and in parts of Mexico, Central and South America. In many areas, such as sub-Saharan Africa, brucellosis is known to exist, but the prevalence is unknown, owing to a lack of diagnostic and reporting mechanisms. The importance of enzootic brucellosis in areas adjacent to countries where the disease is almost eliminated is illustrated by the border between Mexico and the United States. In the border states of Texas and California, most cases of human brucellosis originate from unpasteurized dairy products imported from Mexico (Taylor and Perdue, 1989; Chomel *et al.*, 1994). In counties of Texas bordering Mexico, for example, the prevalence of human brucellosis is eight times higher than elsewhere in the United States (Doyle and Bryan, 2000; Fosgate *et al.*, 2002).

Brucella melitensis occurs primarily in goats and sheep, although in some countries, camels, and even cattle, may be important reservoirs. It is the most frequent cause of human brucellosis worldwide. *Brucella abortus* is found primarily in cattle and other bovidae, such as buffalo and yaks. *Brucella suis* biovars 1–3 are found in swine, whereas biovar 4 is limited to reindeer and caribou. Human infection with *B. suis* is a particular risk for abattoir workers and for hunters of feral swine. *Brucella canis* occurs in dogs, especially under conditions of intense breeding. Pathogenicity of *B. canis* for humans is low, and infections generally involve dog breeders or laboratory personnel.

Human-to-human transmission of brucellosis is rare, although cases believed to be sexually transmitted have been reported (Ruben *et al.*, 1991). Few cases of brucellosis have been reported in people with acquired immunodeficiency syndrome (AIDS), which is surprising in view of their susceptibility to other infections (Moreno *et al.*, 1998).

CLINICAL FEATURES

Presentation

The onset of human brucellosis may be acute or insidious, and the clinical manifestations are protean. The disease is generalized and may involve any organ or system of the body. Presenting complaints are numerous and nonspecific, including malaise, anorexia, fatigue, sweats, weight loss, back or joint pains and depression. Objective physical findings are few, notably fever, mild lymphadenopathy and, occasionally, hepatomegaly or splenomegaly. Fever is present in most patients with active infection. When monitored over time without the intervention of antibiotics or antipyretics, the fever pattern is undulating. The importance of a careful history of animal exposure, travel to brucella enzootic countries or the ingestion of 'exotic' foods such as dairy products made from raw milk cannot be overemphasized. People engaged in ranching, animal husbandry, veterinary medicine, abattoir work, hunting game involving feral swine and laboratory medicine should be considered as being at increased risk of brucellosis (Young, 1983; Memish and Mah, 2001).

Nervous System

Depression and mental inattention are common; however, direct invasion of the nervous system occurs in less than 5% of cases. Meningitis or meningoencephalitis is the most common manifestation

of neurobrucellosis, and it may be acute or chronic. Other neurological syndromes include peripheral neuropathy, myelitis, radiculitis, brain and epidural abscess and demyelinating and meningovascular syndromes. The presence of brucella antibodies in the cerebrospinal fluid (CSF) is essentially diagnostic. With antimicrobial therapy, the prognosis is usually good; however, severe neurological sequelae have been reported (McLean, Russell and Khan, 1992).

Skeletal System

Osteoarticular involvement is the most common complication of brucellosis, occurring in 20–80% of cases (Colmenero *et al.*, 1996). The axial skeleton is frequently involved, and sacroilitis and spondylitis are common findings (Ariza *et al.*, 1993; Solera *et al.*, 1999). Peripheral joint arthritis primarily involves large, weight-bearing joints such as hips, knees and ankles. Radiographic findings are infrequent, but computed tomography is useful for detecting joint destruction, vertebral osteomyelitis and, rarely, paraspinal abscess. A post-infectious spondyloarthropathy has been described. Treatment is antimicrobial drugs, with surgery reserved for spinal instability, abscess drainage or prosthetic joint infection.

Gastrointestinal System

Brucellosis resembles typhoid fever, in that systemic symptoms predominate over gastrointestinal complaints. Nevertheless, more than two-thirds of patients complain of nausea, anorexia, vomiting, weight loss and abdominal discomfort. Inflammation of Peyer's patches and the ileal and colonic mucosa has been described. The liver is probably always involved; however, liver function tests are usually only mildly elevated. The spectrum of histological lesions of the liver is varied, depending, in part, on the infecting *Brucella* species. Nonspecific mononuclear cell infiltrates, epithelioid granuloma and abscess have all been reported. Cholecystitis, pancreatitis and spontaneous peritonitis are rare complications.

Cardiovascular System

Endocarditis occurs in less than 2% of cases but accounts for most brucellosis-related deaths. Both native and prosthetic valve endocarditis have been reported. When the diagnosis is delayed, treatment may require a combination of antimicrobial drugs and valve replacement surgery (Jacobs *et al.*, 1990). Myocarditis, pericarditis and mycotic aneurysms have been reported rarely.

Respiratory System

A variety of pulmonary manifestations have been reported, including bronchitis, pneumonia, lung masses, abscess and empyema. Organisms are rarely found by Gram stain of sputum.

Genitourinary System

Brucellae is isolated from urine; however, renal lesions are rare. Interstitial nephritis, glomerulonephritis, pyelonephritis and renal abscess have been described. Orchitis, usually unilateral, is common and must be differentiated from testicular neoplasm (Navarro-Martínez *et al.*, 2001). Abortion is a prominent complication of brucellosis in animals and may occur in humans as well (Khan, Mah and Memish, 2001).

Chronic Infection

Chronic brucellosis occurs when a focus of infection persists in an organ, such as the spleen, kidney or bone marrow, despite antimicrobial

therapy. Symptoms may recur over long periods of time and are usually associated with objective signs of infection (e.g. fever), accompanied by persistent elevation of IgG antibodies in the serum. Treatment often requires surgical drainage of the infectious focus. This condition must be differentiated from simple relapse of infection following a course of therapy and usually occurs within a few weeks of discontinuing antibiotics. In addition, few patients experience a delayed recovery from acute brucellosis, in which they have nonspecific symptoms, such as fatigue and malaise, but lack objective signs of disease and do not have elevated IgG antibodies.

Childhood Brucellosis

Once considered rare in children, brucellosis infects people of all ages, especially in areas where *B. melitensis* is enzootic. The clinical manifestations and complications are similar regardless of the age of the patient.

LABORATORY DIAGNOSIS

Bacteriological Diagnosis

The diagnosis of brucellosis is made with certainty when brucellae are recovered from blood, bone marrow or other tissues. *Brucella* can be cultured on any high-quality peptone-based media. Growth is enhanced by the addition of blood or serum, but primary isolation may require prolonged (several weeks) incubation. Culture of bone marrow is reported to give a higher yield than the culture of peripheral blood (Gotuzzo *et al.*, 1986). Rapid isolation techniques such as Bactec and BacT/Alert systems have improved recovery rates and decreased the time required for isolation from weeks to days (Yagupsky, 1999). However, findings of rapid bacterial identification systems should be interpreted with caution, since some do not incorporate databases necessary to differentiate *Brucella* from other bacteria, such as *Moraxella phenylpyruvica* or *Haemophilus* sp. Polymerase chain reaction (PCR) and antibody-based antigen detection systems have been devised to demonstrate the presence of organisms in serum or tissues (Morata *et al.*, 2001).

Regardless of the methods used, clinicians should notify the laboratory that brucellosis is suspected, so that cultures are not discarded prematurely, and that appropriate biohazard precautions be taken to protect personnel.

Serological Diagnosis

In the absence of a positive culture, a presumptive diagnosis of brucellosis is made by demonstrating high or rising titers of antibodies to *Brucella* in the serum. A variety of serological tests have been used to detect antibodies to *Brucella*; however, the serum agglutination test (SAT) remains the gold standard against which others are compared (Young, 1991). The SAT measures the total quantity of agglutinating antibodies but does not differentiate between Ig isotypes. To determine the titer of IgG antibodies, serum is treated with disulfide-reducing agents (2-mercaptoethanol or dithiothreitol), which destroys the agglutinability of IgM, but does not alter IgG (Buchanan and Faber, 1980). Non-agglutinating antibodies may also be detected by using Coomb's reagent. The SAT using *B. abortus* S119 antigen can detect antibodies to other smooth species (*B. melitensis* and *B. suis*) but not rough organisms such as *B. canis*. A more sensitive assay that also employs LPS antigen is the enzyme-linked immunoadsorbent assay (ELISA) (Gazapo *et al.*, 1989). Unfortunately, the ELISA antigen is not standardized, making interpretation of results between laboratories difficult. An ELISA employing cytoplasmic antigens has been reported to differentiate between active and inactive disease (Goldbaum, 1999).

Although no single titer is always diagnostic, most patients with active infection have titers $\geq 1:160$, with IgG antibodies predominating. Regardless of the serological test, the results must be analyzed in light of epidemiological, clinical and laboratory information.

MANAGEMENT

Antimicrobial Therapy

Numerous antimicrobial agents have activity *in vitro* against *Brucella*, but a relatively few are effective in treating human brucellosis. The tetracyclines, especially doxycycline, are among the most effective; however, clinical relapse unrelated to antibiotic resistance has led to a preference for combination drug therapy (Young, 2002). Antimicrobial therapy must be continued for a minimum of 6 weeks, and patients should be cautioned to continue therapy even after symptoms have resolved, to assure a cure. Tetracycline (500 mg four times daily by mouth for 6 weeks) plus streptomycin (1 g daily intramuscularly for 2–3 weeks) resulted in the highest cure rate and lowest rate of relapse. Doxycycline (100 mg twice daily by mouth) is now favored over generic tetracycline because of its lower incidence of gastrointestinal upset. Doxycycline in combination with rifampin (600–900 mg daily by mouth), both administered for 45 days, is an acceptable treatment for uncomplicated brucellosis; however, the relapse rate is higher than that with doxycycline plus an aminoglycoside. Gentamicin is as effective as streptomycin; however, no prospective study has compared the two drugs, and the dose and duration of therapy with gentamicin have not been conclusively demonstrated. Most experts recommend gentamicin (5 mg/kg/day) to be administered for 14 days in combination with doxycycline administered for 6 weeks (Solera *et al.*, 1997a). Laboratory studies have shown that the addition of an aminoglycoside to other agents produces a more rapid killing of brucellae *in vitro* (Rubinstein *et al.*, 1991).

The fixed combination of trimethoprim/sulfamethoxazole (co-trimoxazole) has also been used to treat brucellosis, but high rates of relapse have been reported unless the drug is combined with other agents (Ariza *et al.*, 1985; Solera *et al.*, 1997b). Nevertheless, co-trimoxazole has certain advantages, such as in the treatment of pregnant women and children less than 6 years of age, for whom tetracycline compounds are contraindicated because of the risk of staining teeth.

Fluoroquinolone compounds also have activity against *Brucella in vitro*, but treatment is complicated by a high rate of relapse and, possibly, the selection of resistant strains. For this reason, quinolones should generally be used in combination with other drugs such as doxycycline.

Treatment of Complications

The most effective treatments for neurobrucellosis and brucellar endocarditis remain undecided. Many authorities choose doxycycline in combination with two or more other agents, with treatment continued for several months depending on the clinical and laboratory responses. Some third-generation cephalosporins cross the blood–brain barrier well, but they should only be used in combination with other drugs and *in vitro* susceptibility of the infecting strain of brucellae should be assured. Treatment of brucellar endocarditis may require valve replacement, in addition to antimicrobial chemotherapy. Spinal brucellosis generally responds to drug therapy, with surgery being reserved for cases with paraspinal abscess or spinal instability. Prosthesis infection may respond to prolonged drug therapy; however, local relapses are treated with the removal of the prosthetic device. Treatment of brucellosis in pregnancy remains a problem, but rifampin and co-trimoxazole have been used despite the absence of data assuring their safety in this setting.

Prognosis

Before the advent of effective antimicrobial chemotherapy, brucellosis was a chronic, relapsing, debilitating disease with a mortality of about 2%. Although serious disease can be caused by any *Brucella* species, *B. melitensis* is generally more virulent and accounts for most deaths. With appropriate therapy and follow-up, most patients will recover completely, although a few will experience relapses or prolonged convalescence.

Prevention

The prevention of human brucellosis depends on eliminating the disease in domestic livestock. Vaccines employing live, attenuated strains of *B. abortus* (strains 19 and RB51) or *B. melitensis* (strain Rev 1) have been used successfully to control brucellosis in developed countries; however, they have had little impact in much of the Third World. The threat of *Brucella* as a weapon of biological terrorism could serve as a stimulus to develop vaccines for humans.

Actinobacillus actinomycetemcomitans

Brian Henderson¹ and Derren Ready²

¹Division of Infection and Immunity, Eastman Dental Institute, University College London, ²Eastman Dental Hospital, University College London Hospitals NHS Trust, London, UK

INTRODUCTION

'But what if I should tell such people in future that there are more animals living in the scum of the teeth in a man's mouth, than there are men in the whole kingdom'. This is a quote from the 17th century microscopist, Antoni van Leeuwenhoek, the first man to see bacteria. Surprisingly, it is only in very recent years that we have begun to realize how much human morbidity is caused by these animals (oral bacteria) – a fact that is poetically captured in a quote from a recent report of the American Surgeon General about the 'silent epidemic of oral diseases – which disproportionately burdens minorities and the poor' (US Public Health Service, 2000).

The two main oral diseases of humans are caused by bacteria. Caries affects the teeth and the periodontal diseases affect the tissues and supporting structures around the tooth. The periodontal (*perio* – around and *odontos* – tooth) diseases are either acute (gingivitis) or chronic (periodontitis). These diseases cause inflammation of the gums (gingivae) and destruction of the tissues, periodontal ligament and alveolar bone that link the teeth to the jaw bone (Figure 20.1). A number of clinically diagnosable forms of periodontitis exist (Armitage, 1999). The most severe form of periodontitis is localized aggressive periodontitis (LAP), previously called localized juvenile periodontitis,

Figure 20.1 A schematic cross-sectional diagram of the human tooth showing the periodontium.

and the evidence suggests that it is caused by the subject of this chapter, *Actinobacillus actinomycetemcomitans* (Slots and Ting, 1999; Henderson *et al.*, 2003).

DESCRIPTION OF THE ORGANISM

Actinomyces spp. cause a chronic inflammatory lesion, actinomycosis, and a Gram-negative organism isolated from such a lesion by Klinger in 1912 resulted in the name *Bacterium actinomycetum comitans* being coined for this bacterium (Klinger, 1912). Thus begins a history of name changing, starting with *Bacterium comitans* (Lieske, 1921) and *A. actinomycetemcomitans* (Topley and Wilson, 1929). Interest in this organism stemmed from the finding of the bacterium in actinomycotic lesions in which the *Actinomyces* spp. had been eliminated by antibiotics (Holme, 1951). However, subsequent studies revealed that *A. actinomycetemcomitans* is a member of the normal oral microbiota (Heinrich and Pulverer, 1959) and that it is involved in the pathology of periodontitis (Zambon, 1985) and various non-oral infections (Van Winkelhoff and Slots, 1999). The past two decades has seen increasing attention being paid to this organism, and its genome has just been sequenced (Najar, 2002) revealing that this bacterium is closely related to members of the *Pasteurellaceae* such as *Haemophilus influenzae*.

Actinobacillus actinomycetemcomitans is a fastidious, nonmotile, nonsporing, small Gram-negative rod, $0.4\text{--}0.5 \times 1.0\text{--}1.5 \mu\text{m}$ in size. Microscopically, the cells may appear coccobacillary, particularly if the colonies are 2–3 days old and have been isolated directly from a solid medium. Longer forms may be seen in smears from older cultures or from cells grown in a glucose-containing liquid medium. It is a facultatively anaerobic bacterium that grows best in an aerobic atmosphere supplemented with 5–10% CO_2 , although it will grow anaerobically. The colonies of *A. actinomycetemcomitans* on chocolate or blood agar are generally small, with a diameter of 1–2 mm, translucent, often with a rough, irregular morphology (see section on Pathogenicity), dome-shaped and nonhaemolytic and may be adherent to the agar surface (Figure 20.2).

POPULATION STRUCTURE OF *A. ACTINOMYCETEMCOMITANS*

The immunodominant antigen of *A. actinomycetemcomitans* is a high molecular mass *o*-polysaccharide of the lipopolysaccharide (LPS), and six serotypes (a–f) are currently recognized (Kaplan *et al.*, 2001). The serotype a-specific antigen consists solely of 6-deoxyhexose, 6-deoxy-D-talose which is unique among bacteria, and no genes involved in the synthesis of 6-deoxy-D-talose had previously been reported

Figure 20.2 Primary isolation of *A. actinomycetemcomitans* on TSBV selective medium showing the characteristic stellate inner structure.

(Shibuya *et al.*, 1991). Investigation of the distribution of *A. actinomycetemcomitans* serotypes and clonotypes in Northern European, Northern African and African-American populations has established that individuals tend to be stably colonized by a single serotype/genotype (Saarela *et al.*, 1999). Serotype b is found at higher frequency both in patients with periodontitis and those with non-oral infections due to this organism than in healthy controls (Lakio *et al.*, 2002). In contrast, serotype c is more often found in periodontally healthy individuals (Lakio *et al.*, 2002). It is proposed that the organism can be grouped into three major phylogenetic lineages consisting of (i) serotype b strains, (ii) serotype c strains and (iii) serotypes a, d, e and f strains (Kaplan *et al.*, 2002a).

Population genetic studies of *A. actinomycetemcomitans* suggest that it is clonal, consisting of genetically distinct subpopulations that correlate with the known serotypes (Poulsen *et al.*, 1994; Haubek *et al.*, 1995). However, it has been proposed that LAP actually represents two different diseases. In Northern European Caucasian populations, LAP is associated with an oligoclonal population of bacteria, none of which had a specific 530-bp deletion from the leukotoxin promoter (see section *A. actinomycetemcomitans* toxins). The simplest interpretation is that LAP in this population is due to *A. actinomycetemcomitans* from the resident microbiota acting as an opportunistic pathogen. More detailed population studies, which included individuals of African origin, revealed the association between LAP in these individuals and a particular serotype b strain isolate with a 530-bp deletion in the leukotoxin promoter. This deletion results in significant enhancement of leukotoxin production (Brogan *et al.*, 1994). DNA fingerprinting and multilocus enzyme electrophoresis suggest that these isolates belong to a single clone, termed JP2 (Haubek *et al.*, 1997), and disease caused by this clone is proposed to be endemic in Morocco (Haubek *et al.*, 2002). However, this interpretation has recently been challenged by Kaplan and coworkers (2002a) and further studies are needed to resolve this issue.

PATHOGENICITY

The disease with which *A. actinomycetemcomitans* is implicated as a pathogen is LAP (Slots and Ting, 1999). This is a curious disease afflicting only the incisors and premolars and causing rapid destruction of the periodontal ligament and alveolar bone which link these teeth to the jawbone (Figure 20.1). As described, this disease is more prevalent in individuals of African origin. Four systems are thought to contribute to the virulence of *A. actinomycetemcomitans*. The first is a novel adhesion system, first discovered in *A. actinomycetemcomitans* and encoded by the tight adherence (*tad*) locus, more recently coined the ‘widespread colonization island’ – a modified type IV secretion system now recognized to exist in many bacteria and in *Archaea* (Kachlany *et al.*, 2001; Planet *et al.*, 2003). The second set of virulence determinants are the toxins: leukotoxin and cytolethal distending toxin (CDT). The third system is a collection of exported or cell-surface proteins with immunomodulatory functions and/or ability to stimulate tissue destruction. The final virulence characteristic is the ability to invade host cells by apparently novel mechanisms. It should be noted that in the absence of good animal models, and a paucity of *A. actinomycetemcomitans* isogenic knockouts, these proposed virulence mechanisms are largely speculative.

Adhesion of *A. actinomycetemcomitans*

The rough, adherent colony morphology of *A. actinomycetemcomitans* is associated with a dense collection of surface-attached fibrils (Fine *et al.*, 1999). Using the novel transposon, IS903 ϕ *kan*, to generate insertional mutants it was demonstrated that rough colony formation and tight adherence of *A. actinomycetemcomitans* was due to a cluster of novel genes called the *tad* locus (or widespread colonization island) (Planet *et al.*, 2003). The *tad* locus contains 14 genes (Figure 20.3),

Figure 20.3 The *tad* locus also known as the Widespread Colonization Island of *A. actinomycescomitans*. This contains genes encoding for a type IV secretion system that exports the proteins *flp-1* and 2 onto the cell surface.

12 of which are required for the synthesis, and transport to the cell surface, of the bundled Flp pili which produce the tenacious adhesion of this bacterium. Seven distinct *flp-1* allelic classes have been identified which are highly divergent between classes (Kaplan *et al.*, 2002b). A number of the genes in the *tad* locus appear to be homologues of genes encoding bacterial type II and type IV secretion systems. It is now established that *tad*-related genes are found in both bacterial and Archaeal species including human pathogens such as *Bordetella pertussis*, *H. ducreyi* and *Mycobacterium tuberculosis* (Planet *et al.*, 2003). The *tad* locus explains the tight adherence of *A. actinomycescomitans*, and it is postulated that this contributes to virulence. Rough strains show greater colonization of the rat oral cavity than smooth strains (Fine *et al.*, 2001). It has been reported that knockout of the *tadA* gene (an ATPase which energizes secretion of Flp proteins) or the *flp1* and *flp2* genes in *H. ducreyi*, the causative agent of chancroid, has minimal influence on virulence in an animal model (Nika *et al.*, 2002). However, in rats fed *A. actinomycescomitans* there was decreased colonization, lowered immune responses and no bone resorption when the bacterium lacked either *tadA* or *flp-1* compared with the response to wild-type organisms (Schreiner *et al.*, 2003). Thus this adhesion system appears to be an important virulence determinant in *A. actinomycescomitans*.

Actinobacillus actinomycescomitans toxins

Two toxins are produced by this organism. The best studied is an RTX (repeat in toxin) termed leukotoxin (LtxA). The generic RTX toxin operon consists of four genes: *rtxC*, A, B and D in order of transcription. The toxin, RtxA, requires posttranslational modification via lipid acylation, catalysed by RtxC, to be biologically active. Transport proteins, encoded by *rtxB* and *rtxD*, promote movement of the toxin from the cytoplasm to the cell surface (Kachlany *et al.*, 2000; Narayan *et al.*, 2002). Leukotoxin kills lymphoid and myeloid cells from human and some nonhuman primates (Narayan *et al.*, 2002), and the basis of this cell/species selectivity is due to the toxin binding to human cells via the β_2 -integrin receptor, LFA-1 (Lally *et al.*, 1997). At low concentrations, LtxA promotes neutrophil degranulation, resulting in the release of the collagenolytic proteinase, matrix metalloproteinase 8 (Claesson *et al.*, 2002), but it also inhibits phagocytosis possibly by increasing intracellular Ca (Taichman *et al.*, 1991). High concentrations of LtxA can cause cell lysis *in vitro* (Karkelian *et al.*, 1998), and it is also a potent inducer of leucocyte apoptosis (Korostoff *et al.*, 1998). There is experimental evidence to support the hypothesis that LtxA directly perturbs mitochondrial function to induce cellular apoptosis (Korostoff *et al.*, 2000).

There are marked strain differences in leukotoxin expression with the highly virulent strain, JP2, producing large amounts of toxin, apparently due to a 528-bp deletion from the promoter (Kolodrubetz *et al.*, 1996).

The *A. actinomycescomitans* leukotoxin is unique among the RTX toxins in not being secreted but being associated with the cell membrane (Berthold *et al.*, 1992). It has now been established that adherence to the cell surface is related to possession of a working *tad* locus, as mutations in this locus result in release of the leukotoxin

(Kachlany *et al.*, 2000). Here is an interesting interaction between two of the putative virulence mechanisms of this organism.

A second toxin, CDT, is also produced by *A. actinomycescomitans* (Sugai *et al.*, 1998). The toxin is encoded by an operon (*cdtABC*) which is found in a number of pathogens including *E. coli*, *Shigella* spp., *Campylobacter jejuni* and *H. ducreyi* (Lara-Tejero and Galan, 2002). The toxin inhibits cell-cycle progression in G₂, and intoxicated cells will eventually apoptose. The proposed mechanism is cleavage of chromosomal DNA by CdtB, which has nuclease activity resulting in activation of the DNA damage response and cessation of cell-cycle progression. The entry of CdtB is believed to be aided by the actions of CdtA and CdtC (Lara-Tejero and Galan, 2002). Most *A. actinomycescomitans* isolates encode at least one *cdt* gene (Fabris *et al.*, 2002).

The main consequence of the possession of these two toxins is not yet established. The simplest hypothesis is that both toxins are involved in immune evasion (see Henderson and Oyston, 2003 for review of this area). Support for this hypothesis comes from studies showing that CdtB can inhibit human CD4 lymphocyte proliferation and induce apoptosis of this cell population (Shenker *et al.*, 2001).

Exported and Cell-Surface Virulence Factors

There is a growing list of putative virulence factors exported by this bacterium and/or associated with the bacterial surface, and the literature has recently been reviewed (Henderson *et al.*, 2003) and will not be dealt with in detail. Possibly the most interesting of these factors is the molecular chaperone, chaperonin 60. Studies to identify a potent bone-resorbing protein released by cultures of *A. actinomycescomitans* concluded that it was chaperonin 60 (Kirby *et al.*, 1995), and immunogold labelling revealed this protein on the bacterial surface (Henderson and Wilson, unpublished). This surface location has been confirmed, and the chaperonin 60 was also reported to be cytotoxic for epithelial cells (Goulhen *et al.*, 1998). Now that the genome of *A. actinomycescomitans* has been sequenced, it should be much easier to identify the exported virulence factors of this bacterium using functional proteomics.

Cellular Invasion of *A. actinomycescomitans*

A growing number of bacterial pathogens have been found capable of invading nonphagocytic host cells (Wilson, McNab and Henderson, 2002). *Actinobacillus actinomycescomitans* – a member of the normal oral microbiota – has been found inside buccal epithelial cells in the majority of subjects surveyed (Rudney, Chen and Sedgewick, 2001), and about a quarter of the clinical isolates of this bacterium examined were invasive (Lepine *et al.*, 1998). Receptors for uptake include the transferrin receptor and the platelet-activating factor receptor (Henderson *et al.*, 2003). There is much that is not understood about cell invasion by *A. actinomycescomitans*, and this organism displays several unusual phenomena related to invasion. For example, bacterial replication within host cells is substantially faster

than that for the free-living organism (Meyer, Lippmann and Fives-Taylor, 1996). Another unusual aspect of the invasion of epithelial cells by this organism is its rapid exit from the cell after invasion and its ability to move from one cell to another (Meyer, Lippmann and Fives-Taylor, 1996), both of which are dependent on host-cell microtubules (Meyer *et al.*, 1999).

To conclude, *A. actinomycetemcomitans* has an armamentarium of factors and mechanisms which, applying Occam's razor, must contribute to its virulence. Indeed, with so many fascinating evolutionary tricks it is surprising that this organism does not cause more problems. Much work needs to be done to generate panels of isogenic mutants and test them in appropriate animal or human volunteer models to truly identify what behaviour of this organism contributes to virulence and what does not.

EPIDEMIOLOGY

The periodontal diseases are among mankind's most common afflictions. Periodontitis is estimated to have a worldwide prevalence of 10–15%, and it is only because this disease does not kill or maim that it remains so relatively unstudied (Irfan, Dawson and Bissada, 2001). *Actinobacillus actinomycetemcomitans* as well as *Tannerella forsythensis* (previously *Bacteroides forsythus*) and *Porphyromonas gingivalis* was officially designated as aetiological agents of periodontitis in 1996 (American Academy of Periodontology, 1996). *Actinobacillus actinomycetemcomitans* has been shown to be present in up to 95% of periodontal lesions in patients with LAP (Christersson, 1993). However, contrary to these findings other studies have reported a much lower frequency of *A. actinomycetemcomitans* isolation from affected patients (Lopez *et al.*, 1995; Albandar, Brown and Löe, 1997); additionally this organism has been readily isolated from the oral cavity of healthy subjects (Mombelli *et al.*, 1999). These observations suggest that host susceptibility is also an important factor in development of this disease. In a USA study the prevalence of LAP in the adolescent population was shown to be approximately 0.5%, which varied in relation to the subject's racial group, with minority ethnic subjects (African-American and Asian-American) having a prevalence 15 times greater than the Caucasian population (Löe and Brown, 1991). Subjects of African origin have been shown to harbour a particular clone of *A. actinomycetemcomitans* (JP2). The population genetics of this organism has been described in more detail in the section on Population Structure of *A. actinomycetemcomitans*.

An early finding was that LAP is associated with functional abnormalities of neutrophils, such as decreased chemotaxis and phagocytosis, and these abnormalities have been shown to cluster in families (Van Dyke *et al.*, 1985). Mutations in two important neutrophil receptors – the N-formylpeptide receptor (Gwinn, Sharma and De Nardin, 1999; Zhang *et al.*, 2003) and the Fc gamma receptor (Fu, Korostoff, Fine and Wilson, 2002) – have recently been suggested to be important in the development of LAP in African-Americans. Familial transfer of *A. actinomycetemcomitans* has been shown to occur between spouses and from parent to child (Greenstein and Lamster, 1997), which may also be an important factor in the high prevalence of disease found in particular families (Stabholz *et al.*, 1998).

CLINICAL FEATURES

Actinobacillus actinomycetemcomitans has been implicated as an important aetiological agent in periodontitis. Periodontitis is an inflammatory disease of the periodontium which occurs in response to bacterial plaque on the adjacent teeth, characterized by gingivitis, destruction of the alveolar bone and periodontal ligament, generally termed loss of attachment. Clinical features of periodontitis may also include oral malodour, gingival bleeding, pain, swelling, gingival recession and tooth mobility and migration. *Actinobacillus*

actinomycetemcomitans is particularly associated with local aggressive periodontitis, in which bone loss is seen around the incisors, molars and the mesial surface of the second molars. The loss of tissues supporting the tooth may be clinically evident due to an apical and lateral migration of the junctional epithelium between the tooth surface and gingival crevice and the development of a periodontal pocket. Progression of the disease can lead to bone destruction along the affected root surface, which presents as either horizontal bone loss with destruction of the entire thickness of the alveolar bone or vertical bone loss where only a portion of the bone is resorbed. If left untreated, periodontitis may lead to acute periodontal abscess and subsequent tooth loss.

Actinobacillus actinomycetemcomitans is also an opportunistic pathogen and has been isolated from patients with actinomycosis, infective endocarditis, osteomyelitis, brain and subcutaneous abscesses and rarely endophthalmitis (Van Winkelhoff and Slots, 1999). Cervicofacial actinomycosis is a chronic infection of the head and neck, most often occurring in males and resulting from infection with *Actinomyces* spp. and often one or more companion organisms including *A. actinomycetemcomitans*, *H. aphrophilus*, *Eikenella corrodens*, *Prevotella* spp. and *Fusobacterium* spp. Early clinical signs include a small hard swelling in the mouth, neck or jaw, followed by the appearance of many small, communicating abscesses, with surrounding granulation and sinuses which discharge sulphur-like granules. Infections may spread to the brain, nearby bones and soft tissues, with occasional pulmonary and abdominal infections reported. Actinomycosis may also affect the tonsils, tongue, cheek or lips after trauma at the affected site.

Actinobacillus actinomycetemcomitans is a rare but important pathogen associated with infective endocarditis and has been reported in patients with abnormal native heart valves and after the implantation of prosthetic heart valves. This bacterium is included in the HACEK (*H. aphrophilus*, *A. actinomycetemcomitans*, *Cardiobacterium hominis*, *E. corrodens* and *Kingella kingae*) group of organisms which are estimated to cause approximately 3% of community-acquired cases of infective endocarditis (Das *et al.*, 1997). As oral bacteria gain entry to the circulatory system by crossing the gingiva, poor oral health is an important risk factor of infective endocarditis. Many dental procedures can also cause oral bacteria to enter the bloodstream, although the incidence of infective endocarditis following dental procedures in at risk patients is extremely low. Clinical features of infective endocarditis may be nonspecific and vary considerably. If not correctly diagnosed, infective endocarditis can be a common cause of pyrexia of unknown origin. General symptoms may include, fever, malaise, weight loss, splinter haemorrhages under the proximal nails, finger clubbing, splenomegaly, anaemia, dyspnoea and cardiac murmur.

LABORATORY DIAGNOSIS

Specimens

Suitable samples for the isolation of *A. actinomycetemcomitans* include dental plaque, tissue biopsy, aspirates and blood samples. Clinical specimens collected from sites within the oral cavity need to be taken carefully to avoid contamination with the normal oral microflora. The use of swabs should therefore be avoided whenever possible, due to the likelihood of contamination with saliva. A needle and syringe can be used for sampling abscesses and lesions. Samples of subgingival plaque collected from patients with periodontitis should be collected by the use of a sterile curette or by paper points after the removal of supragingival plaque. Once the plaque has been sampled it should be immediately placed into a pre-reduced transport medium such as reduced transport fluid (Syed and Loesche, 1972) and taken to the laboratory for processing within 30 min of collection. Infective endocarditis can be diagnosed by the

presence of positive blood cultures as routinely used in clinical microbiology. The detection of growth in the blood cultures is generally present within 3–4 days, although blood culture bottles from patients with suspected infective endocarditis should be incubated for a total of 14 days.

Growth Requirement

Clinical samples should be plated onto blood agar or chocolate blood agar supplemented with 5% defibrinated horse blood and should be incubated in an aerobic atmosphere supplemented with 5–10% CO₂. *Actinobacillus actinomycetemcomitans* will also grow anaerobically on fastidious anaerobe agar. Faint colonies may be visible after 24 h of incubation. However, 48–72-h incubation is required for colonies of 1–3 mm to appear. The colonies are generally round, convex and colourless in appearance; they may have central wrinkling and be adherent to the agar surface. Colonies incubated for 4–7 days on a serum-containing medium will develop star-like structures centrally, which can be visualized with a plate microscope. This rough star-like morphology may be lost on subculturing producing smooth isolates which are less adherent to the agar surface. A range of selective media can also be used for the isolation of *A. actinomycetemcomitans* directly from clinical samples. Possibly, the most commonly used is Tryptic Soy-serum-Bacitracin-Vancomycin agar, which contains 10% serum, 75 mg/l of bacitracin and 5 mg/l of vancomycin; the presence of these antibiotics suppresses the growth of Gram-positive bacteria, and the absence of blood eliminates the X and V factor requiring *Haemophilus* species and allows the catalase test to be carried out directly on the colony. Finally the presence of serum allows for the characteristic star-like inner structure colony appearance.

Identification

Table 20.1 summarizes the characteristics of *A. actinomycetemcomitans* used for identification purposes. Adherent colonies with a stellate appearance that are catalase positive and reduce nitrates to nitrite are characteristic of *A. actinomycetemcomitans*. This bacterium ferments glucose, galactose and maltose but does not ferment lactose, sucrose, trehalose, salicin or sorbitol. It produces negative reactions for urease activity, indole production, aesculin hydrolysis and *o*-nitrophenyl- β -D-galactopyranoside. There are several commercial kits available that are able to give a positive identification for *A. actinomycetemcomitans*. Confirmation may be achieved by PCR-based methods using the bacterial small-subunit 16S rRNA gene (16S rDNA). The 16S rDNA contains regions which are highly conserved in bacteria as well as species-specific hypervariable regions. Primers designed within the 16S rDNA have been used to amplify these hypervariable regions found in *A. actinomycetemcomitans* with the production of amplicons of known sizes.

These methods have been shown to be simple to perform, rapid and reliable and suitable for the confirmation of cultured *A. actinomycetemcomitans* or direct identification of this bacterium in clinical samples. More recently a multiplex PCR approach has been used, in which *A. actinomycetemcomitans*-specific primers have been combined with primers specific to other periodontal pathogens for use in a single PCR reaction, allowing the simultaneous detection of a number of periodontal pathogens in a single-patient sample. PCR techniques can also be used for the identification of the JP2 strain by using primers to amplify sequences in the leukotoxin promoter region to identify the deletion found in these JP2 strains.

Antimicrobial Susceptibility

Currently there are no specific recommendations for the susceptibility testing of *A. actinomycetemcomitans* by the British Society for Antimicrobial Chemotherapy. However, several studies have tested this bacterium using modifications of the methods recommended for other fastidious bacteria, using either Muller-Hinton medium, *Haemophilus* test medium or Wilkins-Chalgren medium supplemented with 5% (v/v) defibrinated horse blood. Antibiotic susceptibility has been performed by disk diffusion, E-test and the agar dilution method (in which the antibiotic is incorporated into the medium), with incubation at 37 °C in 5–10% CO₂ for 24–48 h. Isolates of *A. actinomycetemcomitans* are generally susceptible to ciprofloxacin. However, resistance to other antibiotics has been recorded including penicillin (range 10–94%), amoxicillin (0–25%), erythromycin (4–10%) and tetracycline (0–4%) (Slots *et al.*, 1980; Eick, Pfister and Straube, 1999; Madinier *et al.*, 1999; Muller *et al.*, 2002).

TREATMENT AND MANAGEMENT

Periodontal therapy aims to reduce the bacterial load present on the root surface; this may be successfully achieved in the majority of cases by mechanical techniques with or without an antimicrobial adjunct. A standard cycle of periodontal therapy consists of oral hygiene instructions and mechanical debridement of the tooth and root surface. Oral hygiene instruction to control plaque is an essential part of a treatment plan for patients with periodontal diseases. By determining where the majority of the plaque accumulates in a subject's dentition, plaque control can be targeted at problem areas. The removal of supragingival and subgingival dental plaque, calculus from the tooth and root surfaces (scaling) and the removal of surface layers of the root surface (root planning) are normally required to assist healing. In some cases, surgical treatment will also be required. There should be an evaluation of the patient with a review and if necessary reinforcement of oral hygiene. Antimicrobial agents and antibiotics may also be used in treatment. The use of a 0.2% chlorhexidine rinse for

Table 20.1 Identification of *Actinobacillus actinomycetemcomitans*

Colony morphology	Microscopic appearance	Catalase	ONPG	Indole	Urease	Nitrate reduction	Aesculin hydrolysis	Acid from							
								Glucose	Galactose	Maltose	Lactose	Sucrose	Trehalose	Salicin	Sorbitol
Adherent to agar; stellate	Small Gram-negative rods; coccobacilli	+	–	–	–	+	–	+	+	+	–	–	–	–	–

+, positive reaction; –, negative reaction.

2 weeks posttreatment is often recommended to assist with plaque control. Tetracyclines are recommended for refractory periodontal diseases in the UK. However, combination antibiotic therapies are frequently used including metronidazole–amoxicillin and metronidazole–ciprofloxacin.

A proportion of individuals may not respond to the above treatment regimes, and to prevent loss of dentition, a range of therapeutic options are under development. These include the use of bone replacement materials with or without associated bone growth factors. Awaiting on the wings is the use of biologicals such as anti-cytokine antibodies or cytokine-soluble receptors to block the effects of cytokines such as interleukin-1 or tumour necrosis factor. Another treatment modality which is probably to be tested soon is osteoprotegerin or RANK-Fc a natural inhibitor of the cells (osteoclasts) that promote bone resorption (Henderson and Nair, 2003).

Francisella tularensis

Petra C. F. Oyston

Defence Science and Technology Laboratory, Salisbury, Wiltshire, UK

INTRODUCTION

Francisella tularensis is the causative agent of tularemia. It is considered a potential bioweapon because of its high infectivity by the aerosol route. There is no vaccine currently available, and antibiotic therapy may need to be protracted. The organism is highly fastidious, requiring rich media for isolation and specialised reagents for positive identification.

DESCRIPTION OF THE ORGANISM

Francisella tularensis was first isolated from ground squirrels dying from a plague-like disease in California in 1911 (McCoy and Chapin, 1912). It is a small (0.2–0.5 µm × 0.7–1.0 µm) Gram-negative coccobacillus, non-motile and obligately aerobic. It produces catalase weakly, is oxidase negative and H₂S positive. It produces acid but not gas from glucose, maltose and mannose, although catabolism of carbohydrates is slow (Sjostedt, 2002).

The taxonomy of *F. tularensis* is complex, the species being differentiated into subspecies on the basis of differences in virulence, geographic distribution and natural reservoir (Sjostedt, 2002). The most virulent subspecies, *F. tularensis* subspecies *tularensis* (also referred to as type A), is usually isolated in North America. The less virulent *F. tularensis* subspecies *holarctica* (also called type B) is distributed more widely (Olsufjev and Meshcheryakova, 1983; Eigelsbach and McGann, 1984). Two other subspecies, *novicida* and *mediasiatica*, have also been described but rarely cause disease in humans (Eigelsbach and McGann, 1984; Hollis *et al.*, 1989; Forsman, Sandstrom and Sjostedt, 1994).

Francisella tularensis requires enriched medium for growth such as cysteine glucose blood agar. Centers for Disease Control and Prevention (CDC) guidelines recommend the use of enriched chocolate agar (cysteine heart agar supplemented with 9% heated sheep red blood cells, CHAB) if the pathogen is suspected (Anonymous, 2001). The appearance of individual colonies may require 2–4 days of incubation at 37 °C. On CHAB, colonies are 2–4 mm in size, greenish-white, round, smooth and slightly mucoid, whilst on media containing whole blood there is usually a small zone of α-haemolysis surrounding colonies. *Francisella tularensis* grows poorly at 28 °C, and this can be exploited to distinguish *F. tularensis* from *Yersinia pestis*, *Francisella philomiragia* and *F. tularensis* subspecies *novicida* – all of which grow well at 28 °C. It can be distinguished from other Gram-negative bacteria except *Legionella* by cysteine dependence. Unlike *F. tularensis*, *Legionella* are motile and do not produce H₂O. *Francisella tularensis* does not grow well in liquid media, even when the medium is supplemented with cysteine, and requires a large inoculum to obtain visible growth within 24 h.

PATHOGENICITY

Francisella tularensis is able to infect a wide range of hosts, including humans. *Francisella tularensis* is one of the most highly infectious bacteria known, with an infectious dose in humans of only ten bacteria (McCrumb, 1961). Very few classical virulence factors have been identified for this pathogen. It does not produce secreted exotoxins, and the lipopolysaccharide (LPS) of *F. tularensis* does not exhibit the properties of a classical endotoxin (Sandstrom *et al.*, 1992). The capsule is essential for serum resistance but is not required for survival following phagocytosis (Sandstrom, Lofgren and Tarnvik, 1988).

EPIDEMIOLOGY

The pathogen has only been isolated in the northern hemisphere and most frequently in Scandinavia, northern America, Japan and Russia (Boyce, 1975; Ohara *et al.*, 1991; Berdal *et al.*, 1996; Stewart, 1996; Tarnvik, Sandstrom and Sjostedt, 1996), but has never been isolated in the United Kingdom. It circulates in populations of small rodents-endemic regions, and outbreaks in human populations frequently mirror outbreaks of disease occurring in wild animals (Tarnvik, Sandstrom and Sjostedt, 1996). *Francisella tularensis* is considered to be an intracellular pathogen *in vivo* (Fortier *et al.*, 1994). It is capable of multiplying in a range of cell types, but its primary target appears to be the macrophage. *Francisella tularensis* has also been shown to be able to replicate to high numbers inside amoebae, which may provide an environmental reservoir for the bacterium (Abd *et al.*, 2003).

CLINICAL FEATURES

Tularemia in humans occurs in several forms, depending on the route of infection. Tularemia is a severely debilitating and even fatal disease, especially when caused by *F. tularensis* subspecies *tularensis*, and many cases of disease caused by lower-virulence strains are undiagnosed. The most common form of the disease is ulceroglandular tularemia which usually occurs as a consequence of a bite from an arthropod vector. Cases of ulceroglandular tularemia in hunters and trappers have been known to arise following the handling of infected meat, with infection via cuts or abrasions. After an incubation period of 3–6 days, the patient experiences the sudden onset of flu-like symptoms, especially chills, fever, headache and generalised aches (Evans *et al.*, 1985; Ohara *et al.*, 1991). An ulcer forms at the site of infection, usually on the lower limbs in the cases of tick-borne disease. This ulcer may persist for several months. Disease with

similar symptoms but without the appearance of an ulcer is termed glandular tularemia. Bacteria disseminate from the site of infection via the lymphatic system to regional lymph nodes, which then become enlarged to resemble the bubo associated with bubonic plague. Subsequent dissemination spreads the bacteria to other tissues such as the spleen, liver, lungs, kidneys, intestine, central nervous system and skeletal muscles. This bacteremic phase of the infection is transient and occurs relatively early in the infection process. Recovery from the disease can be protracted, taking many months, but the ulceroglandular form of tularemia is fatal in fewer than 3% of cases. If the initial site of infection is the conjunctiva, oculoglandular tularemia may develop. Ulcers and nodules develop on the conjunctiva, and without treatment, the infection spreads to the local lymph nodes, similar to typical ulceroglandular disease.

Typhoidal tularemia is an acute disease with septicaemia without lymphadenopathy or the appearance of an ulcer. In addition to the generalised symptoms seen in ulceroglandular tularemia, the patient may become delirious and shock may develop. When caused by the highly virulent *F. tularensis* subspecies *tularensis*, typhoidal tularemia is associated with a mortality rate of between 30 and 60% (Evans *et al.*, 1985; Gill and Cunha, 1997).

The ingestion of infected foodstuffs or of bacteria in drinking water results in tularemia infection. Either oropharyngeal or gastrointestinal tularemia develops, depending on the site of colonisation of host tissues. Oropharyngeal tularemia presents as a painful sore throat with enlargement of the tonsils and the formation of a yellow-white pseudomembrane, often accompanied by swollen cervical lymph nodes. Gastrointestinal tularemia produces a range of diseases, from a mild but persistent diarrhea to an acute fatal disease with extensive ulceration of the bowel, depending on the size of the infecting dose.

Pneumonic tularemia is the most acute form of disease. It arises following the inhalation of bacteria, although pneumonic disease occurs as a secondary complication of the other forms of tularemia (Gill and Cunha, 1997). *Francisella tularensis* is highly infectious by the aerosol route, with fewer than ten bacteria being required to cause infection. Following inhalation of the bacteria, there is an incubation period of 3–5 days. Subsequent diagnosis of pneumonic tularemia is difficult because of the symptoms being variable, but patients usually present with an acute flu-like illness with or without clinical pneumonia or pneumonitis. Symptoms include fever, non-productive cough, pharyngitis, pleuritic chest pain and hilar lymphadenopathy. Severe pleuropneumonitis develops with pleural effusions, but chest signs may be absent in some patients. Pneumonic tularemia is rare and usually arises in farmers who have been handling hay which has previously been the site of residence of infected rodents (Stewart, 1996).

LABORATORY DIAGNOSIS

Francisella tularensis can be isolated from ulcer scrapings, lymph node biopsies or sputum. The organism is rarely cultured directly from blood, although this is becoming feasible with the development of sensitive blood culture systems. In inhalational tularemia, the organism can be detected in sputum, pharyngeal washings and pleural fluid.

Because of the difficulty in culturing *F. tularensis*, most cases of tularemia are diagnosed on the basis of clinical picture and/or serology. Serological tests for the diagnosis of *F. tularensis* infection are attractive because diagnostic work involving culture procedures carries a risk of infection for non-vaccinated laboratory staff. The diagnosis of human cases of tularemia is usually confirmed by the demonstration of an antibody response to *F. tularensis*, which occurs about 2 weeks after the onset of the disease (Koskela and Salminen, 1985). The detection of serum antibodies is most frequently achieved by agglutination or using an enzyme-linked immunosorbent assay (ELISA) (Carlsson *et al.*, 1979; Koskela and Salminen, 1985;

Syrjala *et al.*, 1986). A latex agglutination test commercially available from BBL (Becton Dickinson, Franklin Lakes, NJ, USA) has been used to identify individuals with antibodies to *F. tularensis*: reactions at greater than 1:20 dilutions are considered specific and significant. Commercially available antigens are also used with standard tube agglutination tests. A fourfold increase during illness or a single titre of 1:160 or greater is considered diagnostic (Brown *et al.*, 1980). However, while serological tests are frequently used for diagnosis, strains of *F. tularensis* have occasionally been isolated which fail to induce antibodies that agglutinate commercially available *F. tularensis* antigens (Clarridge *et al.*, 1996).

ELISA-based tests can be used to detect the bacteria in clinical samples. For example, a capture ELISA using monoclonal antibodies against *F. tularensis* LPS recognised all strains of *F. tularensis* tested other than those of subspecies *novicida*, with no cross-reactivity with other bacterial species tested (Grunow *et al.*, 2000). An immunochromatographic hand-held assay has also been developed based on a polyclonal and a monoclonal antibody to LPS. This assay is principally designed for field use, being compact, easy to use and gives results in 15 min; however, the relatively low sensitivity means that a negative result does not exclude tularemia (Grunow *et al.*, 2000).

A range of polymerase chain reaction (PCR)-based assays have been reported for the diagnosis of tularemia. These PCR assays use primers directed against genes encoding outer membrane proteins such as *fopA* (Fulop *et al.*, 1996) or the 17 kDa outer membrane lipoprotein (Junhui *et al.*, 1996; Grunow *et al.*, 2000). In a study with lesion swab samples from 40 human cases of ulceroglandular tularemia, a PCR assay was positive for 73% of the samples, whereas bacteria were cultured from only 25% of the samples (Sjostedt *et al.*, 1997). PCR-based tests have the advantage that they are safer than culturing bacteria. Improved methods for isolating and processing tissue or blood samples and for the transport of samples to the laboratory might further improve the sensitivity and utility of the PCR test. Indeed, a specially formulated filter paper designed for sample collection has been proposed for the rapid preparation of template DNA from clinical or from field collected tick vectors. When linked with a TaqMan 5' nuclease assay or a PCR-enzyme immunoassay, sensitivities of <100 cfu were reported (Higgins *et al.*, 2000).

Molecular methods are also available to discriminate between *Francisella* strains. Long random-sequence oligonucleotide primers and primers specific for repetitive extragenic palindromic (REP) sequences and enterobacterial repetitive intragenic consensus (ERIC) sequences were evaluated. REP-PCR was suitable for identifying strains of *F. tularensis* subspecies *novicida*, but not for separating strains of subspecies *holarctica* and *tularensis*, as the patterns obtained were too similar (Johansson *et al.*, 2000). A one-base difference in the 16S rRNA sequences of subspecies *tularensis* and *holarctica* has been demonstrated, allowing the development of a PCR capable of differentiating the two subspecies (Forsman, Sandstrom and Sjostedt, 1994). PCR amplification of tandem-repeat regions may be highly discriminatory and a useful tool in strain typing (Farlow *et al.*, 2001; Johansson *et al.*, 2001). A specific PCR has been developed which produces amplicons of different lengths (target unknown), which has been used in combination with the 17-kDa lipoprotein PCR and can distinguish *F. tularensis* subspecies *holarctica* from strains of other *F. tularensis* subspecies (Johansson *et al.*, 2000).

MANAGEMENT

The aminoglycosides streptomycin and gentamicin are bactericidal against *F. tularensis* and are currently the drugs of choice for the treatment of tularemia infections. Current PHLS guidelines Lutzomial recommend gentamicin for 10 days. In children, the recommended dose is for

10 days or streptomycin intramuscularly twice daily for 2 weeks. These antimicrobials are not used routinely as monotherapy for the treatment of acute febrile illnesses including pneumonia. Thus, if tularemia is suspected, an aminoglycoside should be added to an appropriate antibiotic regimen and not used as a single agent. Other antibiotics can then be stopped once *F. tularensis* has been confirmed and the antibiotic sensitivity of the organism determined.

The fluoroquinolones have been shown to have good bactericidal activity against *F. tularensis* and are attractive because of their low toxicity and potential for oral therapy. In the UK national guidelines, a regimen of ciprofloxacin intravenously every 12 h, changing to the oral route for 14 days, is suggested for non-pregnant adults. In a recent human epidemic outbreak in Spain, ciprofloxacin was the antibiotic with the lowest rate of therapeutic failure and with the fewest side effects. Ciprofloxacin was also shown to be suitable for treating tularemia in children and in a case of relapse following gentamicin therapy. Tetracycline and chloramphenicol are bacteriostatic against *F. tularensis*, and these antibiotics are associated with high relapse rates, although the chances of relapse are reduced with longer treatment regimens. Owing to the poor penetration of aminoglycosides into CSF, chloramphenicol may be added to streptomycin in cases of meningitis complications. The pathogen is resistant to β -lactam antibiotics, and macrolides are not recommended.

PREVENTION AND CONTROL

Attenuated strains of *F. tularensis* have been used to immunise millions of people against tularemia, especially in the former Soviet Union. The most widely used vaccine strain in recent times is the live vaccine strain (LVS), which was derived from a virulent strain of *F. tularensis* subspecies *holarctica*. In clinical trials in humans, vaccination with LVS by the intradermal route provided either complete protection against a subsequent challenge with fully virulent *F. tularensis* or at least reduced the severity of disease (Saslaw *et al.*, 1961a,b). The LVS vaccine has also been shown to be effective when given by the aerogenic and oral routes of delivery, but the vaccine is usually administered by scarification. However, the precise history of the LVS strain is uncertain and the nature of the attenuation is not currently known. In addition, this strain has been found to be unusual compared with fully virulent *F. tularensis*. For example, the expansion of V γ 9V δ 2 T cells seen in patients with tularemia is not observed following vaccination with LVS (Poquet *et al.*, 1998). Owing to residual virulence in the mouse model and a lack of understanding of the basis of attenuation or the mechanism of induction of protection, this strain is not currently licensed for human use in the United States or Europe.

INTRODUCTION

Members of the order Rickettsiales are represented by a diverse group of Gram-negative bacteria that are largely intracellular parasites. Although many species are adapted to existence within arthropods, they are frequently capable of infecting vertebrates, including humans. Prior to 1986, eight rickettsioses were recognized. In the last two decades this number has increased to 14 with the advent of improved cell culture and molecular identification techniques (Raoult and Roux, 1997). At least 13 species in five genera are pathogenic for humans. The diseases caused by these microorganisms have had significant roles in the history of civilization. However, other diseases that have had greater epidemic potential and that lack effective interventions have overshadowed rickettsial diseases. The discovery of new groups has sparked a renewed interest of late, and rickettsioses are now seen as emerging infectious diseases that potentially threaten human health in locations throughout the globe.

DESCRIPTION OF THE ORGANISMS

Definition

Rickettsiae, members of the family *Rickettsiaceae*, are fastidious Gram-negative, obligate intracellular bacterial organisms that survive within membrane-bound vacuoles (Rikihisa, 1991). Organisms included in the Rickettsiales are distinguished by short, nonflagellated, rod-shaped coccobacilli ranging from 0.8 to 2.0 µm in length and from 0.3 to 0.5 µm in width (Ris and Fox, 1949). All species are characterized by a five-layered outer envelope surrounded by lipopolysaccharide (Schramek, Brezina and Tarasevich, 1976). The genus *Ehrlichia* is made up of three pathogenic species of small obligate intracellular Gram-negative bacteria. *Ehrlichia* coccobacilli have been observed to take two forms while inside host cells: a small (0.2–0.4 µm), electron dense form and a large, light form (0.8–1.5 µm) (Popov *et al.*, 1995). *Ehrlichia* are surrounded by thin outer and inner membranes, but unlike members of the genus *Rickettsia*, show no thickening of either leaflet or of the outer membrane. Morphologically, members of the genus *Ehrlichia* do not appear to contain significant amounts of peptidoglycan.

Classification

Recent restructuring of the order Rickettsiales, based on genetic differences among rickettsial and ehrlichial species (Weisburg *et al.*,

1989; Brenner *et al.*, 1993), has resulted in the creation of two families within the order: *Rickettsiaceae*, which includes members of the genera *Rickettsia* and *Orientia*, and *Anaplasmataceae*, made up of members of the genera *Ehrlichia*, *Wolbachia*, *Anaplasma* and *Neorickettsia* (Dumler, Barbet and Bekker, 2001). This reclassification has moved former members, most notably *Coxiella*, *Bartonella*, *Grahamella* and *Rochalimae*, from Rickettsiales to different orders. *Coxiella burnetii*, the causative agent of Q fever, is now a member of the family *Coxiellaceae* in the order Legionellales, and *Bartonella*, *Grahamella* and *Rochalimae* have been united in the family *Bartonellaceae*, order Rhizobiales (Comer, Paddock and Childs, 2001). The genus *Rickettsia* is comprised of three genetically and antigenically similar groups, namely spotted fever, typhus and scrub typhus groups.

Molecular Characterization

The previous standards for defining rickettsial species include a variety of direct phenotypic features including morphology and antigenic properties, as well as indirect properties such as geographic distribution, host cell type, animal reservoir and disease characteristics. Classical laboratory methods for identifying different rickettsial family members utilized cross-immunity and protection in guinea pigs in addition to complement fixation (CF) and mouse toxin neutralization tests (Philip *et al.*, 1967). Serologic identification of rickettsial isolates met with some success but was plagued by a high level of cross-reactivity between species. As such, phylogenetic analysis of rickettsial species has been conducted to discern the degree of relatedness among groups and in some cases to define new species following molecular analysis of conserved genes. Initial attempts were conducted to determine cross-hybridization of genomic sequences among different rickettsial species. These techniques were confounded by the necessity to generate large amounts of uncontaminated DNA. The use of smaller quantities of DNA during polymerase chain reaction (PCR) tests has allowed for the identification of species.

PATHOGENESIS

Many rickettsiae infect endothelial cells of the microcirculatory system, especially the capillaries. Damage to the vasculature is the basis for similarities in pathology of rickettsial diseases (Walker and Matern, 1980). The primary cellular lesion results from dilation and destruction of intracellular membranes, particularly the rough endoplasmic reticulum (Silverman, 1984). As endothelial cells die, necrosis of the blood vessels leads to the formation of hyaline thrombi

that manifest themselves clinically as petechiae. Gross and microscopic lesions are found in the brain, heart, kidney and lungs.

Unlike the other rickettsiae, infection by the spotted fever group family member (SFG), *Rickettsia rickettsii*, is not confined to the capillary endothelium with the bacterium often found to invade and destroy smooth muscle and vascular endothelium cells of larger vessels. Other SFG rickettsiae may cause interstitial pneumonia. In fatal cases of Rocky Mountain spotted fever (RMSF), the distribution of rickettsiae parallels observed pulmonary vasculitis, suggesting that rickettsial invasion of the microcirculation results in the interstitial pneumonitis. The vasculitis, vascular damage and increased vascular permeability result in alveolar septal congestion and oedema, fibrin formation, macrophage accumulation and haemorrhage and interlobar, septal and pleural effusion (Walker, Crawford and Cain, 1980). Interstitial pneumonitis is more frequent in scrub typhus than in epidemic typhus or spotted fever patients (Allen and Spitz, 1945).

Lesions of the central nervous system (CNS) play an important role in the clinical manifestations of RMSF and typhus. All portions of the brain and spinal cord may be involved, but the midbrain and inferior nucleus are most frequently affected. Focal proliferations of the endothelial and neuroglial cells (once called typhus nodules) are typical. Neurological findings in RMSF are the result of microinfarcts and frequently involve the white matter. Neurological pathology in epidemic and scrub typhus include mononuclear cell meningitis, perivascular cuffing of arteries, focal haemorrhages and degeneration of ganglionic cells (Allen and Spitz, 1945).

Interstitial myocarditis is found in RMSF, epidemic typhus and scrub typhus. RMSF heart lesions are patchy and consist of a mixed mononuclear cell infiltrate. *Rickettsia rickettsii* may be detected in the cardiac vessels by immunofluorescence (Walker, Palletta and Cain, 1980).

The urinary tract is commonly affected in RMSF and typhus. Azotemia is usually prerenal and reflects intravascular volume depletion. Acute renal failure in RMSF is probably due to tubular necrosis that results from systemic hypotension (Allen and Spitz, 1945). Histopathological studies of RMSF, epidemic typhus and scrub typhus have shown that the testes, epididymis, scrotal skin and adrenals may also be involved. Swollen Kupffer cells of the liver are prominent in typhus, and phagocytosis of erythrocytes and inflammatory cells may be noted in the spleen (National Research Council, 1953).

Unlike the *Rickettsiaceae*, members of the family *Anaplasmataceae* primarily infect cells of bone marrow origin. Although ehrlichial agents that infect humans have been classified based on the predominant

type of cells they infect, i.e. monocytes [human monocytic ehrlichiosis (HME)] or granulocytes [human granulocytic ehrlichiosis (HGE)], many species have been found in other cell types. Few studies have been performed to investigate the human pathology of ehrlichial disease; what is known is based on sparse biopsy material from individuals who died from ehrlichiosis (Olano and Walker, 2002).

Bone marrow has been the most examined tissue in cases of HME. The most common finding is myeloid hyperplasia, while other findings may include granulomas, diffuse histiocytic aggregates, haemophagocytosis, lymphoid aggregates and plasmocytosis (Olano and Walker, 2002). Cells infected by *E. chaffeensis* include Kupffer cells, splenic macrophages and macrophages present in perivascular lymphohistiocytic infiltrates, which may be present in several organs including the CNS. Interstitial mononuclear cell pneumonia, pulmonary oedema and diffuse alveolar damage may be observed in the lung (Walker and Dumler, 1997). Severe thrombocytopenia can result in haemorrhage in various organs.

In the case of HGE, caused by *Anaplasma phagocytophila*, lymphoid depletion, erythroleucophagocytosis and apoptosis are observed in the spleen (Olano and Walker, 2002). Lymph nodes may also be affected, showing lymphadenitis early in disease and paracortical hyperplasia later. During the convalescent stage of disease, bone marrow shows normocellularity and paratrabecular and nonparatrabecular lymphoid aggregates. Periportal lymphohistiocytic infiltrates, lobular hepatitis, Kupffer cell hyperplasia and apoptotic hepatocytes may be observed in the liver. In some cases, interstitial pneumonia is observed (Walker and Dumler, 1997).

CLINICAL AND EPIDEMIOLOGICAL FEATURES

The Rickettsiales are often associated with distinct arthropods that in turn serve as vectors for transmission of the bacterium. While a number of rickettsial species exist, distinct groups can be broken out based upon their ability to cause disease in humans (Weiss, 1981). Some of these diseases include RMSF (*R. rickettsii*), epidemic typhus (*R. prowazekii*), murine typhus (*R. typhi*), scrub typhus (*Orientia tsutsugamushi*), boutonneuse fever (*R. conorii*) and rickettsial pox (*R. akari*). Most of the illnesses caused by members of the order Rickettsiales are characterized by acute onset of fever accompanied by nonspecific signs and symptoms. In many diseases a characteristic rash follows the systemic symptoms and may be pathognomonic. Table 22.1 provides a list of agents and a summary of diseases associated with aetiological agents, their geographical distributions and mode of transmission to humans.

Table 22.1 Features of the pathogenic *Rickettsiales* species

Biogroup	Species	Disease in humans	Distribution	Transmission to humans
Spotted fever	<i>R. rickettsii</i>	Rocky Mountain spotted fever	Western Hemisphere	Tick bite
	<i>R. conorii</i>	Mediterranean spotted fever; also called Boutonneuse fever	Primarily Mediterranean countries, Africa, India, Southwest Asia	Tick bite
	<i>R. siberica</i>	Siberian tick typhus	Siberia, Mongolia, northern China	Tick bite
	<i>R. australis</i>	Australian tick typhus	Australia	Tick bite
	<i>R. akari</i>	Rickettsial pox	USA, USSR	Mite bite
	<i>R. japonica</i>	Oriental spotted fever	Japan	Presumably tick bite
Typhus	<i>R. prowazekii</i>	Louse-borne typhus	Primarily highland areas of South America and Africa	Infected louse faeces
		Recrudescence typhus (Brill-Zinsser disease)	Worldwide: follows distribution of persons with primary infections	Reactivation of latent infection
		Sporadic typhus	USA	Contact with flying squirrels <i>Glaucomys volans</i> Infected flea faeces
Scrub typhus Ehrlichiosis	<i>R. typhi</i>	Flea-borne typhus	Worldwide	Chigger bite
	<i>O. tsutsugamushi</i>	Scrub typhus	Asia, northern Australia, Pacific Islands	Trematode in fish
	<i>N. sennetsu</i>	Sennetsu ehrlichiosis	Japan and Malaysia	Tick bite
	<i>E. chaffeensis</i>	Human monocytic ehrlichiosis	USA, possibly Africa and Europe	Tick bite
	<i>A. phagocytophila</i>	Human granulocytotropic ehrlichiosis	USA, Europe	Tick bite
	<i>E. ewingii</i>	Human granulocytotropic ehrlichiosis	USA	Tick bite

Rocky Mountain Spotted Fever

RMSF, caused by infection with *Rickettsia rickettsii*, is an acute, seasonal, tick-borne, potentially fatal disease characterized by fever, headache and rash and frequently myalgia and anorexia after an incubation period of between 4 and 14 days. While first reported in the western United States, RMSF has been found in Costa Rica and further down in South America (Fuentes, 1986). Initial symptoms of disease are nonspecific including high fever, headache, muscle pain and occasional nausea, cough and vomiting. Later complications include vascular damage, increased permeability, oedema, haemorrhage, disseminated intravascular coagulation, interstitial pneumonitis, CNS involvement, myocarditis and renal failure (Clements, 1992). The case fatality ratio (CFR) has been reduced to between 3 and 5% since antibiotic therapy became available, but untreated, the CFR ranged between 23 and 70% (Harrell, 1949). Most of the approximately 600 cases reported annually in the United States are located in the southeast and south central states where the principal vector ticks, *Dermacentor variabilis* and *Amblyomma americanum*, are prevalent. In South America *A. cajenense* is a major vector, but other species may also be involved in transmission. The highest incidence occurs in children aged 5–9 years, and males outnumber females by nearly 2–1. Delay in initiating antibiotic therapy and increased age of patients are risk factors that significantly increase complications and death.

Spotted Fevers

A number of other SFG have been described from a wide geographic range. African tick typhus, Japanese tick typhus, Kenya tick typhus, Israel tick typhus, Indian tick typhus, Siberian tick typhus, Australian tick typhus and Oriental tick typhus are caused by additional spotted fever group rickettsiae that are transmitted by ticks. Mediterranean spotted fever (MSF), caused by infection with *R. conorii*, is similar to RMSF but is somewhat milder and is often characterized by a primary necrotic lesion known as an eschar or tache noir, where the site of tick bite has occurred. Among hospitalized patients, the CFR is 2% (Raoult *et al.*, 1986). The tick vector, *Rhipicephalus sanguineus*, is found mostly in Europe. In North America, the best-characterized, tick-borne rickettsial pathogen is *R. rickettsii*. However, a second SFG member with close homology to the Thai tick typhus rickettsia strain TT-118 has been isolated from *A. cajenense* in South Texas (Billings *et al.*, 1998). Evidence of *R. rickettsii* infections has also been documented through South America, primarily due to the tick vector *A. cajenense* (Ripoll *et al.*, 1999; Martino *et al.*, 2001; Rozental *et al.*, 2002). Interestingly, the degree of virulence and the ability to cause cytopathic injury to human endothelial cells within American strains of *R. rickettsii* have been attributed to polymorphic genetic changes (Eremeeva *et al.*, 2003). Recently a potential new spotted fever group member has been identified in Northeastern Peru (Blair *et al.*, 2004). Demographic and temporal information on vectors and prevalence in humans in the South and Central America should allow for an assessment of risk in these areas.

Louse-Borne Typhus

Louse-borne (epidemic) typhus caused by infection with *R. prowazekii* is an acute febrile disease accompanied by headache, myalgia and rash that is transmitted by the human body louse, *Pediculus humanus*. Complications include interstitial pneumonitis, CNS involvement, myocarditis and acute renal failure. During epidemics, the disease may have CFRs between 10 and 66% (Megaw, 1942; Foster, 1981), depending on the health and nutrition of populations afflicted. Outbreaks of louse-borne typhus occur when pediculosis is wide spread as a result of the disruption of regular hygiene and lack of adequate water supplies for bathing. Typical settings where louse-borne typhus outbreaks occur include refugee camps, prisons and communities

ravaged by war or disaster. An endemic form of the disease occurs in several areas of the world where high altitude and cold weather combine to promote conditions of pediculosis. Of some interest is the evolutionary divergence of *R. prowazekii* from members of the spotted fever group. While both can be traced to a common ancestor some 40–80 million years ago, evidence suggests that *R. prowazekii* has evolved more rapidly, even shedding genetic material while adapting to its specific host (Ogata *et al.*, 2001).

Brill-Zinsser Disease

A recrudescence form of louse-borne typhus (Brill-Zinsser disease) is generally milder than the initial episode but serves as the mechanism for reintroduction of the disease into human populations. Patients who recover from louse-borne typhus may become rickettsemic as a result of diminished immunity due to age, illness or a variety of causes and transmit rickettsiae to their body lice. If infected lice infest susceptible humans they are capable of beginning an epidemic of louse-borne typhus.

Flea-Borne Typhus

Flea-borne (murine) typhus is caused by *R. typhi* infection and is an acute febrile illness typically associated with headache, myalgia, anorexia and rash. While presentation of this disease is mild compared with louse-borne typhus and fatalities are rare (Miller and Beeson, 1946), its importance should not be minimized, as it is endemic across the globe. Indeed, the worldwide distribution of the disease is attributed to the distribution of the rat flea (*Xenopsylla cheopis*). The natural reservoir for typhus are *Rattus rattus* and *R. norvegicus* species and is a major cause of febrile illness in the tropics. Populations that are occupationally exposed to rodents have increased risk of infection. Agricultural workers are often exposed to rodents and their fleas as a result of harvesting crops. A highly sensitive PCR-based assay can detect *R. typhi* in samples of fleas (Webb *et al.*, 1990). Additionally, species-specific monoclonal antibodies have been developed and used successfully to elucidate rickettsial species in flea cryosections (Fang *et al.*, 2003).

Scrub Typhus

Scrub typhus (Tsutsugamushi fever), caused by *O. tsutsugamushi*, is a common febrile disease in South and Southeast Asia. In these areas, more than a billion people are at risk, and roughly one million cases occur each year (Watt *et al.*, 2000). It is characterized by severe headache, myalgia, arthralgia, maculopapular rash and an eschar in about 20% of patients (Berman and Kundin, 1973). Several species of larval mites of the family *Trombiculidae* serve both as vectors and reservoirs of the rickettsiae. The parasitic stage is conducted by a chigger that develops after 7–10 days. The vector is often a member of the order Rodentia, family *Muridae*. Untreated, the CFR is less than 10%, and with antibiotic therapy, fatalities are rare. Populations at risk of acquiring scrub typhus are those who come in contact with mite-infested habitats. Military populations and agricultural workers whose occupations require them to spend time in habitats transitional between forest and field have significant risk of infection. Several strains of *O. tsutsugamushi* cause human illness and infection with one does not confer immunity to subsequent infection with others. *O. tsutsugamushi* has historically been detected by the Weil-Felix serologic test and more recently by molecular and immunological tests.

Rickettsialpox

Rickettsialpox is caused by infection with *R. akari* and is an uncommon febrile illness characterized by sparse, discrete, maculopapular lesions on the face, trunk and extremities that become vesicular. Eschars occur in most (90%) patients and begin as red papules and

develop into shallow, punched out ulcers. Transmission of *R. akari* occurs via the mite *Liponyssoides sanguineus* when humans come in contact with premises infested with the house mouse, *Mus musculus*. Most cases in the United States are from urban environs of low socioeconomic status. Cases have been reported from the Ukraine region of the former Soviet Union.

Ehrlichiosis

Human Monocytic Ehrlichiosis

HME in the United States is caused by infection with *E. chaffeensis*. This acute febrile disease is most frequently characterized by headache, myalgia, nausea, arthralgias and malaise (Fishbein, Dawson and Robinson, 1994). Other manifestations of illness may include cough, pharyngitis, lymphadenopathy, diarrhoea, vomiting, abdominal pain and changes in mental status (Fishbein, Dawson and Robinson, 1994; Paddock and Childs, 2003). Laboratory findings include leucopenia, thrombocytopenia and elevated liver enzymes (Fishbein, Dawson and Robinson, 1994). The disease is potentially life threatening, and complications include disseminated intravascular collapse and death. The CFR is approximately 3%. More than 500 confirmed cases of HME were reported from 1986 to 1997 from all but two states with the majority of cases being reported from the south-central and south-eastern United States (Paddock and Childs, 2003). In 1999 and 2000, 156 and 200 cases of confirmed or probable HME were reported in the United States (CDC, 2002; Paddock and Childs, 2003). More than 70% of cases occur between May and July when vector ticks are actively questing for blood meals (Fishbein, Dawson and Robinson, 1994). Males account for 75% of the HME cases reported. It is not clear whether the difference in incidence between males and females is due to exposure or other factors. Several lines of evidence indicate that *A. americanum* is the vector for *E. chaffeensis* transmission (Anderson *et al.*, 1993; Ewing *et al.*, 1995; Lockhart *et al.*, 1995; Lockhart *et al.*, 1996). The white-tailed deer is the only recognized reservoir for maintaining *E. chaffeensis* in nature, although there are indications that other mammals including goats, dogs, coyotes, red foxes, raccoons and others may serve as hosts (Paddock and Childs, 2003). Risk factors of infection include occupational and recreational exposure to tick-infested areas.

Human Granulocytic Ehrlichiosis

HGE is caused by infection with *A. phagocytophilia* (formerly known as *Ehrlichia phagocytophilia* or *Ehrlichia equi* or the HGE agent). A human granulocytic ehrlichial agent was first identified in 1994 (Chen *et al.*, 1994). Clinical symptoms of HGE are similar to those of HME but to a milder degree (Olano and Walker, 2002). The CFR ranges from 0.5 to 1%. Four hundred and forty-nine cases of HGE were reported as of 1997 (McQuiston *et al.*, 1999). Cases of HGE have been reported in the United States (southern New England, mid-Atlantic, upper Midwest and northern California) and Europe (Blanco and Oteo, 2002; Lotric-Furlan *et al.*, 2003; Ruscio and Cinco, 2003). *Ixodes scapularis* (Bakken and Dumler, 2000), *I. pacificus* (Reubel *et al.*, 1998) and *I. ricinus* (Petrovec *et al.*, 1999) are the vectors responsible for transmission in the eastern and midwestern United States, California and Europe, respectively. The primary reservoir of *A. phagocytophilia* is the white-footed mouse, although other reservoirs may include the whitetail deer, the wood rat, coyotes and cotton mice (Olano and Walker, 2002). Risk factors, seasonality and the predominance of males with infection are similar to those of HME. Another agent that naturally infects dogs, *Ehrlichia ewingii*, has recently been confirmed to cause HGE in four patients who were receiving immunosuppressive therapy, indicating that the infection was likely opportunistic (Buller *et al.*, 1999).

Sennetsu Fever

Neorickettsia sennetsu (formerly known as *Ehrlichia sennetsu*) causes a mononucleosis-like, acute febrile disease characterized by chills, headache, malaise, insomnia, diaphoresis, pharyngitis and anorexia (Misao and Katsuta, 1956). Lymphadenopathy is generalized and characterized by tenderness and is most prominent in the postauricular and posterior cervical areas. Hepatomegaly and splenomegaly occur in about 33% of cases (Tachibana, 1986). The geographic distribution of confirmed cases include Japan and Malaysia. The disease is self-limiting, and no fatalities have been reported. It has been suggested that the primary mode of transmission is from eating fish contaminated with the bacterium (Dumler, Barbet and Bekker, 2001); however, information on potential vectors and reservoirs is lacking. Risk factors of infection are also unknown.

LABORATORY DIAGNOSIS

Laboratory diagnosis of rickettsial diseases is routinely accomplished by serologic assays that detect anti-rickettsial antibodies. Alternative procedures include isolation of rickettsiae from patient tissues and techniques aimed at direct detection of rickettsiae in tissue. However, the later two methods are generally restricted to research laboratories. Although none of the established techniques provides a reliable diagnosis early enough to affect the outcome of the disease, several new rapid diagnostic techniques have shown promise in research laboratories.

Adaptation of some of these new techniques may provide useful tools for early diagnosis of rickettsial diseases in a clinical setting. Specifically, PCR assays for the aetiologic agents of most rickettsial diseases have been developed. These techniques are undoubtedly the most sensitive means by which rickettsiae can be detected directly in clinical specimens. More recently, PCR-based techniques for the genotypic identification of rickettsial agents has been augmented with the addition of RFLP analysis to differentiate species and genotypes and to provide for an estimate of genetic divergences among selected genes (Regnery, Spruill, and Plikaytis, 1991). Additional laboratory techniques that have been used successfully to detect rickettsiae early in the course of infection include detection of antigen in peripheral blood cells and immunoglobulin M (IgM) antibody-capture immunoassays. However, serodiagnosis is still the preferred diagnostic approach, and testing of serum specimens collected during the acute and convalescent phases of illness is recommended. Preferred techniques for diagnosing rickettsial diseases are summarized in Table 22.2.

Serology

Most serologic diagnosis of rickettsial diseases is performed by the indirect immunofluorescence assay (IFA) primarily because of the availability of reagents and the ease and economy with which it can be incorporated into existing antibody screening systems. A variety of other tests have been used for serodiagnosis of rickettsial diseases.

Table 22.2 Preferred laboratory techniques for the diagnosis of rickettsial diseases

Infecting organism	IFA (indirect)	ELISA	Isolation	PCR
<i>R. rickettsii</i>	X	X	X	X
<i>R. conorii</i>	X	X	X	X
<i>R. prowazekii</i>	X	X	X	X
<i>R. typhi</i>	X	X	X	X
<i>O. tsutsugamushi</i>	X		X	
<i>E. chaffeensis</i>	X			X
<i>A. phagocytophila</i>	X			X

Table 22.3 Highlights of various serological techniques for the diagnosis of rickettsial infections

Technique	Minimum positive titre	Time after onset antibody usually detected	Comments
IFA	16–64 depending on investigator and organism	2–3 weeks	Relatively insensitive, requires little antigen; can be used for all rickettsiae and related organisms
CF	8 or 16, depending on investigator	3–4 weeks	Less sensitive than IFA or ELISA but very specific
ELISA	Optical density 0.25>controls	1 week in some instances	IgM capture assay promising for early diagnosis
Latex agglutination	64	1–2 weeks	Lacks sensitivity for late convalescent sera
IHA	40	1–2 weeks	Sensitivity \geq IFA; more sensitive than CF
Immunoperoxidase	20	7 days	Not evaluated for all rickettsiae; useful in field situations
Microagglutination	\geq to 8	1–2 weeks	Requires considerable antigen; less sensitive than IFA
Weil-Felix	40–320, depending on investigator	2–3 weeks	Lacks sensitivity and specificity

A summary of the more common techniques can be found in Table 22.3, and details can be found in the respective references at the end of this chapter. However, relatively few of these techniques are used regularly by a majority of laboratories, and those that cannot prepare the needed reagents are limited to techniques that utilize commercially available antigens. Some tests compromise sensitivity (latex agglutination and Weil-Felix) for convenience, while other highly sensitive tests [enzyme-linked immunosorbent assay (ELISA)] are cumbersome in clinical settings.

Rickettsioses must be distinguished from several viral and bacterial illnesses, including meningococcaemia, measles, enteroviral exanthems, leptospirosis, typhoid fever, rubella and dengue fever. The interpretation of serologic tests is frequently confounded by the lack of specificity of available rickettsial reagents. Whole rickettsiae are used as antigens for many antibody assays, and as rickettsiae share common antigens (or epitopes) with other bacteria (e.g. *Proteus* species), sera from nonrickettsial patients can react at low titres with rickettsial antigens. This has necessitated the designation of minimum positive titres (Table 22.3) to confirm recent rickettsial infections. As the establishment of minimum positive titres is assigned somewhat arbitrarily, testing of acute- and convalescent-phase serum specimens is recommended.

Recommending a preferred serologic technique is not entirely straightforward. ELISA techniques, particularly IgM-capture assays, are among the most sensitive procedures available for rickettsial diagnosis, but they require large quantities of purified antigens that are unavailable commercially. ELISAs are also quite amenable for the large-scale screening of serum specimens, but this advantage is usually lost for rickettsial diseases, because with the exception of epidemic typhus, rickettsioses usually occur sporadically at a relatively low frequency. A variety of agglutination type assays are in use for serodiagnosis of rickettsial disease. In general these assays require a minimum of specialized equipment but do not compare favourably with the sensitivity of ELISAs or IFA.

Indirect Fluorescent Antibody Assays

The IFA procedure for the rickettsiae is similar to conventional IFA techniques, with inactivated yolk sac or tissue culture suspensions of rickettsiae being used as antigens (Newhouse *et al.*, 1979). The IFA assay has been almost universally successful for diagnosis of disease caused by rickettsiae and rickettsiae-like organisms including those of the typhus group, spotted fever group and scrub typhus. IFA is the gold standard for laboratory diagnosis of ehrlichial diseases (Walker and the Task Force on Consensus Approach for Ehrlichiosis (CAFE), 2000). For all rickettsiae, demonstration of a fourfold or greater increase in antibody titre between acute- and convalescent-phase serum samples is also confirmatory. IFA tests are reasonably sensitive, although the subjectivity of endpoint determinations is an obvious disadvantage. For the majority of patients with ehrlichial disease, titres will be negative in the first week of illness; so obtaining a convalescent sample is generally crucial to confirm diagnosis (Childs *et al.*, 1999). An additional disadvantage is that serologic testing by IFA is

generally group reactive, rather than species specific, for the rickettsiae and related organisms.

Complement Fixation

CF tests have been used for many years for the diagnosis of most rickettsial diseases. In general, these tests while specific are less sensitive and more cumbersome than IFA or the agglutination assays and, for these reasons, are no longer used widely. Group-specific soluble antigens from either typhus or spotted fever group rickettsiae are prepared by methods that employ ether extraction. Antibodies reactive with these group-specific soluble antigens generally appear in the patient's serum 10–14 days after onset of disease and may last a year or longer. Species-specific antigens have been utilized to differentiate infections caused by members within the typhus or spotted fever groups. These specific CF assays rely on differential titres obtained with antigens from individual species of *Rickettsia* (Elisberg and Bozeman, 1969). The development of CF assays for diagnosis of ehrlichiosis has not been reported.

Enzyme Immunoassays

A variety of enzyme immunoassays (or ELISAs) have been developed for serologic diagnosis of rickettsial diseases. These tests offer several major advantages over other serologic assays in that they lend themselves well to automation, are not reliant on user interpretation of results and allow large numbers of sera to be run. Disadvantages generally include decreased specificity over some other assays, length of set-up time is not practical for small numbers of sera and the lack of standardization between laboratories may give rise to conflicting results. For these reasons, ELISA is generally limited to being performed in research laboratories.

Generally, the lack of specificity that is associated with rickettsial ELISAs can be avoided by not using whole-cell preparations of rickettsiae as antigens. Enzyme immunoassays that utilize lipopolysaccharide antigens have been successfully developed for spotted fever and typhus group rickettsiae (Jones *et al.*, 1993). The antibody response to this antigen appears to be group specific. Development of ELISAs for diagnosis of ehrlichial disease is still in progress (Paddock and Childs, 2003). Specifically, major antigenic surface proteins of *E. chaffeensis* (Yu *et al.*, 1999; Alleman *et al.*, 2000) and *A. phagocytophilia* (Ijdo *et al.*, 1999; Tajima *et al.*, 2000) are being targeted as antigens for these ELISAs.

Agglutination Assays

The indirect haemagglutination (IHA) test has received only limited evaluations, but its sensitivity is apparently equal to that of IFA. An erythrocyte-sensitizing substance (ESS), which can be obtained from typhus and spotted fever group rickettsiae by alkali extraction, is adsorbed

onto sheep or human group erythrocytes, and the coated cells are then used as antigens for simple agglutination tests. The respective ESSs exhibit group-specific antigenic reactivity and appear to be lipopolysaccharide in nature. The convenience of the IHA technique makes it suitable for a clinical setting, although the relatively short shelf life (6 months) of sensitized erythrocytes is a disadvantage (Elisberg and Bozeman, 1969). Nonetheless, it is potentially valuable as a bedside technique, particularly in field situations.

The latex agglutination test has been used with some success in a number of public health laboratories in recent years. Latex spheres are coated with ESS, and the sensitized particles are used as antigens in an agglutination test. The simplicity of the latex agglutination test offers a convenience that is best appreciated at the hospital level, but because it is primarily an IgM assay, it occasionally lacks sensitivity for late-convalescent-phase sera. The convenience of the latex test makes it useful as a bedside diagnostic procedure. It is recommended for that setting over the Weil-Felix test which is still used in similar circumstances.

The Weil-Felix test became popular in the 1920s after it was observed that certain *Proteus* strains would agglutinate early-convalescent-phase sera from patients with suspected rickettsial disease (Weil and Felix, 1916). The test fell into disfavour because it lacks both sensitivity and specificity (Hechemy *et al.*, 1979; Brown *et al.*, 1983), but it has managed to survive because of its convenience in a clinical setting. Despite its simplicity, it does not reliably provide either early or specific diagnosis of rickettsioses.

Diagnostic Criteria

Fourfold rises in titre detected by any technique (Weil-Felix technique excepted) are considered evidence of rickettsial and ehrlichial infections. With single-serum specimens, CF titres of ≥ 16 in a clinically compatible case are also considered positive. With the IFA test, single titres of 64 or higher are considered of borderline significance for typhus and spotted fever group infections. For *E. chaffeensis*, patients with single titres of 1:64–1:128 are considered probable, while single titres of $\geq 1:256$ are considered confirmed. Single antibody titers of $\geq 1:80$ against *A. phagocytophilia* are considered positive. Although these titres are somewhat higher than those recommended by others (Table 22.2), they usually present no problem in identifying recent infections if appropriately timed sera are available for testing.

The rickettsial species responsible for an infection is difficult to identify by conventional serologic tests. Rickettsiae within either the spotted fever or typhus group are antigenically related, resulting in extensive serologic cross-reactivity. For example, both murine- and louse-borne typhus are endemic in certain areas of the world, and routine IFA tests cannot distinguish between these two infections. Antibody adsorption (Goldwasser and Shepard, 1959) or toxin neutralization (Hamilton, 1945) tests can distinguish patients who have epidemic or murine typhus infections, but only specialty laboratories can perform these tests. In addition, convalescent-phase sera from patients with RMSF or typhus occasionally cross-react with typhus or other spotted fever group rickettsiae, respectively (Ormsbee *et al.*, 1978a). However, such cross-reactions are infrequent, and the heterologous titres are routinely much lower than in homologous reactions. An ELISA utilizing lipopolysaccharide antigens that eliminates cross-reaction between typhus group and spotted fever group infections has been developed (Jones *et al.*, 1993). Cross-reactivity between *E. chaffeensis* and *A. phagocytophilia* occurs in 10–30% of all patients; for this reason it is recommended that patient's serum be tested against antigens from both species (Comer *et al.*, 1999). An IFA assay has been described for HGE using cell-culture-derived antigen that ablates cross-reactivity of serum from patients infected with other human ehrlichial agents (Nicholson *et al.*, 1997).

Determining the specific aetiology of spotted fever group infections can be more or less problematic depending on the country of origin. In

the Western Hemisphere, RMSF is by far the most prevalent spotted fever group infection. However, in the United States, RMSF must occasionally be differentiated from rickettsialpox; differences in the respective clinical and epidemiological features are valuable for determining the likely aetiology. Furthermore, in contrast to RMSF, sera from patients with rickettsialpox are uniformly negative in Weil-Felix tests. Recent data from Europe and Asia suggests that the distributions of *R. conorii* and *R. sibirica* may overlap more than previously known and could confound attempts to identify specific aetiological agents by conventional serologic testing. However, as all rickettsiae are susceptible to the tetracyclines, it is not necessary to identify the specific aetiological agent to ensure that individual patients receive proper treatment.

The antigenic diversity of the scrub typhus rickettsiae presents a different problem with respect to serologic diagnosis. The most important consideration is an awareness of the antigenic diversity of *O. tsutsugamushi* strains in a given area. Unless an appropriate combination of strains of *O. tsutsugamushi* is included in the battery of test antigens, the titres of some serum specimens could appear falsely low, and some infections could even go undetected (Bourgeois *et al.*, 1977).

Finally, although laboratory testing is central to the diagnosis of rickettsial diseases, clinical findings can contribute to diagnosis, particularly in the face of equivocal serologic results. Although there are no unique pathognomonic features for the rickettsioses, eschars (at the site of arthropod attachment) are useful indicators of MSF and scrub typhus in endemic areas, the vesicular rash of rickettsialpox is unique among the rickettsioses and the triad of fever, headache and rash is a useful indicator of RMSF. Because of the hazards of working with living rickettsiae, isolation attempts are usually limited to situations where the outcome is fatal and postmortem tissues are the only specimens available for testing. Even then, direct fluorescent antibody tests of formalin-fixed, paraffin-embedded tissues are faster and safer than rickettsial isolation for diagnosis.

Culture/Isolation

Primary Isolation

The growth of rickettsial organisms in the laboratory necessitates either living host cells or cell cultures. Isolation and identification of members of the genus *Rickettsia* is not recommended for routine diagnosis of rickettsial diseases. These procedures are only recommended for research laboratories that have biosafety containment level 3 facilities and whose personnel have extensive experience in cultivating rickettsiae. Postmortem tissues are usually contaminated with bacteria; therefore, suspensions of these tissues are inoculated into susceptible animals for attempted isolation of rickettsiae. In most cases, the guinea pig is the animal of choice for rickettsial isolation. They are susceptible to infection by *R. typhi* and *R. rickettsii* (Ormsbee *et al.*, 1978b), which can be monitored by measuring the body temperature. Moreover, male guinea pigs often present with scrotal swelling when infected with *R. typhi* or *R. rickettsii*. Mice are the animal of choice for isolation of *R. akari* and *O. tsutsugamushi*; however, some inbred mice are resistant to infection by scrub typhus rickettsiae (Groves *et al.*, 1980), and outbred mice should be used for isolation of these agents.

Blood specimens are collected from animals that develop overt signs of illness following inoculation; ill animals are then humanely killed, target tissues are harvested aseptically and blood and tissues are repassaged in animals, embryonated eggs or tissue cultures. Gimenez stain (Gimenez, 1964) or direct immunofluorescence may be used to confirm the isolation of rickettsiae. Further passage into tissue culture or embryonated eggs is necessary to increase the yield of organisms. Surviving animals are bled 28 days postinoculation and the sera tested for rickettsial antibodies. Animals that were seronegative

before inoculation and are positive after 28 days are considered to have been infected with rickettsiae. Seroconversion in the absence of illness probably indicates the presence of a strain of reduced virulence for the animal of choice.

Successful isolation of both *E. chaffeensis* (Dawson *et al.*, 1991; Dumler *et al.*, 1995; Paddock *et al.*, 1997; Standaert *et al.*, 2000) and *A. phagocytophilia* (Goodman *et al.*, 1996; Klein *et al.*, 1997; Nicholson *et al.*, 1997; Heimer, Tisdale and Dawson, 1998) has been reported, but isolation of *A. phagocytophilia* is more frequent (Olano and Walker, 2002). After inoculation of patient blood onto susceptible cell lines, the resulting isolate must then be identified. The only methods currently available that permit species-level identification of isolates are PCR-based techniques, that amplify the 16S RNA gene, combined with sequencing (Anderson *et al.*, 1991) or hybridization probes (Anderson *et al.*, 1992). Independent confirmation of PCR results by IFA on convalescent serum specimens is desirable.

Propagation of Isolates

Propagation of members of the genus *Rickettsia* is a hazardous procedure that should be attempted only under biosafety level 3 conditions. Cell cultures provide a convenient method for rickettsial propagation. Numerous cell lines have been used successfully for growing rickettsiae; Vero, primary chicken embryo, WI-38, HeLa and virtually any other cell line are suitable for this purpose. Infected animal tissues are homogenized thoroughly in sterile diluent and inoculated onto monolayers of susceptible cells. Cultures are incubated at 35 °C and monitored for up to 14 days. No other special growth conditions are necessary, although it is known that *R. rickettsii*, *R. prowazekii* and *R. typhi* (but not *O. tsutsugamushi*) grow better in an environment with 5% CO₂ than they do when exposed to the 0.2–0.3% CO₂ that is found in atmospheric air (Kopmans-Gargantiel and Wisseman, 1981). Rickettsial growth can be monitored by scraping monolayers off the flask with an inoculating loop and preparing smears then staining for rickettsiae by the Gimenez technique (Gimenez, 1964) and by the direct fluorescent-antibody procedure, if appropriate. Rickettsiae also grow quite well in the yolk sac of embryonated hen eggs, although this technique is quite labour intensive.

Final confirmation of *Rickettsia* isolation requires that the isolate be morphologically similar to rickettsiae, grow intracellularly, fail to grow on bacteriologic media and react with appropriate immune serum but not with nonimmune sera. Species-level identification of *Rickettsia* can be performed by restriction endonuclease digestion of PCR-amplified products from isolates. Additional details concerning the procedures for rickettsial isolation can be found in the review by Weiss (1981).

Isolation of *E. chaffeensis* involves layering EDTA-anticoagulated blood onto Histopague and removing the leucocyte-rich fraction to flasks containing a semiconfluent or confluent layer of DH82 canine peritoneal macrophages (Paddock *et al.*, 1997; Standaert *et al.*, 2000). Cells are then incubated at 37 °C with 5% CO₂. Detection of morulae is performed by staining using Diff-Quik. *Ehrlichia chaffeensis* has also been culture isolated from cerebrospinal fluid (Standaert *et al.*, 2000). Culture of ehrlichial species homologous to the HGE agent have been performed by inoculating either whole blood (Nicholson *et al.*, 1997) or buffy coat (Lin *et al.*, 2002) onto HL-60 cells (human promyelocytic leukaemia cell line) and incubating the cells at 37 °C with 5% CO₂. Infection is detected by staining of cells.

Direct Detection of Organisms

Immunofluorescence

Rickettsiae have been detected by immunofluorescence in tissue biopsies obtained from the site of tick attachment and from cutaneous lesions (Woodward *et al.*, 1976). Technical improvements in the

biopsy assay have resulted in a highly specific assay for confirming MSF. Evaluations of this technique indicate that it will detect *R. rickettsii* or *R. conorii* in about 50% of patients with RMSF or MSF, respectively. All of the factors that contribute to the lack of sensitivity are not known, although most false-negative results were from patients who had received specific antibiotic therapy before the biopsy was performed.

Rickettsiae are also present in circulating endothelial cells. Because of their relatively low number, detection by direct fluorescence microscopy was not feasible until Drancourt and colleagues (Drancourt *et al.*, 1992) utilized monoclonal antibody-coated beads to concentrate circulating endothelial cells from patients with MSF and then detected rickettsiae in the cells by direct immunofluorescence. The procedure had a sensitivity of 66% in initial evaluation. It takes less than 3 h to perform and shows promise as a rapid diagnostic assay for MSF and other rickettsial infections.

Direct fluorescent antibody testing of tissues collected postmortem is a useful approach for the retrospective diagnosis of rickettsial diseases. This technique was first applied to the rickettsiae by Walker and Cain (1978), who successfully detected rickettsiae in kidney tissue of seven of ten patients who had died of suspected RMSF.

Ehrlichial organisms can be seen in intracytoplasmic inclusions, termed morulae, in monocytes and neutrophils, in the cases of HME and HGE, respectively (Olano and Walker, 2002). Use of eosin-azure stains is necessary for visualization (Paddock and Childs, 2003). Although the presence of morulae is diagnostic, it is not sensitive and even when visualized they are detected in less than 5% of circulating leucocytes (Paddock and Childs, 2003).

Polymerase Chain Reaction

Studies by Tzianabos, Anderson and McDade (1989) showed that rickettsial DNA can be detected in blood during rickettsial infections. Using nucleotide primers corresponding to a portion of a defined rickettsial gene, they successfully detected *R. rickettsii* DNA in seven of nine patients with confirmed cases of RMSF by using PCR. Additional testing with clinical specimens indicated that the technique is highly specific but lacks sensitivity; PCR detected rickettsiae best in patients who were seriously ill with RMSF and is of potential importance in the early diagnosis of RMSF and other rickettsial infections. In other work, multiple genes have been utilized to discern subgroups. For instances, the analysis of the 16S rRNA [ribosomal DNA (rRNA)] (Roux and Raoult, 1995) has been used to diverge major groups of rickettsial organisms. Other genes include the common 17-kDa antigen (Tzianabos, Anderson and McDade, 1989), citrate synthase (*gltA*) (Roux *et al.*, 1997), *rOmpA* (Roux, Fournier and Raoult, 1996) and *rOmpB* (Roux and Raoult, 2000). These genes contain immunogenic antigens that cross-react well among subgroup members (Raoult and Roux, 1997). More recently, the type 1 signal protein lepB (Rahman *et al.*, 2003) and the 120-kDa antigen (Dash and Jackson, 1998) have been used to characterize SFG members. It seems likely that molecular analysis of rickettsial agents, whether by PCR or restriction fragment length polymorphism (RFLP) analysis, will continue to provide the means by which group members are added to this diverse family. That said, novel new molecular techniques including real-time PCR (Jiang, Temenak and Richards, 2003) and the analysis of intergenic spacer regions in DNA sequences (Vitorino *et al.*, 2003) should also prove useful.

PCR detection of *E. chaffeensis* and *A. phagocytophila* has been performed directly from blood samples using a variety of genes as targets, the most common of which is the gene that encodes 16S rRNA. Recently, Massung and Slater (2003) systematically compared PCR assays for detection of *A. phagocytophila* using primer sets published in the literature. The highest sensitivity and specificity was obtained using a 16S rRNA-nested assay and a direct assay using primers against the major surface protein of *A. phagocytophila*. Most of the direct assays to amplify 16S rRNA lacked specificity and amplified sequences from *E. chaffeensis* (Massung and Slater, 2003). PCR for

the specific detection of *E. chaffeensis* in the blood of patients with ehrlichiosis has been described (Anderson *et al.*, 1992). Blood collected in EDTA is used to prepare DNA template for amplification using *E. chaffeensis*-specific primer pair HE1 and HE3 to the *16S rRNA* gene. The identity of the PCR-amplified products is confirmed with oligonucleotide probe HE4. PCR amplification of *E. chaffeensis* DNA can also be performed using primers against the 120-kDa protein gene and the variable length PCR target (VLPT) (Standaert *et al.*, 2000). The majority of patients with ehrlichiosis do not develop antibody responses within the first week of infection; thus, detection of organisms may be possible by PCR when antibody tests are not yet positive (Childs *et al.*, 1999).

TREATMENT

Antibiotic therapy is, in general, of great benefit to patients infected with rickettsiae. RMSF cases when treated with doxycycline, tetracyclines or chloramphenicol have a CFR much reduced from untreated patients (Harrell, 1949) and show rapid evidence of clinical improvement including defervescence and cessation of constitutional signs and symptoms. Other spotted fevers, most notably MSF, have been successfully treated with erythromycin and ciprofloxacin (Beltran and Herrero, 1992). Tetracyclines, doxycycline and chloramphenicol are the antibiotics of choice for treatment of most rickettsial and ehrlichial illnesses.

PREVENTION AND CONTROL

Prevention of the arthropod-borne diseases caused by rickettsiae-like agents includes a variety of measures that reduce the likelihood of contact between vector and susceptible humans. In general, avoiding exposure to habitats known to be endemic for the diseases and/or infested with vectors of the diseases is prudent advice but not usually practical. Persons who are exposed to vector-infested endemic areas must rely on personal protective measures to minimize contact with potentially infected vectors. Recommendations for prevention of tick-borne rickettsiae and ehrlichiae infections include avoidance of tick-infested habitats and, when that is not feasible, taking personal precautions that prevent tick bite. Tick infestations may be reduced by wearing long trousers that fit tightly around the ankles and shirts that fit tightly around the wrists. Clothing impregnated with permethrin or other repellents may also prevent tick infestation. Early removal of ticks, either before they imbed their mouthparts into the skin or within hours of imbedding, may prevent infection. Similar precautions for preventing louse-borne infections include prevention of louse infestations by regular bathing and washing clothes with soap and hot water. Disinfestation of human populations infested with body lice is an effective measure to contain epidemics. The use of a vaccine containing formalin-killed organisms may also have been a factor in limiting the spread of louse-borne typhus during World War II. Prevention of scrub typhus depends on avoiding the habitat infested by vector chiggers. Elimination of vegetation that supports mites and their small mammal hosts may be an effective means of reducing human infections. Prophylactic administration of antibiotics has been shown to be effective among populations occupationally exposed to risk (Olson *et al.*, 1980). Prevention of flea-borne typhus depends on measures similar to those of plague control and includes the use of insecticides to reduce populations of fleas on rodents, followed by rodent-control programs. The effectiveness of repellent-impregnated clothing, however, remains to be evaluated for the prevention of most diseases.

Immune Mechanisms

Immunity to both spotted fever group and typhus group rickettsial infections (like other intracellular bacteria) involves both the cellular and humoral arms of the immune response. Several vaccines for rickettsial

disease have been produced, although none have been completely effective. Vaccines for human ehrlichiosis have not yet been developed.

In the case of spotted fever group rickettsiae, vaccines have been developed but have not been effective in preventing RMSF. Individual antigens have been identified that play a role in eliciting immunity in both the mouse toxin neutralization assay and the guinea-pig model. Two high molecular weight surface proteins, rOmpA (also termed the 190- or 155-kDa antigens based on differing molecular mass estimates) and rOmpB (also termed 135- or 120-kDa antigen) have been shown to contain protective epitopes. Both rOmpA and rOmpB proteins from *R. rickettsii* contain amino acid sequence homology with the species protective antigen of *R. typhi*. These surface proteins show promise as candidates for subunit vaccines (McDonald, Anacker and Garjian, 1987). Attempts to define protection are being augmented by studies to define specific immune responses. Of note has been work to identify CD8 T-cell epitopes against the OmpB gene of *R. conorii* (Li *et al.*, 2003). Protective epitopes for *E. chaffeensis* as yet have not been characterized.

Bartonella spp.

J. M. Rolain and D. Raoult

Unité des Rickettsies, CNRS UMR 6020A, Faculté de Médecine, Université de la Méditerranée, Marseilles, France

INTRODUCTION

Bartonella species are emerging and reemerging bacteria that belong to the $\alpha 2$ subgroup of Proteobacteria (Birtles and Raoult, 1996; Houpiakian and Raoult, 2001). The interest in these microorganisms has increased since they are agents of common clinical infectious diseases such as cat-scratch disease (CSD), bacillary angiomatosis or blood culture-negative endocarditis (Maurin and Raoult, 1996; Anderson and Neuman, 1997; Maurin, Birtles and Raoult, 1997; Brouqui and Raoult, 2001). The current knowledge in the field is due essentially to the improvement of new molecular biology methods, especially polymerase chain reaction (PCR) and sequencing (Relman *et al.*, 1990). These bacteria have a unique feature among prokaryotes, the ability to induce angiogenic tumors such as bacillary angiomatosis and verruga peruana (Dehio, 2001). People usually become infected with *Bartonella* species incidentally, with the exception of *Bartonella bacilliformis* and *Bartonella quintana*, as the organisms are normally found in the reservoir hosts, which include animals such as cats and dogs that live in close contact with people (Jacomio, Kelly and Raoult, 2002).

DESCRIPTION OF THE ORGANISM

Historical Background

Until 1990, only two diseases were recognized to be caused by *Bartonella* species: Carrion's disease due to *B. bacilliformis* and trench fever due to *B. quintana* (Karem, Paddock and Regnery, 2000). *Bartonella bacilliformis* was first viewed in 1909 by Alberto Barton in erythrocytes of patients suffering from Oroya fever, the acute form of Carrion's disease in Peru (Ihler, 1996). In 1993, Brenner *et al.* proposed unifying species of the former genus *Rochalimaea* with the genus *Bartonella* based on comparison of 16S rRNA gene sequences. Thus, the species *Rochalimaea quintana* (the agent of trench fever, isolated in 1918) (Strong *et al.*, 1918), *Rochalimaea vinsonii* (isolated in 1946 from small rodents) (Baker, 1946) and *Rochalimaea henselae* (first described in 1992 and the agent of CSD) (Regnery *et al.*, 1992a) have been renamed as *Bartonella quintana*, *Bartonella vinsonii* and *Bartonella henselae*, respectively. Moreover, Birtles *et al.* (1995) proposed unifying the bacteria of the genus *Grahamella* with the genus *Bartonella* based on phylogenetic studies. Numerous other species have been described in the past few years in several animals (Breitschwerdt and Kordick, 2000) (Table 23.1).

Human infections due to *Bartonella* spp. include old and newly characterized diseases. *Bartonella bacilliformis* was reported for the first time in 1913 (Strong *et al.*, 1913), and *B. quintana* was first described during World War I in 1918 (Strong *et al.*, 1918). *Bartonella quintana* is transmitted by the human body louse and was

responsible for more than one million deaths during World War I. Sporadic cases have been reported since these periods, especially in homeless patients in United States, France, Russia, Peru and Burundi (Brouqui *et al.*, 1996).

Bartonella henselae was first described in 1992 (Regnery *et al.*, 1992a), and its role in bacillary angiomatosis was demonstrated using molecular biology and PCR sequencing (Relman *et al.*, 1990). In 1983, Stoler *et al.* described the presence of cutaneous angiomatosis lesions in acquired immune deficiency syndrome (AIDS) patients. Small coccobacilli were viewed in histological biopsies by Warthin–Starry staining (Wear *et al.*, 1983). The species *B. quintana* was first identified in cutaneous biopsy samples by using PCR sequencing (Relman *et al.*, 1990). At the same time, a new species was isolated from the blood of a bacteremic patient (Slater *et al.*, 1990) and also in peliosis hepatitis in AIDS patients (Perkocha *et al.*, 1990). Further studies demonstrated that this bacterium was a new species, and this new species was named *B. henselae* (Regnery *et al.*, 1992a). Subsequently, Regnery *et al.*, in 1992, demonstrated that most patients suffering from CSD, disease first described in 1950 by Debré *et al.*, had antibodies directed against *B. henselae* (Regnery *et al.*, 1992a). Subsequent studies have demonstrated the role of *B. henselae* as the etiologic agent of CSD.

In recent years, new *Bartonella* species have been linked to human infections, and thus, the genus *Bartonella* now comprises 21 characterized species, of which 8 are potentially pathogenic in humans: *B. bacilliformis*, *B. quintana*, *B. henselae*, *Bartonella vinsonii* subsp. *berkhoffii* in a patient with endocarditis (Roux *et al.*, 2000), *Bartonella vinsonii* subsp. *arupensis* isolated in a patient with fever and bacteremia (Welch *et al.*, 1999) and in one case of infective endocarditis (unpublished data), *Bartonella grahamii* in a case of retinitis (Kerkhoff *et al.*, 1999), *Bartonella elizabethae* in a case of endocarditis (Daly *et al.*, 1993) and *Bartonella washoensis* in a case of myocarditis (Chang *et al.*, 2001; Kosoy *et al.*, 2003).

Classification – Phylogeny

Phylogenetically, the genus *Bartonella* belongs to the α -subgroup of Proteobacteria, very close to the genus *Brucella*, *Agrobacterium* and *Rhizobium* (Birtles and Raoult, 1996). Bacteria of the genus *Bartonella* are facultative aerobic, intracellular, oxidase and catalase negative, short Gram-negative bacilli. All are nonflagellated organisms, with the exception of flagellated *B. bacilliformis* and *Bartonella clarridgeiae* (Kordick *et al.*, 1997). Members of the genus *Bartonella* possess few phenotypic markers useful for species delineation. Most of the current knowledge about *Bartonella* taxonomy is supported by several genes, namely the 16S rRNA (Birtles *et al.*, 1995), the citrate synthase (*glIA*) (Birtles and Raoult, 1996), the 16S/23S intergenic

Table 23.1 Species of the genus *Bartonella* previously reported: epidemiological and clinical data

Species	Reservoir host	Disease in humans	First description (year)	Vector or detection in arthropods	Detection in erythrocytes
<i>Bartonella bacilliformis</i>	Human	Carrion's disease	1919	Sand fly (<i>Lutzomia</i> spp.)	+++
<i>Bartonella talpae</i>	Mole	Unknown		Unknown	
<i>Bartonella peromysci</i>		Unknown	1942	Unknown	
<i>Bartonella quintana</i>	Human	TF, BA, BAC, END	1961	Human body lice, fleas	+
<i>Bartonella vinsonii</i> subsp. <i>vinsonii</i>	Rodents	Unknown	1946	Unknown	
<i>Bartonella henselae</i>	Cats	CSD, BA, BAC, END	1990	Fleas (<i>Ctenocephalides felis</i>)	++
<i>Bartonella henselae</i>	Rats	END (1 case)	1993	Fleas	
<i>Bartonella grahamii</i>		RET (1 case)	1995	Unknown	
<i>Bartonella taylorii</i>		Unknown	1995	Unknown	
<i>Bartonella doshiae</i>		Unknown	1995	Unknown	
<i>Bartonella clarridgeiae</i>	Cats	Unknown	1995	Fleas (<i>Ctenocephalides felis</i>)	++
<i>Bartonella vinsonii</i> subsp. <i>berkhoffii</i>	Dogs	END (1 case)	1995	Fleas and ticks	
<i>Bartonella tribocorum</i>	Rats	Unknown	1998	Unknown	
<i>Bartonella koehlerae</i>	Cats	Unknown	1999	Fleas (supposed vectors)	+
<i>Bartonella alsatica</i>	Rabbit	Unknown	1999	Fleas or ticks	
<i>Bartonella vinsonii</i> subsp. <i>arupensis</i>	Rodents	BAC (1 case)	1999	Unknown	
<i>Bartonella bovis</i> (<i>weissii</i>)	Cows	Unknown	2002 (1999)	Unknown	
<i>Bartonella washoensis</i>	Rodents	MYOC (1 case)	2000	Unknown	
<i>Bartonella birtlesii</i>	Rats	Unknown	2000	Unknown	
<i>Bartonella capreoli</i>	Ruminant	Unknown	2002	Unknown	
<i>Bartonella schoenbuchensis</i>	Ruminant	Unknown	2001	Unknown	

BA, bacillary angiomatosis; BAC, bacteremia; CSD, cat-scratch disease; END, endocarditis; MYOC, myocarditis; RET, retinitis; TF, trench fever.

**Figure 23.1** Neighbor-joining tree resulting from comparison of sequences of the *groEL* gene of most *Bartonella* spp. identified to date.

spacer region (*ITS*) (Roux and Raoult, 1995), the *rpoB* gene (Renesto *et al.*, 2001) and the 60-kDa heat-shock protein (*groEL*) (Marston, Sumner and Regnery, 1999). A phylogenetic neighbor-joining tree resulting from comparison of sequences of the *groEL* gene of most *Bartonella* spp. identified to date is presented in Figure 23.1. Comparison of phylogenetic organizations obtained from these genes allowed six statistically significant evolutionary clusters to be identified (Houpikian and Raoult, 2001). *Bartonella bacilliformis* and *B. clarridgeiae* appear divergent species. *Bartonella henselae*, *Bartonella koehlerae* and *B. quintana* cluster together, as well as *Bartonella vinsonii* subsp. *vinsonii* and *B. vinsonii* subsp. *berkhoffii*. The fifth group includes bacteria isolated from various rodents, and the sixth group comprises *Bartonella tribocorum*, *B. elizabethae* and *B. grahamii* (Houpikian and Raoult, 2001).

With the exception of 16S rRNA gene, all the sequences studied have good discriminatory powers, but the usefulness of some genes is restricted by high similarity values between some species (La Scola *et al.*, 2003). The only genes with lower interspecies similarity values are *rpoB* and *gltA*. Cutoff sequence similarity values have been proposed for species definition in *Bartonella* genus (La Scola *et al.*, 2003). A new *Bartonella* isolate should be considered as another species if a 327-bp *gltA* fragment shares <96.0% sequence similarity with the validated species and if an 825-bp *rpoB* fragment shares <95.4% sequence similarity with the validated species (La Scola *et al.*, 2003).

PATHOGENESIS

The growth of the bacteria is dependent upon hemin (Myers, Cutler and Wisseman, 1969) and, for some species, CO₂. Isolates can be obtained in rabbit or sheep blood agar plates. Culture on axenic media is difficult since the bacteria are fastidious and culture is usually obtained only after 2–4 weeks of incubation. Subcultures are usually more easy in 3–5 days on agar plates. In primary isolation, colonies are usually rough and become smooth after several passages in agar plates. These bacteria are considered to be facultative intracellular bacteria since target cells in mammals could be either endothelial cells or red blood cells (Dehio, 2001).

In vivo, *B. bacilliformis* has been observed in human erythrocytes in patients suffering from Oroya fever (Pinkerton and Weinman, 1937) as well as *B. quintana* in homeless people (Rolain *et al.*, 2002). Interestingly, *B. quintana* has also been observed in erythroblast cells in bone marrow in bacteremic homeless patients (Rolain *et al.*, 2003b). In cats, *B. henselae* (Kordick and Breitschwerdt, 1995; Rolain *et al.*, 2001) and *B. koehlerae* (Rolain *et al.*, 2003c) have also been observed in erythrocytes. *Bartonella tribocorum* was also observed in erythrocytes of rats (Schulein *et al.*, 2001). It was shown in red blood cells of rats that the bacterial replication of *B. tribocorum* was regulated and stopped at a maximum of 8 bacteria/cell (Schulein *et al.*, 2001). The mechanism responsible for this is unknown, but it prevents hemolysis and allows the persistence of *Bartonella* spp. within erythrocytes (Schulein *et al.*, 2001). Adherence to red blood cells is mediated by the flagella in *B. bacilliformis* (Walker and Winkler, 1981; Scherer, DeBuron-Connors and Minnick, 1993; Rolain *et al.*, 2003g). As the other *Bartonella* do not possess polar flagella, other mechanisms are involved in adhesion to red blood cells, especially the bundle-forming pili of *B. henselae* (Greub and Raoult, 2002). It has been speculated that the binding of *Bartonella* to spectrin may be a first step necessary to alter the erythrocyte membrane for internalizing the bacteria (Buckles and McGinnis, 2000), but a bacterial protein, namely deformin, may also be involved (Mermaugh and Ihler, 1992; Iwaki-Egawa and Ihler, 1997).

Apart from their tropism for red blood cells, a second typical pathogenic feature of *Bartonella* spp. is their ability to trigger angiogenesis. The tropism of these bacteria for endothelial cells seems correlated with the ability to induce angioproliferative lesions: verruga peruana for *B. bacilliformis* and bacillary angiomatosis for *B. henselae* and *B. quintana*. *In vitro* culture of *B. henselae* or *B. quintana* in endothelial cells increases the lifetime of the culture, stimulates cellular multiplication (Palmar *et al.*, 1996) and leads to morphological changes of the cells similar to those observed with angiogenic factors (Koehler *et al.*, 1992; Maeno *et al.*, 1999). This angiogenic effect is mainly due to an increase in the production of vascular endothelial growth factor (VEGF) by the endothelial cells infected with *Bartonella* (Kempf *et al.*, 2001). *In vitro*, *B. bacilliformis*, *B. quintana* and *B. henselae* are cultivated in human endothelial cells (Zbinden, Höchli and Nadal, 1995; Brouqui and Raoult, 1996; Dehio *et al.*, 1997). Isolation of *Bartonella* in these cell-culture systems usually leads to a more rapid isolation in 10–15 days (Koehler *et al.*, 1992). *Bartonella henselae* binds to human endothelial cells by outer membrane proteins (Burgess and Anderson, 1998). The endothelial receptors involved in *Bartonella* adhesion include intercellular adhesion molecule-1 (ICAM-1) (Dehio *et al.*, 1997). Endothelial cells are invaded either by endocytosis or by the way of an invasome (Dehio *et al.*, 1997).

EPIDEMIOLOGY

Bartonella bacilliformis is the agent of Carrion's disease and is transmitted to humans by the sand fly *Lutzomia* in the Peruvian Andes (Peru, Ecuador and Colombia) (Alexander, 1995; Amano *et al.*, 1997). Humans are the only known reservoir of this disease. In these areas, the prevalence of the disease may be high, even though most of the cases are asymptomatic (Herrer, 1990). The disease is also observed in areas where *Lutzomia* is absent, suggesting that other vectors may exist.

Bartonella quintana infections are transmitted by the body louse (Brouqui *et al.*, 1999). Humans are the only known reservoir of *B. quintana* (Maurin and Raoult, 1996), a worldwide species. Transmission of the disease to humans by the body louse (*Pediculus humanis corporis*) has been demonstrated first as trench fever during World War I (Ohl and Spach, 2000). The bacterium has been detected in cat's fleas from France, suggesting that other vectors or animal reservoir may also exist (Rolain *et al.*, 2003d). After World War I, the incidence of trench fever decreased; however, during World War II, the disease reemerged (Foucault *et al.*, 2002). Reports have indicated a

reemergence of *B. quintana* infections (bacteremia in homeless people, bacillary angiomatosis and endocarditis) in Europe and the United States (Drancourt *et al.*, 1995; Spach *et al.*, 1995b; Maurin and Raoult, 1996; Foucault *et al.*, 2002). Epidemiological factors significantly correlated with infection by *B. quintana* are poor living conditions (homeless), presence of body lice and alcoholism (Spach *et al.*, 1995b; Brouqui *et al.*, 1996; Koehler *et al.*, 1997). A study in the United States has demonstrated that intravenous drug use is a risk factor for *B. quintana* infections, suggesting that this bacterium could be transmitted intravenously (Comer *et al.*, 1997).
